years, from 1890 to 1892 inclusive, with the number of inhabitants to the acre in each ward in 1892, and the maximum and minimum elevation in feet above mean low water. The full line indicates the ratio of reported cases to the thousand of population, and the broken line the maximum and minimum elevation in feet. In Wards 1 and 2, comprising East Boston, it will be seen that the ratio is 1.18 and 2.11 respectively. There seems to be no satisfactory explanation of the difference between the ratios in these two wards. In this district the question of wells as a source of water-supply cannot be considered, as no wells were found where typhoid fever occurred. In Charlestown, comprising Wards 3, 4 and 5, there is very little difference in the ratios which range from 1.35 in Ward 3, to 1.69 in Ward 4. Situation near tide level is not an important agent in causing the prevalence of the disease in this locality, for the highest ratio was reached in the ward that has the greatest elevation, namely, Ward 4. The slight increase in the frequency of the disease in this ward is probably due to the fact that in this locality the majority of the population leave the city for a greater or less length of time during the summer months, and contract typhoid fever in the country. Mystic water as compared with Cochituate can have no great influence in causing the prevalence of the disease as the ratio of cases in Charlestown is lower than that of most of the other wards of the city. In the city proper, comprising Wards 6, 7, 8, 9, 10, 11, 12, 16, 17 and 18, the ratio varies from 3.20 to the thousand in Ward 6, to 1.05 in Ward 10. The average ratio for these wards is 1.77. The high rate in Ward 6 may be explained by the character of the population, which is composed of newly-arrived immigrants who are particularly susceptible to the disease, of laborers employed outside of the city in places where the water-supply is taken from wells, and of peripatetic merchants who are exposed to influences which are likely to cause typhoid fever. Ward 16, with a ratio of 1.94, the most crowded ward in the city having a population of 213 to the acre, the inhabitants of which, as a rule, remain at home during the entire year presents a marked contrast to Ward 6, with a ratio of 3.20. Concerning the other wards of the city proper, as the variation of the ratios is so little, the difference in elevation so slight, and the social conditions of the inhabitants so varied, it is impossible to draw any satisfactory conclusions regarding the prevalence of the disease. In Wards 13, 14 and 15, comprising South Boston, the highest ratio, 2.03, is reached in Ward 14, the lowest in Ward 15, .96. On general principles it would nat urally be supposed, considering the character of the houses and their situation near tide level, that we should have a high ratio of cases of typhoid fever in Ward 15, and the only explanation of its comparative immunity is the fact that the majority of the inhabitants remain at home during the entire year and are not subjected to the influences of a contaminated water-supply. In Roxbury, which includes Wards 19, 20, 21 and 22, the ratios vary from 1.80 in Ward 19, to 1.44 in Ward 22. The morbidity of these four wards throws no light on the cause of the frequency of this disease. Ward 23, or West Roxbury, has a population of three to the acre, a maximum elevation of 301 feet above mean low water, and a minimum elevation of 35 feet. There is nothing in the natural condition of this ward that would seem to predispose to typhoid fever. The ward is not crowded, there is no made land in it; there are comparatively few tenement-houses, and yet its ratio of cases of typhoid fever is larger than in twenty of the other wards of the city. In only two instances during the past year have cases of typhoid fever occurred in houses where the water-supply was taken from wells, so that it is evident that contaminated wells have not been active agents in spreading the disease in this locality. In Ward 24, or Dorchester, which is not nearly so elevated as Ward 23, and in which there is a very considerable extent of marshy land, the ratio of cases to the thousand of inhabitants is 1.42, a considerable diminution as compared with Ward 23. In Ward 25, or Brighton, which is somewhat elevated and has a sandy soil, the ratio of cases to the thousand of the inhabitants is comparatively low, being 1.62.

Map E represents the city divided into sanitary districts according to the ratio of reported cases of typhoid fever to the thousand of population, for three years, from 1890 to 1892, inclusive. The districts are indicated by letters. Sanitary district A, consisting of only one ward, namely, Ward 15, has an average ratio for the three years of .96. Sanitary district B includes Wards 1, 3, 4, 5, 7, 8, 9, 10, 11, 12, 16, 18, 19, 20, 21, 22, 24 and 25. The average ratio of cases to the thousand of population is 1.53. Sanitary divis-

ion C, composed of Wards 2, 13, 14, 17 and 23, has a ratio of reported cases of 2.07. Sanitary district D, Ward 6, has a ratio for the three years, 1890, 1891 and 1892, of 3.20.

The influence of defective drainage on the prevalence of typhoid fever in this city is very slight, for of the 1,537 houses where the disease occurred during 1891 and 1892, only 699 were found to have broken or improper drains. Privy vaults are so few in Boston that they can have no causal relation to typhoid fever.

It has been shown, by the fact that typhoid fever has steadily diminished in Boston the past few years, that our water-supply is above suspicion. It has been proved by the statistics of the reported cases for the past three years, that neither situation, so far as tide level is concerned, nor a crowded condition of a locality are important agents in causing the prevalence of

Map E.

typhoid fever. In order, therefore, to explain the frequency of the disease in Boston, it is a reasonable supposition that contaminated milk may be an active agent in spreading the disease. In the Boston *Medical and Surgical Journal* of July 19, 1888, is an extremely interesting and instructive paper by Dr. Charles Harrington, entitled, "An Epidemic of Typhoid Fever due to Infected Milk." This epidemic occurred during November and December, 1886, in the city of Cambridge. Investigation proved that 58 of 73 cases occurred in 36 families who obtained their milk from the same source. It was found that this milk came from a farm where there had been two cases of typhoid fever three weeks previous to the outbreak of the epidemic in Cambridge. As there was no local condition at this time to explain the outbreak of the disease, it therefore seems evident that the cases of typhoid fever on the milk farm were the cause of the disease in Cambridge. Prof. Wm. T. Sedgwick read a paper, January 26, 1893, before the Massachusetts Association of Boards of Health upon "An Epidemic of Typhoid Fever due to Infected Milk." After very carefully investigating the course of the epidemic, which occurred in Somerville, Prof. Sedgwick was thoroughly convinced, and with reason, that the cause of the outbreak of the disease was due to contamination of the milk by the discharges from a man in the first stages of typhoid fever. It was a significant fact that when this man was ill enough to go to bed the epidemic commenced to decline. It is unnecessary to more than allude to the many other instances on record where epidemics of typhoid fever can be absolutely traced to infected milk. As bearing on this fact, it is of interest to note that in the foreign cities where the ratio of deaths from typhoid fever is much lower than in this country, there is a most rigid and careful supervision of the milk farms both as to their sanitary condition and as to the health of the employés. In London, for instance, where typhoid fever is comparatively rare, large dairy companies have been formed whose supply of milk is based on most minute and rigorous regulations. To prevent the spread of infectious diseases by milk, the farmer is required by his contract to call a physician if any person employed in his dairy is taken ill. If the disease is infectious, the secretary of the company must be at once informed, who will indicate the measures to be taken. In the event of serious disease the delivery of milk from the farm is forbidden. Arrangements are made with local medical offices of health to obtain information as to each case of infectious disease arising in the neighborhood of a dairy. In Berlin, also, there are stringent regulations regarding persons who have come in contact with any infectious disease having anything to do with milk. Similar observations are true regarding Vienna and Glasgow. In Paris, a large proportion of the milk comes from dairies situated in the city. The employés of these dairies are subjected to a careful medical supervision, and it is very reasonable to suppose that this has a decided effect in reducing the death-rate from typhoid fever in that city. In Boston, the milk comes from so many different places and such long distances, and passes through so many hands that it would be difficult to absolutely trace the source of infection in a given case. But there can be no doubt that in Boston, as well as in many other cities, infected milk may be, and is, much more frequently than is generally supposed, a cause of an outbreak of typhoid fever. While this statement so far as Boston is concerned, may not be capable of positive demonstration, it is certainly worth the careful consideration of the members of this society.

It is perfectly evident from a study of typhoid fever in Boston for the past few years that the disease, in the different sections of the city, is not due to a common cause such as the water-supply, for if the water was at fault we should have practically the same ratio of cases in each of the wards. Such is not the fact, however, for we find as great a difference between the wards of the city as there is between Boston and London, and Boston and Philadelphia. It may be asked if contagion is not an element in increasing the frequency of the disease. In reply to this it may be said that such a small proportion of cases could be traced to any previous exposure, that no satisfactory deductions could be reached on this point.

An attempt has been made in this paper to show:

(1) That the prevalence of typhoid fever in Boston is not due to the water-supply.

(2) That situation near tide level is not conducive to the frequency of the disease.

(3) That imperfect drainage is not an important factor.

(4) That, as the germs of typhoid fever can be easily and readily conveyed by milk, it seems reasonable to assume that the comparative prevalence of the disease in this city is due, in a great measure, to infected milk.

THE SANITARY CONDITION OF BOSTON.[1]

BY S. H. DURGIN, M.D.

THE sanitary condition of the city may be estimated in a variety of ways and with a greater or less degree of satisfaction. A superficial view of surfaces and surroundings may give sufficient evidence to one; the lack of prevailing bad odors, the want of a high death-rate, the absence of epidemic diseases or the existence of a well-ordered and equipped health organization may be satisfactory evidence to another, that the sanitary conditions are good.

All of these conditions might temporarily exist and furnish presumptive evidence of a good sanitary condition, while a careful investigation beneath surfaces and within doors, would alone furnish data upon which a positive statement could be made. A clean dry surface, a clean well-drained soil, good public and private sewerage, immediate destruction or removal of all decomposable wastes, good food and water-supplies, and a good surveillance over all, would constitute favorable conditions for a healthful city.

For the purposes of this brief paper, I shall confine myself to a statement of a few of the principal outdoor and in-door conditions as they appear to me. We cannot do better, perhaps, than to inquire as to how many of these favorable conditions we can lay claim to.

The area of the city now measures about 37 square miles, or 23,707 acres. Of this area, 1,812 acres are included in parks and public grounds. There are 558 miles of streets, of which 51 miles are paved, 204 miles are macadamized, and 282 miles are formed of gravel.

There are 56,809 dwelling-houses, and of this number there are 10,763 tenement-houses of three or more families each. A portion of the remainder of the city is occupied by various out-buildings for business purposes, leaving large tracts of unoccupied land, especially in the outlying districts.

The parks and public grounds for the most part may be said to represent good sanitary conditions. Some of the parks are not wholly completed but are rapidly approaching that desired end. The condition of some of the ponds will be improved by time; the pond on the public garden needs grading and paving for sanitary purposes. The paved streets have been greatly improved in the last two years, and, for the most part, are kept in a cleanly condition. Some of them, for the want of better paving, are very difficult to keep clean. Most streets in all cities present an unclean and offensive surface. This condition may be due to a faulty pavement, want of pavement, or a lack of care supported by a popular notion that an unclean and muddy condition of the streets has no appreciable effect upon the public health.

The macadamized streets, where much used, are unclean and offensive at least six days in the week. It would be in the interest of the public health, a cleaner atmosphere, greater public convenience and economy if all the macadamized streets, within the built-up portions of the city, were paved with asphalt or hard brick with close joints.

There are large tracts of vacant land in the outlying districts and some lying nearer the centre of the city. Some of this land is at a low grade, and in portions of it are found creeks and ponds of more or less stagnant water. This water becomes offensive and troublesome when found within the neighborhood of dwellings by becoming mixed with drainage or other foul matters.

Difficulty has been found in various ways in securing a total abatement of many of these nuisances. A resort to the courts and the use of the city's money has resulted in the abatement of the larger and more serious specimens of this class of nuisances; but there are still many delinquent owners under orders, or whose cases are in court at the present time. An improved law for use in securing the filling of such lands to a proper grade is now under consideration at the State House. It would be difficult to say to what extent this class of external or distant nuisances affect the public health, but they are unsightly, noisome, sometimes extremely offensive to smell and, doubtless, to some extent, prejudicial to the health of those within their immediate vicinity.

A very large part of the occupied area of Boston, exclusive of Dorchester, Roxbury and Brighton, has been made by raising the grade of marshes and by filling on tide-water flats. This made land is found particularly in South Boston, Charlestown, East Boston, and at the so-called North, South and West Ends of the city.

This made land is occupied principally for dwelling purposes with a dense population, and partly for business purposes. The grade of the streets in these sections is from twelve to eighteen feet above mean high water, while the cellars are below average high water, are frequently wet, and many of those in the business sections are so low as to require boxing to keep out the tide and surface-water.

It does not necessarily follow that a territory will be unhealthy because the land is made by filling and reclaiming it from tide water. A healthful residence upon such soil depends rather upon the height of the surface of the soil above the ground water-level, the character of the soil between those levels and the exclusion of the soil air from the cellar. The cellar, situated near the ground water-level and in the unclean soil, must continually receive unclean and damp air from such a soil, unless provided by special means to prevent it. Portions of this land have been made with the refuse and dirt of the city, while other portions have been filled by clean gravel from suburban hills. The cellar in one case gets the foul and damp air from the soil, and in the other it is a question of shutting out the dampness from below. For the most part, the soil of the higher elevations of the city is damp and wholly without artificial drainage, while the filled portions are at too low a grade to exclude dampness without extraordinary means.

The alley-ways of the city are numerous, occupying

[1] Read before the Boston Society for Medical Improvement, May 8, 1893.

no insignificant portion of the city's area, and are an important part of the city's conveniences. Until recently, there has been no definite understanding as to who should take care of them. This care has been exercised in part by the city and in part by the abutters, and the condition has been most unsatisfactory. For the most part they have been unpaved, uncleaned, and a source of much complaint. It has recently been decided, however, that the city will do no more cleaning in these private ways, and the Board of Health has undertaken to secure the proper care of them by the abutters who, alone, hold the fee in them and are responsible for their condition. These places should first be well paved, and then their cleanly condition may be secured at a trifling cost.

The cleaning of private yards and spaces about dwellings is a matter requiring the utmost vigilance of the health inspectors. There is no law or power known to the Board of Health by which certain people can be made to keep their premises clean for more than a few days at a time.

The old privy vaults and cesspools, with their accumulations of filth which were once so common, are now rapidly disappearing from the city. Nearly 7,000 of the privy vaults have been demolished in the last few years, and the few remaining, where a public sewer abuts the premises, are under orders to go. The yard cesspools, which are also common nuisances, are being changed from receptacles for sink and other house drainage, to those for surface drainage only,

The public sewerage is mainly good, including the improved intercepting system. More sewers are needed in many parts of the city where accumulations of filth are now being stored in vaults and cesspools, and are causing considerable annoyance. Many of the old sewers at the North and West Ends of the city are in a dilapidated condition, are very foul, and should be rebuilt without delay. The whole sewage of Cambridge, Somerville, Charlestown, Chelsea and East Boston still discharges into the Charles River and upon the flats in those sections, creating a most serious nuisance.

We see no remedy for this state of things except in the completion and use of the metropolitan intercepting sewer, which is still under construction and which ought to be completed at the earliest practical moment.

Private drainage in our city, like that in most cities, is unsatisfactory, the cause of an immense amount of inspection, complaint and annoyance, and, undoubtedly, the cause of much ill health.

To relate all that need be said concerning house drainage or plumbing in our city would make a very long story, which need not be told to-night. We have statute laws and city ordinances which specify the method, material and workmanship necessary in constructing house drainage. Plans for construction and repairs are submitted to, and the work approved by, the Inspector of Buildings. The Board of Health is called upon to find defects and to order repairs. Such repairs number each year about 4,500.

For the purpose of ascertaining to what extent defective conditions of plumbing exist, and to what extent traps are supplied and water-closets substituted for vaults, we have taken a large number of blocks of dwellings, both new and old, each season for thirteen years, and made house-to-house inspections with the following results:

Want of traps first five years, averaged 50 per cent.; during thirteen years 32 per cent.; and during the last year 22 per cent.; defective conditions of plumbing, first five years, averaged 49 per cent.; whole thirteen years 39 per cent.; and last year 34 per cent. Use of privy vaults, first five years 28 per cent.; for thirteen years 14 per cent; last year three per cent. This means not only a very poor state of plumbing, but a want of commendable progress in the substitution of a better condition, in other words, it indicates poor construction and inefficient repairs.

The removal and disposal of refuse material has become a very serious question to the city as a corporation, and to the individual citizens. At present, it is stored for a time about the dwellings, then removed by the city carts through the streets at a cost of about $170,000 per annum, and afterwards sold to the farmers to create nuisances elsewhere.

The street sweepings, house dirt, ashes, and a great variety of rubbish and refuse material, including some of the garbage, to the amount of 2,500 loads, or 100,000 cubic feet per week, are dumped in the harbor. It has always seemed to me that the kitchen waste should, by some special provision in the stove, be disposed of as soon as it is made. By this means all subsequent nuisance and expense would be avoided. In regard to the other wastes of the city which are now dumped in the harbor or upon vacant lots for filling, we are of the opinion that such material should first be burned and then used for filling.

Tenement and lodging-houses are objects for constant attention. Poor people and our newly-made citizens from abroad are much inclined to crowd into small spaces where they soon create a most unhealthful condition of things if left to themselves. We have vacated many of the worst of these buildings, have cut down and limited the number of occupants in others, burned much of the bedding, disinfected the remainder, and are enforcing a better degree of cleanliness, light and ventilation in both tenement and lodging-houses. This work can only be regarded as a most incessant and aggressive one in certain quarters of the city.

MASTOID MEASUREMENTS.

BY W. P. COUES, HARVARD MEDICAL SCHOOL.

I recently examined 400 crania at the Peabody Museum in Cambridge, with the view of determining (1) the relative frequency of the asymmetric mastoid processes, and (2) whether the mastoid process being small or the digastric fossa deep made any difference in the depth and direction of the lateral sinus.

I found that out of the 400 crania examined 13 (or 3.25%) had asymmetric mastoid processes; only marked differences such as could be plainly seen were taken.

This examination shows that in 96.75% the mastoids were symmetric; of the 400 crania examined 164 had either a small mastoid or a deep digastric fossa. Out of these 164, 136 (or about 83.3%) had a very deep lateral sinus coming up towards the mastoid antrum.

This percentage shows that where the digastric fossa is deep, or there is a small mastoid process, the lateral sinus is almost invariably deep, coming up towards the mastoid antrum and encroaching on the mastoid cells, so that in operating on the mastoid, if we find it small, or the digastric fossa deep, great care must be taken lest the lateral sinus be wounded.

Clinical Department.

FRACTURE AND INJURIES TO THE HEAD.

BY DAVID DANA SPEAR, A.M., M.D., FREEPORT, ME.

CASE I. A young man, age seventeen, fell upon a large broad belt, and was carried over a drum making some two hundred revolutions per minute. Thrown against the side of the building, striking his head against the rusty end of a clapboard nail, about one-third of the nail was driven through the left parietal bone and broken off flush with the surface. He was alone at the time of the accident, but was found face down upon the floor, unconscious, with stertorous breathing. The pulse was full and slow, pupils dilated — unconsciousness was complete. He could not be made to swallow anything placed in the mouth. It was impossible to remove the nail by forceps; and, of course, the only remaining thing to be done was to remove a disk of bone including the nail with a small trephine. This was done, with almost immediate return to consciousness. In about six weeks the young man returned to his work, complaining only of slight headaches when he became tired. This case occurred in the early part of my practice, previous to the days of antiseptic surgery, and may be only of interest in connection with the other cases following as illustrative of what happens to fall to the lot of village and country practice.

CASE II. Two children were coasting down a steep hill, their ages respectively six years and nine years. The sled struck against a tree; and the youngest child was dashed against it, striking the left side of her head with sufficient force to fracture the entire upper two-thirds of the parietal bone. The line of fracture was easily felt. When summoned, I found the child lying in bed, completely unconscious. Her limbs would remain in any position in which they were placed; the respiration was quiet and feeble; the pulse was feeble, frequent, and intermittent; the pupils were contracted. On placing any liquid in the mouth, it would be swallowed. I decided not to attempt any operative procedure at this time, but waited, carefully watching my patient's condition.

At the end of eleven days consciousness gradually returned; and at the end of four weeks she had so far recovered as not to need constant care and attention. During the first eleven days, ice was applied by means of a bladder placed upon her shaven head. The bowels were moved every alternate day with salines; and iodide of potassium was given in three-grain doses four times daily. At the end of six weeks recovery seemed permanent; and over the now intervening space of twelve years there have been no serious symptoms attributable to the injury.

CASE III. R. R., aged nine years, fell from a bridge a distance of fifteen feet, striking his head and left shoulder upon the rocks below. He was picked up insensible, and carried home on a mattress by several men. A physician was called, and pronounced the injury necessarily fatal. I saw the little patient about half an hour later. A fracture was found in the left parietal and frontal bone. One straight fissure extended from the lambdoid suture to the orbit, terminating a few lines internal to the supra-orbital foramen. The line of fracture crossed the coronal suture at right angles; and the whole line of fracture was three-fourths of an inch external to the median line of the vault. There was also a stellate fracture covering the upper half of the temporal bone; and the bone was so broken in three places as to allow the fragments to be driven down firmly upon the dura mater. The pupils were widely dilated, and the eyelids were closed. It was impossible to arouse the little patient. The respiration was quite full and noisy; the pulse was full but slow; deglutition absent, and any liquid placed in the mouth flowed out of it. Upon making an incision external to the fracture and around it, I was able to remove the pieces from the dura mater, to raise the depressed portions of the parietal, and to trace the first-described line with the supra-orbital foramen to the orbital portion of the frontal. The cellular tissue about the orbit was inflated, and the condition of emphysema obtained, showing that the frontal sinus had been opened.

The operation was carefully made, and with antiseptic precautions. The hair was cut from the head; the head was washed thoroughly with soap and water, and finally with a 1 to 1000 solution of bichloride. The instruments used were all sterilized, the hands washed in bichloride solution, and the sutures were of chromatized catgut.

An hour after the operation the boy became conscious. The second day the pulse reached 140; but the temperature never exceeded 99° F. After the second day the pulse became normal, and the recovery has been rapid and apparently perfect, without a single unfavorable symptom.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR Meeting Monday, May 8, 1893, the President, DR. C. F. FOLSOM, in the chair.

DR. J. H. MCCOLLOM read a paper on

TYPHOID FEVER IN BOSTON.[1]

DR. CHARLES HARRINGTON read a paper on

THE PRESENT CONDITION OF THE BOSTON WATER SUPPLY.

DR. S. H. DURGIN read a paper on

THE SANITARY CONDITION OF BOSTON.[2]

PROF. T. M. DROWN: The subject of the water-supply of Boston is one I am much interested in. I do not know that I can add anything to what Dr. Harrington has said with regard to this water-supply. I agree with him that the water-supply is good and is not growing worse, that it is growing better. I, too, have been asked scores of times whether the Boston water is fit to drink, and my answer has always been that it is good water. Those who prefer spring water on æsthetic grounds because it is colorless, have a right to their preference; but those who say there is danger in drinking the Cochituate water are simply ignorant of the conditions under which the water-supply of Boston is collected and stored. I regard it as safer drinking-water than many of the spring waters which are sold. It is impossible to get a supply of fifty million gallons a day from an uninhabited region unless we go to a

[1] See page 295 of the Journal.
[2] See page 298 of the Journal.

great distance. A near-by supply to a great city will always have upon its borders a greater or less population. The collecting area of the Sudbury River, about 75 square miles in extent, has a population of about 350 to the square mile. Lake Cochituate has a small drainage area of 19 square miles and a population of about 850 to the square mile, the combined water-sheds having a population of approximately 450. The Mystic supply has about 850 to the square mile. By comparison it may be mentioned that the Croton water-shed in New York has 70 to the square mile.

The way in which house drainage usually reaches a stream is important. If sewage enters a stream directly and the polluted water is delivered promptly to the consumer, we have the maximum of danger. Where there is no sewerage system and the water gradually soaks into the ground and reaches the reservoir or collecting basin only after prolonged filtration the danger is reduced to a minimum. Many of you may have heard of the care that is supposed to be taken with the Croton water-shed. In one of the reports of the New York State Board of Health may be seen a great number of photographs of all the houses on the water-shed. There is very little said about the care of the Boston water-shed; but I know that there is as careful supervision of it as in New York. The superintendent, Mr. Fitzgerald, has a record of every house, barn and stable, on the water-shed, and of the changes which take place from year to year. Inspection is done very thoroughly and completely to detect accidental or intentional pollution.

The drainage of South Framingham, Marlborough, and Westborough, which formerly went indirectly by soakage, through the ground into the Cochituate supply, is now entirely removed by systems of sewerage, and goes outside the drainage area. The result of this is that the drainage of a very large population on the Sudbury water-shed has no more relation to the Boston water-supply than if it were in the western part of the State.

There is another ground for safety in the Boston water-supply and that is the large size of the reservoirs and the long time it would take for any disease germs entering these reservoirs to reach the consumer. I suppose it would take any matter entering Lake Cochituate by Pegan Brook (which drains Natick) two months before it reached the consumer in Boston, and more likely it would be a much longer time. The same may also be said of the reservoirs on the Sudbury River. But to make security doubly sure filters are now being constructed to filter all the water of Pegan Brook before it enters the lake.

Few are aware of the great purifying power of porous ground. A familiar instance in this vicinity is the filter gallery on the shore of Horn Pond in Woburn. This pond is highly polluted with the drainage from tanneries, yet the filtered water in the gallery which is one hundred feet or less from the pond, is almost perfectly purified as far as organic matter is concerned. Now the ordinary ground-water of a region like the Sudbury and Cochituate water-sheds has, on the average, been filtered a great deal more thoroughly than the water of Horn Pond. Moreover, the efficacy of filtration, both in nature and in artificial sand filtration, in the removal of bacteria is very great, so that the possibility of the passage of disease germs into a water-supply after a long passage through the ground is very remote. When a drainage area becomes very densely populated, it naturally becomes unfit for a source of water for drinking. In such case there is the alternative of artificial sand filtration or the seeking of a new supply.

Prof. W. T. Sedgwick: In listening to the speakers to-night the first feeling that I had was one of satisfaction, as a citizen, that the interests of the city of Boston are in the hands of people who are studying the subject with so much apparent intelligence as we see in these papers. If any one will take the trouble to ask what is going on in some other cities of our country and to see the class of people who have charge of their sanitary interests, I think he will return home with a good deal of satisfaction. Unfortunately I lost a portion of Dr. McCollom's paper, but what I heard of it interested me very much. It is a fact that we have more typhoid fever than some other cities in proportion to our population, less also than many others; and the question naturally arises, What does it mean? I have given no special study to this side of the subject, and was therefore very glad to hear what Dr. McCollom had to say; and it seemed to me that on general principles any one interested in sanitary science must heartily agree with most of it; for if there is anything clear nowadays it is that broken drains *per se*, new-made land, bad smells, etc., are not the principal causes of typhoid fever, if, indeed, they have anything whatever to do with it. Dr. William Budd showed, years ago, that pig-sties, dung heaps and the like could exist in a country town without causing any typhoid fever. When once this was introduced, however, it might flourish in such towns more than in others similarly situated. I was interested to hear Dr. McCollom speak of the wells. I have been studying some epidemics of typhoid fever; and although I have seen a number of them, involving possibly five hundred cases, I have not yet seen a single epidemic of typhoid fever or any cluster of cases of it which I could trace to a polluted well. I earnestly believe that polluted wells have occasionally produced typhoid fever, but I think that we have laid too much stress on these; and the experiments of the Lawrence Experiment Station have taught us much in that regard. A few feet of good filtering material will effectually protect against the germs of typhoid fever and ordinary bacteria.

The State Board of Health has been making in the last three years an interesting series of experiments of epidemics of typhoid fever, and some of the conclusions that have been arrived at may be stated in this way:

One of the leading causes of typhoid fever is polluted water-supply.

The next, perhaps, in importance, or one of the next, is polluted milk-supply — I mean here infected as well as polluted. If anything stands out clearly, it is that ordinarily polluted water will not produce typhoid fever. The city of Lowell is drinking very dilute sewage all of the time, but it is only now and then that it has epidemics of typhoid fever. One of the wells in Lowell is so bad in its chemical and bacterial analysis as to stand out conspicuously among all the wells we know, and yet careful investigation has shown that people using that water are not suffering from typhoid fever more than their neighbors who do not use it. The reason is simply that it is not infected.

The third cause, and probably throughout the State the principal cause of typhoid fever, is secondary infection, not usually direct contagion but in any one of

the many ways in which indirect infection may arise; and as this is less well recognized than it might be by physicians and sanitarians, it may be worth while to say just a word or two about it. One case was discovered in Provincetown in which the family consisted of ten persons. Typhoid fever was introduced into the family probably through one of the children who had been playing with the children of a neighbor's family in which there was typhoid fever. These families were Portuguese. You know how such people live. On the table of the common living-room there often stands the greater part of the day the beginning or the end of a meal — pieces of bread, cake, etc. The children come in from play. One or more of them is in the early stages of typhoid fever. They visit the privy, come back, finger the bread and cake, eating some and leaving some. Other children come in and eat of the food, and by some such vehicle as this one of the children of this family brought the germs of the disease from another family. Just two weeks from the date of the first case two more of the family of ten came down with typhoid fever. Two weeks later more came down and there were in all five successive crops of typhoid during which nine out of the ten in that family had typhoid fever at intervals of two weeks. There was no reason to suspect the sink-drain, the well or the privy — as these latter were used in common by other families. This particular family then had five successive crops of typhoid fever two weeks apart almost to a day.

The State Board of Health has collected other examples of the same sort and I think it may be safely said that the three causes which I have mentioned are the principal causes of typhoid fever.

It seems to me that it is pretty safe to conclude with Dr. McCollom that the water-supply of Boston is not productive of the typhoid fever of Boston. It seems to me, however, that it should be borne in mind that typhoid fever has been declining as the water-supply has been improving; and in the present state of our ignorance of the duration of the life of typhoid-fever germs, while we believe that such germs do not come through the water-supply of Boston, it may be wise to keep an open mind in that direction. I do not believe, however, that the typhoid fever of Boston is to be connected with the water-supply. With regard to the milk-supply, it seems to me much may be said. We have a most efficient milk inspector; but milk comes from all over New England, and no one knows the source of it exactly. Before we can decide that milk gives us this extra amount of typhoid fever, we must inquire whether our milk-supply is worse than that, for example, of New York, which has less typhoid than we have. I do not think that it is; and yet I do believe that there is a loop-hole here. I believe that some of the cases of typhoid fever in Boston are due to infected milk. Then there is the point of the people going out of town. I believe that this is a serious point. I believe that Boston, surrounded as it is with suburbs and not far from infected districts, such as Lawrence and Lowell, necessarily suffers through imported cases. Finally, there comes the matter of secondary infection, in the efficacy of which, I most firmly believe. I know of some cases in Boston in which secondary infection can be clearly traced. No one of these principal causes is in itself, probably, sufficient to account for the whole. What little excess there is, however, is probably chiefly due to the geographical situation of Boston and the migratory habits of the inhabitants. Boston is a place near regions of polluted water-supply, a place with milk-supply not entirely under control, and last and probably not least, there are abundant opportunities for secondary infection.

DR. F. W. DRAPER: The papers we have heard and the remarks we have had are full of suggestion to the sanitary student, and it is difficult to select out of the mass of material supplied, a single theme for further discussion. What I shall say will be in the line of reinforcing two points, one in Dr. McCollom's paper and the other in Dr. Durgin's. I want to emphasize what has been said by Dr. McCollom with reference to the milk-supply as a menace which should be watched continually and which has not received, it seems to me, in sanitary administration, the attention which it deserved as a probable potential source of the typhoid fever which we have in Boston. I think it is perfectly clear that the water-supply of Boston is above reproach in that matter and that we must search in other directions for the explanation of the etiology of the disease here. The milk-supply, it seems to me, presents a fair field for discussion in that relation. Occasionally, as we know, the matter has been discussed in this and other societies, but the practical results have been extremely small and not in proportion to the importance of the subject. The various epidemics that have been studied by Professor Sedgwick and others, are a demonstration that this menace is not imaginary but real. There is one other source of danger which has not been mentioned to-night in the discussion of the causation of typhoid fever, and perhaps an insignificant one from one point of view, and yet it ought not to be left out of view. I refer to the transportation of the typhoid infection by insects. The domestic house-fly is not a fastidious creature, either in its food or its habits. It can travel far and fast, and I think it quite probable that the house-fly can be the means of transporting to food from exposed typhoid stools the typhoid bacilli, and the practical lesson is in the nursing care of all typhoid patients, to promptly and thoroughly disinfect the stools so that they shall not be a source of danger.

One point suggested in Dr. Durgin's paper was the wasteful and highly improper method of disposing of the refuse of a great city. He has graphically described the method used here, and it seems to me one reform that can be inaugurated and carried out with propriety, is that the waste of the city should be more economically disposed of than at present. Cremation is the proper method and the sooner the City of Boston establishes a proper plan for that purpose, the better will our interests as a community be served and the safer will our public health be.

DR. S. W. ABBOTT: I have been much interested in these papers, particularly in the first upon typhoid fever, and I may add that during the past year or two I have made especial analyses of the whole State upon this subject, grouping the cities and towns according to the rate of deaths from typhoid fever to the population, for a period of twenty years (1871–1890). We do not know much about the reported cases except in the cities.

In the final grouping I find that Dr. McCollom's statement in regard to overcrowding is fully borne out, and that is, that typhoid fever is not a disease which is due to overcrowding. On the other hand, in

seven other diseases which were considered, measles, scarlet fever, diphtheria, small-pox, cholera infantum and phthisis; in each one of these overcrowding and density of population did much to contribute to their spread; but in typhoid fever we had the highest death-rate in the more sparsely-settled districts. The Connecticut River valley seemed to be more affected than any other part of the State.

PATHOLOGICAL SPECIMENS.

DR. RICHARDSON: The first specimen is an enormously dilated vermiform appendix, containing two large fæcal concretions. The patient, a young woman, presented the usual symptoms of a severe localized peritonitis of five days' duration. In the right lumbar region a marked dulness was found that extended towards the median line and gradually became lost in the normal abdominal resonance. Great tenderness and pain in this region indicated unmistakably an acute inflammatory process starting, probably, in a perforated appendix situated behind the ascending colon. The local conditions demanded immediate exploration. A very small amount of fetid pus was found behind the cœcum, the posterior wall of which was apparently the seat of a very great inflammatory thickening, and through which there was a small perforation. Further search, however, showed the tip of the appendix adherent to the under surface of the caput cœci, and situated so as to point towards the bladder. On separating the presenting end of the appendix with the finger, it was found that the thickened mass was the appendix itself, slightly adherent throughout its distal portion, and inseparably grown to the bowel along its proximal half. The body of the appendix was as large as the small intestine, and contained two slender and smooth concretions, one an inch and a half and the other an inch in length. There were two perforations, one at the tip and the other near the base. By an incision through the latter, the appendix was removed close to the cœcum and the parts tamponed with gauze. The patient is doing well.

It is unusual to see a specimen like this. Appendices may be very long or very short; they may be slender or thick, but it is remarkable to find one over an inch in diameter, even when inflamed.

Recent adhesions may be separated safely and easily in this disease, but it is always dangerous to make violent or prolonged efforts to break up the adhesions of long-standing inflammation.

In this instance the peritoneal cavity was opened — a complication much to be deplored whenever unnecessary, some authorities to the contrary notwithstanding. I was gratified in reading Senn's remarks today in support of this view (Chicago *Clinical Review*, vol. II, page 86).

The second specimen consists of several gall-stones of unusual shape and outline, resembling blackberries. All, found in a normal gall-bladder, made their presence known by occasional attacks of biliary colic, varying in direction and intensity. For the first time, having closed the gall-bladder with interrupted sutures, I left it in the abdomen, without drainage, — the so-called ideal operation. Convalescence was unusually brief.

The third specimen, closely related to this subject, is a dissection of the cystic, common, and hepatic ducts. The internal surface of the cystic duct shows numerous transverse folds of mucous membrane, with sharp edges, which prevent the passage of an instrument in either direction, even when by tension the canal is made straight. Much more difficult, if not impossible, would be the passage of a probe when the cystic duct is in its normal position of double curve. The hepatic and common ducts present no such obstacles to instrumentation. Even the normal constriction at the duodenal orifice permits the passage of a probe of considerable size.

These peculiarities, hitherto little if at all studied with reference to surgical interference, have become of very great importance in the progress of surgical art; they illustrate the necessity of teaching, in addition to the regions of classical surgical anatomy — limited as they have necessarily been to the extremities chiefly — the relations of those deep parts which are now the field of surgical progress.

During the past two years I may have had occasion to apply a knowledge of the anatomy of the carotid and jugular, or of the parts in Scarpa's triangle half a dozen times; during the same period I have needed a familiarity with the parts about the foramen of Winslow twenty, and about the vermiform appendix at least fifty times. The surgeon of to-day must be able to recognize, therefore, arteries, veins, and other structures in regions hitherto demonstrated only by the pathologist or by the pure anatomist. The field of anatomy, therefore, taught as an applied science, may be said to include the whole body; and the student who expects to keep up with the progress of surgery must know not only the surgical anatomy of the bend of the elbow, the axilla, or the groin, but also the cerebral convolutions, the foramen of Winslow, or even the spinal cord.

Recent Literature.

Forensic Medicine and Toxicology. By J. DIXON MANN, M.D., F.R.C.P., Professor of Medical Jurisprudence and Toxicology in Owens College, Manchester, etc. Philadelphia: P. Blakiston, Son & Co. 1893.

The literature devoted to legal medicine is not so full as to render a genuine addition to it unwelcome or superfluous. A book that shows real merit; that is not written with a purpose merely to gratify the writer's vanity, or simply to advance the publishers' commercial enterprise; that represents recognized authority; that gives new and attractive treatment to old themes; — such a volume will always win its way to favor. Judged by these tests, the work of Dr. Mann is a valuable contribution to modern medico-legal writings. Clear and didactic in style, judicial in spirit, concise yet comprehensive, it is a volume that can cordially be admitted to fellowship with older writings relating to forensic medicine and that will find congenial association with the masterpieces of Taylor and Casper and Beck and Orfila. Its primary merit is that while it discusses the usual variety of topics which are included under medical jurisprudence, it discusses them with an intelligent purpose to give them a modern and fresh flavor. It thus results that it is an attractive exception in its class; it is not a mere rehearsal and re-issue of old and familiar facts, grouped and studied by a new author; nearly all the citations are

dated within the past decade and while ample justice is given to older authorities their teachings are reviewed in the light of the latest experience and observations. The tone of the book is therefore distinctly original and progressive.

It is fair to state that the chapters show some inequality in merit. The section on Wounds, for example, is clearly inferior to that on Infanticide and the Proofs of Living Birth, and to that on the Signs of Death, Cadaveric Rigidity and Putrefaction. It would seem that some themes stimulated the author's zeal and industry more than others and that, while not indifferent to any parts of his work, there were certain portions which, he felt, he could discuss with relatively greater authority and ability.

An occasional lapse from smoothness and grammatical accuracy has escaped the notice of the proof-reader of this first edition and it is to be hoped that these signs of heedlessness will not appear in later issues. The critical reader, who reasonably looks for absolute freedom from error in a treatise on forensic medicine, feels a little shock of surprise when he comes on such expressions as these: "a goodly array of examples are at hand"; "neither the one nor the other are discoverable"; "the vulva are open and tumid"; "both cornuæ of the hyoid bone"; "pregnant sufficiently long as to render possible the birth of a living child"; "there was no blackening, neither round the wound, nor on the neck, nor face." Such words, too, as "quieten," "negligible," "disposedness," "unrespired," are novelties without standing in the dictionary.

But these isolated and infrequent departures from rhetorical rectitude are not mentioned to throw discredit upon a book which can justly lay claim to recognition as a reliable and attractive treatise to which the student and practitioner of legal medicine can turn with confidence that it will offer wise and trustworthy counsel for safe guidance.

Fonctionnement de la Maison d'Accouchements Baudelocque, Clinique de la Faculté, dirigée par le Prof. A. Pinard: Année 1892. Par DR. G. LEPAGE, Chef de clinique. 8vo, pp. 107. Paris: G. Steinheil. 1893.

This work is the annual report of the labors which have taken place during the year 1892 in the Baudelocque Clinic. This clinic is freely used for purposes of teaching, 224 students and numerous French and foreign graduates having received instruction during the year. The principles of asepsis are rigidly taught and enforced, as will be seen by the record of septic deaths, namely, three only in 1,834 cases, or 0.16 per cent., — a very creditable showing in a clinic so freely used by students.

The report is carefully classified, and will be useful to teachers and writers for statistical purposes. Chapter VI will be of especial interest at this time for its record of the results in the clinic with the revived operation of symphyseotomy. This operation was performed in thirteen cases, which are reported in detail. The mothers all recovered, although in several cases the convalescence was pathological; of the thirteen infants, all were born alive; but two died on the second day, and one on the third.

As a whole the report is highly creditable to the clinic; but we cannot forbear pointing out, as we have so often done, that the value of all obstetrical writings is greatly enhanced by the use of a uniform nomenclature. We cannot understand why the French obstetricians adhere to their old nomenclature. Had the new nomenclature been introduced by a German, we should not have expected the French to have adopted it; but as it was brought forward by a Scotchman at a Congress held in the United States, and as it was adopted for general use by a representative, international body, we fail to see why it should not be universally adopted, to the great convenience of all.

Elements of Human Physiology. By ERNEST H. STARLING, M.D., (Lond.), M.R.C.P. Small 8vo, pp. 437. Philadelphia: P. Blakiston, Son & Co. 1892.

This is an American reprint of the excellent little book by a lecturer on the subject at Guy's Hospital. It is the best *small* physiology known to the reviewer. Almost all purely histological matters are very properly omitted. Nearly every topic treated shows careful consideration of the freshest researches, there being perhaps, here and there, a tendency to lay a little too much stress upon the work of certain British experimenters. The illustrations are generally well selected and instructive. Naturally there is some disproportion of space allotted to the various topics but this is a necessary evil of small books about a big subject. The book is well calculated to supplant all "quiz-books" and "compends" as a syllabus for following lectures or for use in the cramming process which is sometimes unavoidable. The only criticisms which a somewhat cursory examination suggests are: a little weakness in the portion devoted to the chemical constituents of the body (especially as to starches and sugars); a somewhat "step-motherly" treatment of deglutition; and the statement that the residual air "amounts to about 2,000 c. c."

The Chemical Basis of the Animal Body: An Appendix to Foster's Text-Book of Physiology. Sixth edition, pp. 288. By A. SHERIDAN LEA, M.A., D.Sc., F.R.S. New York and London: Macmillan & Co. 1893.

This new edition of the "Appendix," the first for some ten years, will be welcome to all. It has grown into an independent work, being about four times as large as formerly, and is correspondingly better, good as it was before. In fact, there is no equally good account of the chemical side of physiology in English at the present time. Its convenient size and the fact that the part is sold separately at a reasonable price, must commend the book. Its pleasing freedom from obscuring technicality makes it an excellent book for medical students and for the practitioner who may wish to get an idea of the present views concerning ferments, ptomaines, proteids and so on. The new light recently thrown upon the composition of the sugars is briefly, but perhaps sufficiently reflected. The extensive references to the literature (quite complete to 1891) will be very useful to the student.

A slight defect is the neglect to note the synonyms of the various ferments. For example, the fat splitting ferment is now called "pialyn," but no intimation appears to be made of the existence of another name, "steapsin," which had already come into quite general use. Pialyn is also a particularly unfortunate innovation on account of its close resemblance in sound to "ptyalin," which it in no respect resembles. "Rennin," to which Foster had already committed himself,

is also retained in preference to the much more suitable "pexine" of certain French writers — at least more suitable except possibly for its likeness to "pepsin."

The Creation of God. By DR. JACOB HARTMANN, M.D., St. Louis Medical College; M.B., Toronto University; M.B., Trinity College, Ontario; Member of the College of Physicians and Surgeons, Ontario; Licentiate of the Royal College of Physicians and Surgeons, Edinburgh, Scotland; Member of the County Medical Society of New York, etc., etc. New York: The Truth Seeker Company. [No date.] Pp. viii, 432.

This little volume gives Dr. Hartmann's views as to the way God was created. It will not commend him (the author) to Presbyterian synods and general assemblies, but contains an immense fund of information concerning the universe and other matters. It is illustrated by a curious "map of the intellectual faculties" and their distribution over the convolutions, which will be very instructive to students of modern views of localization. There is also a useful "map of the deluge and Garden of Eden" at the other end of the book. The thoroughness of the author's physiological training will be seen by a glance at his account of the "third nerve, motor acuti," the "hyperglossal" nerve, and of the way in which "the spinal accessory supplies some muscles of the back" (p. 236), and also of "the centre through which the vægus (pneumogastric) influences the secretions of pancreatic juice, and possibly of the other digestive juices" (p. 237). The regenerative character of his learning is also indicated on p. 304 from which we quote two sentences: "Vegetable chemical compounds, organic substances, can be produced only under certain vitalizing conditions and influences," "wherever upon the surface of this earth, the sun's rays produce a certain degree of heat, temperature, CHO may combine and evolve vegetable life."

Occasionally poetry is introduced. As it is mostly without quotation marks, we may be permitted to infer that the exhausting and extended reading of our author has not altogether prevented occasional dalliance with the muse. One sample must suffice:

> "No soul you will ever find,
> Trust not in its life or death;
> Education makes the mind;
> Oxygen is the life's breath."

Medical Pocket-Atlases. — Obstetrics: Part I, Labor. Delineated in 98 plates. By O. SCHÆFFER, M.D., Assistant at the University Frauen-Klinic in Munich. Translated and published under the supervision of J. CLIFTON EDGAR, M.D., Adjunct Professor of Obstetrics in the University of the City of New York, etc. New York: L. Hydel. 1893.

This little volume is the first of a proposed series of medical pocket-atlases, which are "intended to illustrate clearly and succinctly the entire field of medicine." In this atlas Dr. Schæffer has aimed to represent "the various obstetric presentations step by step in a continuous series of diagrams, which, though partly schematic, show the delivery of the child and placenta in a scientifically accurate way." The text, which is intentionally brief, is printed under each figure. There are seven folding sheets, each containing fourteen figures; the size of the book is convenient for the pocket.

Plate I is devoted to the first vertex position (O. L. A.) and its natural development; Plate II, to the varieties of the first vertex position and their normal development. Plate III treats the first face position, its natural and its operative development by version. In this latter operation Schæffer's figure makes the operator bring down both feet; we believe it is better practice to withdraw only one foot in podalic version, leaving one leg to protect the funis from pressure during the extraction. Figure 42 in this plate shows admirably the proper method of manual extraction of the placenta.

Plate IV portrays the first oblique position (transverse presentation) and its natural development by spontaneous version and by spontaneous evolution; and Plate V, the first breech position (S. L. A.), its natural and its operative development by extraction. Figure 64 makes the operator prefer the posterior groin for digital traction: the anterior buttock is almost invariably the lower and more accessible. Figures 69 and 70 picture the introduction of the operator's finger into the child's mouth in the extraction of the after-coming head: we think it is better practice to obtain, when possible, and it generally is possible, a *point d'appui* on the upper jaw, as there is always some risk of injury, from traction on the lower jaw, either to the jaw itself or to the soft parts in the mouth.

Plate VI figures various versions in oblique presentations, development of the incomplete footling presentation, and corrections of cephalic presentations. Many useful obstetric manœuvres are portrayed in this plate.

Plate VII is devoted to the application of forceps: some of the figures are excellent; but others will be less valuable to American students, as the nomenclature employed is not always that with which they are familiar.

In a work of this character the labor of the translator is inconsiderable. Although we have not the German edition at hand, we have no question that Dr. Edgar has performed his task with accuracy and success. The printing was evidently done in Germany, or, if in this country, by printers unfamiliar with English. Doubtless the occasional typographical errors will be corrected in subsequent editions. We believe the atlas will be found very useful by medical students, and we welcome it as a useful addition to the teacher's armamentarium.

Nursing: Its Principles and Practice. For Hospital and Private Use. By ISABEL ADAMS HAMPTON. Illustrated, pp. 475. Philadelphia: W. B. Saunders. 1893.

This book, written by the Superintendent of Nurses and Principal of the Training School for Nurses, Johns Hopkins Hospital, shows wide and thorough acquaintance with the details of institutional nursing and instruction. Much space is given to the methods of carrying on the nursing in a large hospital and to the best arrangement of the studies of the nurses. It will prove of especial use in arranging the work in the many small hospitals now being established. For a nurse in private practice it is less useful though it contains many useful facts and hints. There is a good deal of theory and practice of medicine in the book and a few good, though rather unnecessary, illustrations.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 21, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

IMPROVEMENTS IN THE REGISTRATION OF CAUSES OF DEATH.

A COMMITTEE of the British House of Commons was appointed in March, 1893, "to inquire into the sufficiency of the existing law as to the disposal of the dead, for securing an accurate record of the causes of death in all cases, and especially for detecting them where death may have been due to poison, violence, or criminal neglect."

This Committee has held twenty-one sessions, has taken much evidence, and has made its report. This report, dated September 1, 1893, shows that there are still many defects in the registration laws of Great Britain, the class of deaths to which these defects refer being mainly those which are due to violence or to suspicious causes.

A prominent principle is brought out in this report, which is probably true everywhere, though not always in the striking degree which prevails in the crowded cities of England and Scotland. It is expressed in the following quotation: "The percentage of uncertified deaths is at its minimum at the period of life when men and women are self-supporting, when their lives are economically most valuable as bread-winners, namely, between twenty and forty, and that it increases on each side of that age-period precisely as childhood or old age renders the deceased, as a class, a burden on their friends." The percentage of uncertified deaths in England is at present about 2.7 per cent. of the total mortality, and in Scotland is as high as 5.8 per cent., and in some small districts much higher.

The coroner's system comes in for a share of criticism in this inquiry, and as usual proves to be sadly wanting, as compared with the systems of investigation in use in most Continental countries as well as in Massachusetts.

The Committee expresses itself in no doubtful language with reference to the need of reform in the matter of uncertified deaths. "We are much impressed," they say, "with the serious possibilities implied in a system which permits death and burial to take place without the production of satisfactory medical evidence of the cause of death. It is a most important duty of society to guard its members against foul play, and it appears to your Committee, that, as far as may be, it should be made impossible for any person to disappear from his place in the community without any satisfactory evidence being obtained of the cause of his disappearance. Your Committee, fortified with the weighty opinions of the witnesses who have appeared before them, have arrived at the conclusion that uncertified deaths, should, as a class, cease to exist, and that means should be devised whereby a medical certificate should be obtained in every case not certified by a registered medical practitioner in attendance."

In Paris and in other large French cities, a "Médecin Vérificateur" views every dead body, and an order for burial cannot be given till his report is made. If he finds the cause of death to be violent, suspicious or doubtful, he reports the case to the Mairie, who orders an official examination through the Procureur de la République. The proceeding in Germany is also of a like nature.

The Committee suggested, as an improvement in this direction, that medical officers should be appointed, who should investigate all causes of death which are not certified by a medical practitioner in attendance. It was also their opinion that this duty should devolve upon the medical officer of health of each district.

The Board of Health of Boston has taken the commendable course of requiring all cases of death from doubtful or unknown causes to be investigated by a competent physician; if found to be due to violence, such cases are referred to the medical examiner for further investigation. In its report for 1892 it appears that 557 deaths were thus investigated by the Board, and their causes determined. The ends of justice would be much better served if the Board of Health of every city and large town should follow the same example. A statute providing for such action would prove a useful amendment to the existing law.

Prominence is given to the fact that the true cause of death is often concealed, because the attending physician is tempted to defer to the feelings of the relatives where death has resulted from some cause which might reflect discredit upon the family, as in cases of death from delirium tremens, syphilis, insanity, etc. Hence some other cause is assigned. This disadvantage may be partially avoided by requiring that the certificate of death shall not be handed to the representatives of the deceased, but sent directly to the registrar.

The report shows that pit-burial is not uncommon in the densely crowded old cities of England; it being a common practice to dig large pits in which from fifty to sixty bodies are buried, such pits remaining open from four to six weeks, until they are filled.

With reference to other modes of burial, the Com-

mittee alludes to the subject of cremation, and states as the only objection, the liability to destruction of the evidence as to the cause of death in case of poisoning. As a remedy it is suggested in the report, that with the careful precautions adopted by the Cremation Society, there is little probability that cases of crime would escape detection, but as these precautions are voluntary, they should be made the subject of legislation.

With reference to the undertaker's fad of embalming all dead bodies, the Committee suggests that since such process introduces poisonous substances into the body and thus may hide the evidence which is essential to legal investigation, it should, therefore, be made necessary to obtain proper authority to deal with a dead body in this manner. An attempt to secure such a law was made before the Massachusetts Legislature a year ago but it was defeated.

The following is a summary of the recommendations of the Committee:

(1) That in no case should a death be registered without production of a certificate of the cause of death signed by a registered medical practitioner, or by a coroner after inquest, or in Scotland by a procurator-fiscal.

(2) That in each sanitary district a registered medical practitioner should be appointed as public medical certifier of the cause of death in cases in which a certificate from a medical practitioner in attendance is not forthcoming.

(3) That a medical practitioner in attendance should be required, before giving a certificate of death, to personally inspect the body, but if, on the ground of distance or for other sufficient reason, he is unable to make this inspection himself he should obtain and attach to the certificate of the cause of death a certificate signed by two persons, neighbors of the deceased, verifying the fact of death.

(4) That medical practitioners should be required to send certificates of death to the registrar, instead of handing them to the representatives of the deceased.

(5) That a form of certificate of death should be prescribed, and that in giving a certificate medical practitioners should be required to use such form.

(6) That it should be made a penal offence to bury or otherwise dispose of a body, except in time of epidemic, without an order from the registrar stating the place and mode of disposal, which order, after it has been acted upon, should be returned to the registrar who issued it.

(7) That it should be made an offence to retain a dead body unburied or otherwise legally disposed of beyond a period not exceeding eight days, except by permission of a magistrate.

(8) That the practice of burial in pits or common graves should be discontinued.

(9) That still-births which have the stage of development of seven months should be registered upon the certificate of a registered medical practitioner, and that it should not be permitted to bury or otherwise dispose of the still-birth until an order for burial has been issued by the registrar.

(10) That, subject always to the discretion of the Crown Office, the result of precognitions taken by the procurators-fiscal in Scotland, or the precognitions themselves, should be communicated to the representatives of the deceased when application is made for the same.

THE PHARMACOPŒIA OF 1890.

It is a pleasure, on account of its excellence, to announce to the readers of the Journal the appearance of the new Pharmacopœia, which will be official on January 1, 1894, and this seventh decennial edition puts the medical profession again under obligation to the Committee on Revision. It differs from that of 1880 in various ways. Ninety articles, formerly official, have been wisely omitted and among these may be mentioned the abstracts, preparations that have never justified themselves. Nearly as many articles have been added to the official list and the Committee have shown much discrimination in the selection of them. The following illustrate the character of their choice: cocaine hydrochlorate, strophanthus, vegetable cathartic pills, which cannot produce the serious symptoms sometimes following the continued use of compound cathartic pills, a ten-volume solution of hydrogen peroxide, here called hydrogen dioxide, the strength of which is so determined that this solution is the equivalent of a twenty volume solution as it is at present estimated in the United States, suppositories of glycerine, salts of strontium.

The Committee have adopted the metric system, using in most cases weights for solids and measures for liquids; they did not see fit to adopt the newly-proposed spellings, such as bromin and iodid for bromine and iodide; but they have introduced a change in chemical nomenclature, already widely accepted, in the designation of such chemical compounds as salts and oxides; by this change chloride of sodium becomes sodium chloride, nitrate of silver, silver nitrate. Likewise a number of alterations have been made in the official Latin titles; if we wish to be correct, we must write, after January 1st, opium deodoratum instead of denarcotisatum; the old term "mixtura" has been discarded and the new term "emulsum" substituted therefor in certain liquid preparations, which are properly speaking emulsions. Mixtura asafœtidæ, for instance, will therefore read emulsum asafœtidæ.

Certain changes have been made in the strength of the pharmaceutical articles and the more important of these have been tabulated so that their differing strengths in the present and the preceding Pharmacopœia may be compared at a glance. By the new method the stronger liquid preparations of opium are required to yield, on being assayed, 1.3 per cent. to 1.5 per cent. of crystallized morphine. In calx chlorata 35 per cent. instead of 25 per cent. of available chlorine is required, in liquor sodæ chloratæ 2.6 per cent. instead of 2 per cent. is required.

The tables of atomic weights, of thermometric equivalents, etc., are of especial use to pharmacists; unfortunately the very useful table of solubilities which the Pharmacopœia of 1880 contained is here omitted.

Substances which can be produced only under a patented process or which are protected by proprietary rights are not mentioned.

The profession will be repaid for familiarizing themselves with this revision.

MISDIRECTED SATIRE.

IT seems that Mark Twain has recently come across a Dictionary of Medicine published about one-hundred and fifty years ago, and has proceeded to make fun of it in his characteristic style. This has aroused the indignation of an English contemporary, who considers that antique medicine is too serious a subject to be trifled with. Our contemporary allows that Mark Twain succeeds in finding prescriptions in the work, which, "read by the light of recent clinical experience, may be pronounced as tentative, crude, and even risky"; but believes that he has erred in making "no allowance for the comparatively immature physiology and pathology of the days preceding biological chemistry and the microscope and the thousand and one aids to diagnosis elaborated in the intervening century and a half of time, which have strengthened the hands of men far inferior in native ability to the author of the literary fossil referred to."

The author suspects that Mark Twain has heard of Bonetus only in this dictionary, and grieves that his treatment for a pain in the head, namely, local bloodletting, should be the occasion of his misdirected and ill-inspired ridicule. "It may be news to Mark Twain to hear that Théophile Bonet (in Latin, Bonetus) was for his time an exceedingly able and accomplished physician, the medical adviser of the then Prince of Neufchâtel, and that he has an honourable niche in every great History of Medicine, including the quite accessible article in the 'Encyclopædia Britannica,' and by every philosophical student of scientific progress is regarded as a link, and a not inconsiderable link, in the chain of medical evolution. Nothing but the implication that his readers were as unenlightened as himself could have warranted the American humorist in making fun of a well-known figure in the gallery of medical portraits." Mark Twain is warned that he "could have found much more legitimate targets for his undoubted command of the risible susceptibilities of his readers in the country of his birth than any fossil which he has succeeded in extracting from the once useful but long superseded Dictionary of Medicine at which he levels so much misdirected satire."

Although the wit of Mark Twain has often amused the British public, this looks as if he were not entirely understood in England. We doubt whether any American would expect him to make allowance for the "comparatively immature physiology and pathology of the days preceding biological chemistry," or expect him to read up an article in the "Encyclopædia Britannica," on Bonetus, before criticising his prescriptions.

MEDICAL NOTES.

CHOLERA. — The cholera throughout the Mediterranean countries has declined during the last week. Russian statistics give no increase in the number of cases in St. Petersburg or Moscow, and point to a diminution in the number of cases through the provinces, but the official reports are not to be relied on. Roumania and the lower Austrian districts have no material change. In Antwerp there have been no new cases reported, but the disease appeared in Hamburg this week with a total of twelve cases up to date. Naturally considerable alarm has been felt by the people. In England another death has occurred in Hull, one in Grimsby and two cases have been reported from London. No new cases have occurred in New York or Jersey City and the quarantine against the port which was declared by Portugal has been removed. The disease is said to have appeared in Rio Janeiro, but no confirmation of the report has been received.

SMALL-POX. — Four new cases of small-pox have occurred in New York, and five cases in Brooklyn. The new cases all occurred in a tenement-house occupied by about fifty people.

IMMIGRATION VIA CANADA. — The request of the United States Government to be allowed to inspect all immigrants landing at Canadian ports, with a view to preventing the introduction of contagious diseases has been emphatically refused by the Canadian authorities. As the number of immigrants entering this country through Canadian ports is several thousand a month, the danger of infection is by no means slight; and a quarantine inspection of all trains coming from Canada is as important as that at our own seaports, though much more difficult.

PASSAGE OF A THERMOMETER THROUGH THE ALIMENTARY CANAL. — The swallowing of a clinical thermometer by an insane patient at Besançon recently was not without its usefulness. The thermometer, a self-registering one, was entirely of glass and 113 mm. long. No disturbance was noticed, and nine days later it was passed at the anus. The scale registered a maximum temperature of 38.7° Centigrade, but a subsequent verification of the instrument reduced this to 38.1°. The axillary temperature which had been taken twice a day during the passage of the thermometer was never higher than 37.2°.

RHINOCEROS' URINE IN HINDU MEDICINE. — Rhinoceros' urine is a much approved remedy among Hindu physicians for chronic fevers and splenic enlargements and the Calcutta Zoölogical Garden derives so considerable a revenue each year from the sale of the water passed by its rhinoceroses, that men are detailed to collect the urine as it is passed. It is a very pale urine with a specific gravity of 1,000, slightly alkaline reaction, abundant phosphates and free ammonia.

NEW ENGLAND.

HOSPITAL BEQUESTS. — Among the bequests in the will of the late Margaret Capen is one of five thousand dollars to the New England Hospital for Women and Children, and one of fifteen thousand to the Perkins Institution for the Blind.

FIVE UNBROKEN GENERATIONS. — There is in this city a household with five full generations all living. The descent is by the female line in each case so that

there are the great-great grandfather and mother both over ninety but well and active, the great grandmother and her husband, the grandmother and her husband, the mother and father and the daughter, nearly two years old.

NEW YORK.

The Public Schools. — On September 8th the public schools were reopened after the summer vacation, and the names of 162,000 children were registered. Before admission to the schools each child must present a certificate of vaccination, and since the day of opening the health authorities have been vaccinating pupils at the rate of three hundred a day. Four new school buildings have been opened this season, and the sanitary condition of the older school-houses is said to have been considerably improved. A number of new features have been introduced in the school system. Among them there is a more general and thorough course of instruction in physical culture, and Dr. J. Gardner Smith is to have the direction of this department. To many of the primary schools the kindergarten system will also be added.

The Westchester Hospital. — An excellent free hospital has recently been opened at Westchester, the first institution of the kind in that town, and the citizens have been very generous in offering donations of money and supplies. On the consulting staff of the hospital are the following New York medical men: Physicians, Drs. J. E. Ellis, Frank W. Jackson and W. B. James; Surgeons, Drs. Joseph B. Bissell, Arnold Naudain and Z. E. Lewis; Gynæcologist, Dr. Clement Cleveland; Pathologist, Dr. J. S. Thatcher.

Miscellany.

EARLY NOCTURNAL PAIN IN SYPHILITIC SPINAL DISEASE.

Charcot[1] calls attention to a symptom of syphilitic disease of the spinal cord which is of value in localizing the seat of the lesion in its early stage. The occurrence of nocturnal pains in the cervico-dorsal or dorso-lumbar regions of the spine at a regular hour, usually in the latter part of the night, is a marked symptom of early syphilitic spinal meningitis. The duration is usually a few weeks, and the pain is a precursor of the paralytic phenomena by several weeks. Careful observation of this symptom may be of great importance in treatment of the patient.

DOCTOR LAILLER.

The death of Dr. Lailler — "Père Lailler" as he was fondly called by his fellow townsmen — which occured a fortnight ago in the little village of the Eure, closed the career of a most interesting man. Few probably have heard of his name, not even those who owe indirectly the most to his ingenuity.

Shortly after the cholera epidemic of 1848 when Lailler had shown the greatest daring in his work among the sick came the incident which marked the beginning of his valuable labors. At that time the only portrayal of skin diseases was by hand-colored drawings. Passing by the Opera one day, Lailler met an Italian lad selling wax fruits. At once a brilliant idea came to the enthusiastic physician, "Come to-morrow to the Hospital St. Louis, and I will give you a hundred sous to model a hand." The first attempt of the young modeller was a failure; but the physician saw the possibilities of his pupil, and taking him into his service educated him in this new line of work.

Such was the beginning of the great dermatological museum of the Hospital Saint Louis to which Lailler devoted all his energies until its establishment was accomplished, and he saw it the first and greatest of its kind, with its models copied for many foreign museums. Medicine was to him not a road even for honest fame, but a work of priestly sacrifice and well doing, and he refused to allow his name to be given to this museum he had founded.

The Commune found him at his post; and when the insurgents driven by the army of Versailles reached the walls of Saint Louis where they wished to make their last stand, Lailler prevented the Director from opening the gates to them and boldly appealing to the mob to spare the sick and wounded whom he was caring for, the risk of massacre in the fight, persuaded them to keep on as far as Père-la-Chaise. A few minutes later the men of the Versailles army met the same brave opposition. On seeing the decoration of the Legion of Honor on the officer's coat, Lailler tore his own cross off and threw it to the ground, refusing to wear a decoration which was also borne by men who attacked hospitals. In all the after days of peace he kept his word, and was never seen again with the red ribbon on his coat.

On the establishment of peace, this earnest opponent of the empire, who had given time and money for his cause, retired from public life to a quietness which was almost oblivion, even his friends scarce hearing of his death.

A CASE OF WASP STING WITH RAPID CONSTITUTIONAL SYMPTOMS.

A correspondent sends to the *British Medical Journal* the following account of a case of wasp-sting:

On July 18th, at 5.30 P. M. I was called to see Mr. A., who, less than an hour previously, had been stung on the nape of the neck by a wasp. To soothe the pain, which was somewhat severe, he applied bicarbonate of soda. Some fifteen minutes later he felt his eyes watering but not painful. Getting worse he looked at himself in the glass and found his face somewhat swollen and his eyes bloodshot. He felt his body getting itchy, and taking off his clothes found his chest and abdomen covered with a red rash. Half an hour after being stung his condition became aggravated, his eyes watered much, the face was so swollen that he could scarcely see, and he noticed cyanosis of the lips and round the eyes. His wife also remarked how swollen and blue his face was, and this caused them to send for medical assistance. When I arrived the following was his condition: On the nape of the neck and to the right side was a white well-elevated wheal, ovoid in shape and about almond size, where the wasp had stung him. The face was flushed and showed

[1] Rev. de Clin. et de Thér., June 28, 1893.

slight cyanosis, but almost all traces of the previous swelling had disappeared. The conjunctivæ were markedly congested and the flow of tears increased, but the pupils were of moderate size and otherwise normal. The neck and whole trunk, back and front, were covered with a deep scarlatinal-like rash, showing a slight mottling, disappearing on pressure but at once returning. The left palm was likewise reddened but the limbs were otherwise quite free from any rash. All the parts affected with this rash — trunk and palm of left hand — had been very itchy, but this was now passing off. The left axilla was swollen but not tender to pressure, and the patient himself remarked that it was curious the left armpit should be swollen and the left palm red when he had been stung on the right side of the neck. The left hand had not been stung and showed no wound. The temperature was 98° F., pulse 60, regular and of medium tension. The patient, beyond feeling alarmed at his condition, was conscious of no other symptoms. Four hours later the rash began to fade, and next morning he was quite well.

THE MENTAL SYMPTOMS OF MYXŒDEMA.

THE mental disturbances usually seen in cases of myxœdema are those of lessened activity and a gradual deterioration of the intellectual powers. There are cases, however, in which mental symptoms of a severer and more active character occur, which may amount to actual insanity. At the recent meeting of the British Medical Association, Dr. Clouston reported nine cases of myxœdema, one man and eight women, who had been sent to an asylum on account of their insanity.[1]

The mental symptoms of these cases differed greatly. One case had the symptoms of suicidal melancholia, one was simple melancholia, and the other seven were classified as mania on their first admission. Two of them after their discharge were readmitted as cases of melancholia. The symptoms of the mania differed greatly in different cases and in the same case at different times, from general simple, mental exaltation, systematized delusions of grandeur, to inability to understand simple questions and delirious incoherence of speech. They had all begun by slowness of mental action and lethargy; most of them had then been somewhat depressed, next there had appeared irritability, morbid suspicion, and loss of self-control. Under the discipline and life in the asylum four of the seven earlier cases had improved so much as to have been discharged as "recovered," that is, no longer technically insane. Two of these had relapsed and were readmitted. The cases that lasted long showed signs of general enfeeblement of mind after the early acute symptoms had passed off. Before death, a very striking hebetude and mental torpor had come on. Three of the cases had died in the asylum. The two last cases admitted had been treated with thyroid extract, and had made satisfactory recoveries, both from the myxœdema and the insanity; one of them had died at home on the tenth day after discharge, from syncope, after overexertion and whiskey. An analysis of the symptoms in the nine cases showed that in seven of them sensation was blunted, the memory was affected in eight, the normal power of attention was diminished in all the cases, with an accentuation of the attention on disagreeable things and on delusions in six cases. There were hallucinations of the senses of sight, hearing and smell in four cases. In every case the affective faculty was abnormal, natural affection being diminished in all, and, in most, hatred set up instead of love to near relations. There was depressed emotion in five cases and exaltation of feeling in three cases. The intellect was affected in all by slowness of working and by delusions, mostly of suspicion, in six cases. Volition and the originating faculty was impaired in some way or other in all the cases. The effect of the thyroid treatment was manifest within the first month of treatment in mental improvement. One of the cases treated had been for one year markedly insane, the other for three years. The myxœdema had existed for over five years in both. Both were enfeebled in mental power, this having succeeded exaltation, morbid suspicions and excitement at the beginning of the attacks of insanity. One case was cured in four months, and the other in six. A slow intermittent treatment by small doses — one-sixteenth of a thyroid twice a week — was found to be, on the whole, the best. The mental improvement went on *pari passu* with the disappearance of the bodily symptoms until the general enfeeblement disappeared; the general sense of well-being became normal, the memory improved, the delusions disappeared, the affections returned, and the volition and originating power became gradually normal.

[1] British Medical Journal, August 26, 1893.

THERAPEUTIC NOTES.

RECTAL AND GASTRIC ABSORPTION. — Lemanski and Main have reported to the Therapeutic Society their experiments upon the comparative absorbing powers of the rectum and stomach for certain drugs. Iodide of potash, given by rectum, appeared in the saliva at the end of ten minutes while the same amount given by the mouth required fifteen for its elimination to begin. In the same way salicylate of soda appeared in the urine ten minutes sooner when given by the rectum than when taken by mouth. Methyl-blue, on the other hand, was more than three times as long in appearing when given by enema. Salol requiring the action of pancreatic fluids for its decomposition was detected forty minutes after injection and thirty after ingestion. Turpentine was apparently not absorbed at all by the rectum as no violet odor was detected in the urine after enemata. As far as their experiments went, it seemed as if soluble drugs were more quickly absorbed from the rectum than from the stomach.

THYROID FEEDING IN PSORIASIS. — At the last meeting of the British Medical Association Dr. Byrom Bramwell read a paper on the influence of thyroid feeding on the nutrition of the skin, especially in cases of psoriasis. His attention had been drawn to the improvement of the skin in patients under thyroid treatment for myxœdema and hoping to aid the nutrition of the skin in psoriasis he made trial of this remedy in selected cases of long-standing psoriasis. To thoroughly test the treatment all other remedies were omitted and a small dose of the thyroid given daily. In all his cases a visible improvement occurred after a few days' administration. The inflammatory redness was lessened and there was considerable desquamation of cuticle over the affected parts. In one

patient the eruption grew worse, in two there was no benefit, but in every other instance there was marked and continued improvement. In one case only has there been a slight relapse. "All the patients who were thus treated had the disease in a chronic and obstinate form, and had been subjected to all kinds of ordinary treatment, but without success." Dr. Arthur Davies also reported independent observations on two cases of psoriasis which had improved very rapidly under thyroid treatment, one reaching a complete cure. The uncertainty of obtaining permanent results in treating psoriasis should restrain undue confidence in this new remedy, but the careful selection of cases and the exclusion of other treatment during the trial, lends force to Dr. Bramwell's report — and further trial will be watched with interest.

Correspondence.

LETTER FROM CHINA.

HANKOW, CHINA, June 17, 1893.

MR. EDITOR: — Six hundred miles from Shanghai, up the Yang tse at junction of Haar River, this city of some seven hundred thousand, is one of three, reminding one of the "New York-Brooklyn-Jersey City" *tripolis*. Hanyang forms the second member, adjoining Hankow; Wuchang the third, lies opposite, on the south side of the great river nearly a mile in width: it is the provincial capital, where thousands of aspirants for the mandarin dignity come to the scholastic examinations. This is indeed the tea city *par excellence*. Pictures of long ago take moving form, the traditional typical two "tea boxes" perambulate the fine foreign-made streets, supported on the shoulders of a placid-faced Oriental, with saucer-shaped hat.

More interesting perhaps to you than the language or the wonderful great tiger skins which cost only about sixty silver dollars, will be a short account of the medical and hospital arrangements here.

In connection with the Wesleyan Mission Dr. Hodge has a hospital accommodating thirty men and fifteen women. A room for "opiatics" would contain five. Several victims to abuse of the *papaver somnifera* have been treated. The general plan is tonics and nourishment, with occasional nervine sedatives. The consensus of many missionary physicians hereabouts is to the effect that excessive smoking is "very injurious" owing to the scanty vegetable diet of the people and the resulting lowered vital resistance.

The London Mission Hospital (near the settlement), in charge of Dr. Thomas Gillison, now undergoing repairs and enlargement, has beds for about fifty males and fifteen females. A daily average of fifty or more receive care in the out-patient department. These people smile when the surgeon asks them if they are not afraid that he will take out their eyes to be used for medicines or devilish rites; for such are the stories, with which the populace sometimes are incited against the doctors. I have myself seen the famous *Hunan* (a province) Chinese book with pictures showing how the eyes of children and breasts of women are being removed for poisons, medicines, etc. The Chinese text tells that the foreign devil does such things for selfish and wicked purposes. In commercial ports, however, where there is much intercourse with Europeans, such ideas are of less force. They dislike amputations from religious ideas, the body being thus multitated.

Women physicians are doing good work. "The Daughters of Charity," an Italian Roman Catholic Mission have been about twenty years in Hankow, though the present structures are of a few years more recent origin. A thousand Chinese are recipients of their loving ministrations; five hundred living outside, the remainder finding homes within the walls of the institution. These latter are of both sexes and all ages. Many of the small girls have been saved from a castaway's death, and here are practising profitable trades. Others grown older in this home are married from this haven.

In connection with the "Daughters of Charity" is an excellent hospital building of two stories, accommodating about one hundred Chinese, with rooms for ten or more foreigners. Dr. Begg, the physician, sees about sixty outdoor patients every week-day. Many of them will attribute a lame back, headache or pain to a blow received four or ten years before. The average mind is filled with witchcrafty superstition; this idea governs the location and outlook of buildings, the conduct of various enterprises, and ordinary life. There were many cases of dyspepsia and lying was not infrequent. An early sign of leprosy was a smoothing out of face wrinkles and lines in a man about thirty years of age. The doctor showed an amputation of *membrum virile* for *lupus*. He first cut the integument, and drew off the skin; then incised the corpora; the urethra, the last divided, formed a sort of apex to an irregular cone. When healed, the meatus would *not* be found at the bottom of a hole — often covered with skin — but quite on a level, or slightly projecting from the other tissues. The stump was rather less than an inch in length. The surgeon wished to remove the entire structure deep down with convexis; but the mother and consort of the man decided otherwise.

The examination season is drawing near, when it is wise for foreigners to keep away from the scenes of contest — such crowds of *patriots* there do congregate, — as a later day missionary of university education casually remarked.

F. B. STEPHENSON, M.D., *Surgeon U. S. N.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPTEMBER 9, 1893.

Cities.	Estimated population for 1893.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Consumption.	Diarrhœal Diseases.	Typhoid fever.	Diphtheria and croup.

Deaths reported 2,046: under five years of age 919: principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhœal diseases, whooping-cough, erysipelas and fevers), 558, diarrhœal diseases 377, consumption 240, acute lung diseases 136, diphtheria and croup 84, typhoid fever 37, cerebro-spinal meningitis 21, whooping-cough 17, scarlet fever 12, malarial fever 6, measles 2, small-pox 2.

From cerebro-spinal meningitis New York 10, Washington 3. Worcester 2, Cleveland, Lynn, Somerville, Chelsea, Quincy and Amesbury 1 each. From whooping-cough New York 7, Philadelphia 3, Cincinnati 2, Boston, Washington, Fall River, Cambridge and Chelsea 1 each. From scarlet fever Philadelphia 4, Milwaukee 3, New York, Boston, Cleveland, Lynn and Somerville 1 each. From malarial fever New York and Charleston 2 each, Philadelphia 1. From measles New York 2. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending September 2d, the death-rate was 20.6. Deaths reported 4,075; acute diseases of the respiratory organs (London) 138, diarrhœa 677, diphtheria 73, whooping-cough 73, measles 63, fever 62, scarlet fever 48, small-pox (Bradford 4, West Ham 3, London 2, Birmingham 1) 10.

The death-rates ranged from 15.5 in Norwich to 31.5 in Hull; Birmingham 20.4, Bradford 23.8, Croydon 19.1, Halifax 18.2, Leicester 17.2, Liverpool 26.6, London 19.0, Manchester 23.2, Newcastle-on-Tyne 23.0, Nottingham 20.1, Sheffield 20.9, Sunderland 26.0.

METEOROLOGICAL RECORD,

For the week ending September 9, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 9, 1893, TO SEPTEMBER 15, 1893.

Leave of absence for one month, to take effect on or about October 1, 1893, is hereby granted LIEUT.-COL. J. V. D. MIDDLETON, deputy surgeon-general, U. S. A., with permission to apply for an extension of fifteen days.

FIRST-LIEUT. CHAMPE C. MCCULLOCH, JR., assistant surgeon, is relieved from duty at Fort Sam Houston, Texas, and ordered to Fort Ringgold, Texas, for duty, relieving CAPTAIN JAMES E. PILCHER, assistant surgeon.

CAPTAIN PILCHER, upon being relieved, ordered to Fort Niagara, New York, for duty, relieving CAPTAIN RUEBEN L. ROBERTSON, assistant surgeon.

CAPTAIN ROBERTSON, upon being relieved, ordered to Fort Omaha, Nebraska, for duty.

CAPTAIN LOUIS A. LAGARDE, assistant surgeon, will, upon the completion of his duties in connection with the World's Columbian Exposition, report in person to the commanding general, Department of the Colorado, Denver, Col., for duty as attending surgeon and examiner of recruits in that city.

FIRST-LIEUT. HENRY R. STILES, assistant surgeon, is relieved from duty at Fort Omaha, Nebraska, and will report in person to the commanding officer, Fort Meade, South Dakota, for duty at that post.

By direction of the Secretary of War, the leave of absence granted CAPTAIN CHARLES E. WOODRUFF, assistant surgeon, is extended four months.

The leave of absence granted CAPTAIN JUNIUS L. POWELL, assistant surgeon, is extended ten days.

Leave of absence for one month is hereby granted to MAJOR J. VAN R. HOFF, surgeon, U. S. A.

Leave of absence for one month, to take effect about the 5th inst., is granted COLONEL J. C. BAILY, assistant surgeon-general.

Leave of absence for one month, to take effect between the 25th inst., and the 5th proximo, is granted MAJOR CHARLES L. HEIZMANN, surgeon, Fort Douglas, Utah.

Leave of absence for one month is granted MAJOR DAVID L. HUNTINGTON, surgeon, U. S. A.

Leave of absence for two months, to take effect from August 25, 1893, is granted LIEUT.-COL. CHARLES R. GREENLEAF, deputy surgeon-general, U. S. A.

SOCIETY NOTICE.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The following business committee has been announced by the President of this Society, Dr. Herman Bendell, of Albany; Dr. Henry Flood, of Elmira; Dr. L. Bolton Bangs, of New York; Dr. Edward Clark, of Buffalo, to whom all communications regarding papers for the next meeting of the Society in February, 1894, may be addressed.

F. C. CURTIS, M.D., *Secretary*, Albany.

RECENT DEATHS.

LYMAN B. HOW, M.D., of Manchester, died at Hanover, N. H., September 15th, aged fifty-five years. He graduated from Dartmouth in 1860 and from the medical school in 1863. He was for twenty-five years professor of anatomy at Dartmouth and held the position until this year, when his failing health obliged him to give up work. He was a member of the American Academy of Medicine and at one time President of the New Hampshire Medical Society.

H. B. MILLARD, M.D., of New York, died in Paris, September 14th, of typhoid fever.

EDWIN COLT, M.D., died in Brooklyn, N. Y., September 15th, aged eighty-three years. He was one of the founders of the Eastern District Hospital and the Eastern District Industrial Home.

W. T. WHITE, M.D., died in New York, September 17th, aged sixty-four years. He was Recording Secretary of the Academy of Medicine for seven years, and one of the founders of the New York State Medical Association. He was also editor of "The Medical Register of New York, New Jersey and Connecticut" for fifteen years.

E. WARREN BEY, M.D., a well-known American physician of Paris, died in that city September 16th. He was in practice in Baltimore before the rebellion, served as surgeon in the Confederate Army, and was later a professor in the Baltimore Medical College. Subsequently he was offered a commission in the Egyptian Army, in which he rose to the rank of surgeon-general. Later he practised in Paris, where he spent the remainder of his life.

BOOKS AND PAMPHLETS RECEIVED.

Local Boards of Health in the State of New York. 1893.

Circumcision; its Advantages and how to Perform It. By M. Clifford, L.R.C.P., London, M R.C.S., England. 1893.

Experiences in Pelvic Surgery. Peritonitis from a Surgical Standpoint. The Technique and Management of Pelvic Surgical Cases. By A. V. L. Brokaw, M.D., St. Louis, Mo. Reprints. 1892-93.

Inguinal Hernia in the Male. Analysis of One Hundred and Thirty-three Cases of Hernia Operated Upon for the Purpose of Radical Cure. By Henry O. Marcy, A.M., M.D., LL.D., Boston, Mass. Reprint. 1893.

Medical Report of the Philadelphia Dispensary for Skin Diseases Covering a Period of Ten Years and Nine Months (February, 1880, to November, 1890). By the attending physician, Henry W. Stelwagon, M.D.

Traitement du Pied Bot Varus Equin par l'Ablation de la Plupart des Os du Tarse. De l'Emploi des Essences et Surtout de l'Essence de Cannelle ou Cinnamol Comme Topique en Chirurgie. Par le Dr. Just Lucas-Championnière. Extrait. 1893.

Twenty-ninth Report of the Trustees of the Boston City Hospital; with Report of the Superintendent, the Medical and Surgical Statistics, Rules for Admissions and Discharges, Prospectus of Training-School for Nurses, Rules for the Convalescent Home, etc., for the Year, February 1, 1892 to January 31, 1893.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XVI.

INJURIES OF THE SPINE.

It is hard to believe that there can be such a thing as simple concussion of the spine producing lasting consequences. Of course, the spine may be shaken up; but that it can be shaken up in such a way as to produce permanent injury, without positive lesion to other parts, seems difficult to believe. The spine is in a water-bed; floats; cannot swing much from side to side; it is in the midst of a bony column which is linked like a chain; and is not stiff. It is buried beneath a mass of strong muscles; lies in the centre of the body almost. You are surprised to see in the dissecting-room when you cut away the muscles of the back how far the spinal column is in toward the centre of the body. It is wonderfully protected from shocks and jars; so that the delicate nerve-tissue of the spinal cord itself can hardly be damaged very much unless the parts near it are broken in a certain way. Now it is surrounded by a copious blood-supply. The rachidian veins which are developed in and between the membranes are very numerous. If you look in Bourgery's plates of anatomy, which are rather highly-colored, but still pretty true to nature, you will find how extremely vascular the parts around the cord are. It is much more probable that a blow or accident, which happens to the spine, not severe enough to injure the bones or detach them, but severe enough to jar the parts, — it is much more probable that it should rupture some of these numerous dilated rachidian veins, than that it should shake up and lacerate the cord itself, floating in its water-bed as it is; so that it seems to me improbable that concussion of the spine, as such, amounts to much, unless it is also accompanied by the same sort of injuries that happen in the brain. We have seen that simple concussion of the brain was rare; that where any symptoms persist they are due to positive lesions; and those lesions we call contusion of the brain; we have little vessels ruptured and miliary extravasations. Now I believe, and I think pathology supports it, that injuries of the cord which are supposed to be concussions, but from which the patient does not promptly recover, are due to a positive lesion. That lesion generally is the rupture of a vessel and the subsequent symptoms produced by a clot. Now a clot between the membrane and the spinal cord must act very differently as regards compression from a clot in the cerebral cavity. In the first place, it will gravitate, and it trickles down between the membranes and perhaps lodges about the points of exit of some of the nerves and compresses local portions of the cord; and gives rise to local changes of nutrition or motion, or sensation, but not affecting the whole of the body below where the injury is received. That is the history of moderate injuries of the spine. Either they amount to nothing at all; or if they amount to anything, they are followed by local, limited paralysis, due to effusions of blood.

One will see, on the other hand, a good many people get shaken up in the back, who are lame, stiff, and are weak and incapacitated for a good while; and yet they do not have any local paralysis. How are such symptoms as that to be explained? Apparently the consequences of a very large number of these injuries are external to the spinal cavity itself; that is to say, they are about the ligaments of the vertebræ, the fasciæ, and the muscles around them. You can remember how fully these parts are supplied with ligaments; how many articulations there are; how many ligaments there must be to support them; how much the erector spinæ and other sets of muscles are made up of fascia. The amount of ligamentous tissue and fibrous tissue throughout the whole back is very much larger than in any other part of the body. Bruises, blows and sprains are extremely slow to recover from. We know that when we sprain the wrist or ankle, or twist some part, that the sprain is slower to be recovered from than a broken bone. Undoubtedly many of the cases of railroad concussion, so-called, are cases of sprains and ruptures of the ligamentous tissues of the back. These are slow to repair. The back remains stiff. A form of rheumatism sets in. Pains located there are hard to distinguish from pains located in the cord itself; and, if the patient is at all of a nervous temperament, a neuralgia is set up, or other symptoms due to what we call hysteria; and owing to the long series of aches, and pains, and disabilities, the observer is led to think that there must be an injury to the cord itself. Frequently there is nothing of the kind. We can test that in two ways. First, by the lapse of time; inasmuch as if the cord is injured, it will undoubtedly go on to further inflammatory and degenerative changes; and a few months will make the patient much worse, and show symptoms which will be decisive. We can test it in case it has gone on some months without any change one way or the other, by electrical tests; and see whether the contractile power of the muscles is diminished.

Most shakings up of the back are due to injuries outside of the cord. Those which are more severe produce hæmorrhages; and the hæmorrhages are positive lesions, and require time for their recovery; but they do finally get well. Finally, we have the extreme class of injuries where in the spinal column, the bones are injured; and where positive fracture, dislocation, compression, meningitis, softening of the cord, etc., follow.

The cases which are due to the effusion of blood into the spinal canal are pretty easily diagnosticated after a few days. The symptoms are localized, persistent, and they can hardly be mistaken. Partial paralysis of one arm, partial paralysis of one side of the neck, or any portion of the body indicates that certain nerves have been compressed, and compressed within the spinal cavity where they emerge, by a clot. This may be so extreme in some cases as to produce paraplegia. A man receives a severe blow in the small of the back. No evidence of fracture or dislocation occurs. The patient is apparently paralyzed below the pelvis and remains so; but after six or eight weeks begins to recover sensation and motion; and after some months recovers perfectly. Such a case is undoubtedly due to effusion of blood; compression of the cord occurs; afterwards it is absorbed, and finally gets well. The milder class of cases give rise to local paralyses; and when we find them we have reason to

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

give a good prognosis, after sufficient time has elapsed. It must be borne in mind, however, that recovery from this sort of injury is excessively slow. It is not to be measured by weeks, but by months; sometimes a year or two, before the patient gets the parts finally restored.

Now in sprains, bruises and twists of the ligaments about the back the patient is often benefited by having an immobilizing apparatus put on. He is better off to lie in bed, and have on a light plaster, and keep the parts perfectly still, just as we would treat a badly sprained ankle. Subsequent to that he needs light massage; frictions and liniments, and electricity, the continuous current, etc., until he finally recovers.

Fracture and Dislocation of the Spine. — Now we pass to the very serious class of cases called fracture and dislocation of the spine. They almost always go together. It is hard to conceive that the spine can be dislocated without fracture taking place. It is rare; and usually fracture and dislocation are combined.

The symptoms produced must be immediate. There cannot be any waiting for the formation of a clot of blood here. Whatever happens, happens at once. The patient receives his injury; is immediately paralyzed below the seat of the injury; and the amount of the paralysis depends on where the injury is. In the middle of the back he has paraplegia, and also begins to have phenomena of impaired respiration and digestion; and if still higher up, still more startling phenomena appear. Bear in mind that the most common place for the structure to give way is where the neck joins the body. We have here, just above the vertebra prominens, a movable part, the neck, attached to a comparatively immovable part: which comprises the thorax, ribs and sternum, and an injury received upon the back is transmitted above. Fractures and dislocations are most common above the vertebra prominens. If the injury occurs up by the atlas and axis, the odontoid process is thrown forward on the medulla, and instant death is the result; death I presume more rapid than from any other form of injury, except by an extremely strong electrical current.

Between the third and fourth cervical vertebræ come out the filaments which form the phrenic nerve, which supplies the diaphragm with its pumping power in carrying on respiration. If fracture involves that nerve death is very speedy. If, as is frequently the case, fracture and dislocation take place about the fourth and fifth, fifth and sixth, or sixth and seventh vertebræ, then we have a very curious class of phenomena. The patient is paralyzed below the nipples. The chest is fixed. The inspiratory power of the serratus and intercostals is wholly lost. The patient can breathe only with the uninjured fibres of the phrenic nerve; and respiration has to be purely diaphragmatic. The chest does not rise in respiration. He lies on the back, incapable of moving, with the chest as fixed as in a marble statue. He breathes, however, fairly well. There is no suffering. The patient regains consciousness to a perfect degree. He cannot believe he is so seriously hurt; cannot understand that he is fatally hurt. He is sure to die; and in about thirty-six hours, sometimes forty-eight. Death is bound to occur from two causes: one is the compression on the diaphragm from the accumulation of gas in the paralyzed bowels; gas accumulates and is not passed on, fills up the abdomen, enormous distension takes place, the diaphragm is pressed up against the lungs, the lungs cannot expand, and are slowly compressed from the force underneath. Meanwhile another change takes place in the lungs themselves, which is still more dangerous, that is that the elastic power of the bronchi to expel mucus is wholly lost, and the lungs fill up with the secretions of the bronchial tubes. The patient is unable to cough, or expectorate. Between compression below and filling up above, at about the end of twenty-four hours he usually begins to be dull and cyanotic, and his finger-nails to grow blue; and he grows a little colder; becomes stupid, and gradually dies by slow suffocation; by a merciful form of death, since he is rendered unconscious.

We recognize the injury by these terrible phenomena when we see the patient. We can hold out but very little hope when the injury has been so high up that the respiratory power of the intercostals and serratus is lost. The patient breathes wholly with his diaphragm; is holding on to life by a very feeble thread; and he is almost sure to die in the way I have described.

If the injury occurs a little lower down he breathes better, but he is paralyzed. A little lower down, and he has no disturbance of the heart or lungs; has paralysis of the functions of the rectum and bladder, and paraplegia, and lives indefinitely. The broken backs and dislocated backs, in the middle of the dorsal region, live sometimes months or several years; once in a while recover, but very rarely.

The most important point for us to consider is whether we can do anything in these cases. The symptoms are so marked that we cannot help making a diagnosis; and we are occasionally assisted in the diagnosis, but not always, by an evident distortion in the line of the spine. In the neck it is not very easily recognized, however. The muscles are thrown into tension. The neck may be set back or forward a little; but it is difficult to feel displaced vertebræ in the neck, often. We frequently may be deceived as to the gravity of the injury, at first, by the fact that feeling the point of injury we find crepitus and broken bone. That usually means nothing at all; means a spinous process broken off; but it is the occurrence of all these symptoms of paralysis at once, with or without distortion, which indicate what has taken place.

Nature can do very little. The question is whether man can do anything to help. The most tempting field would seem to be to cut down upon the part; to use antiseptic precautions; saw out and trephine the laminæ of the vertebræ; remove depressed fragments; restore the cord to its natural position and circulation just as we do the brain when a bone is driven in upon it; and occasional instances of cure have resulted; but unfortunately they are very rare; and the reason is this: when this dislocation and fracture of the spinal column takes place the bodies jump over each other, and compression of the cord is almost always on the anterior portion, where it is out of reach of the surgeon. He may uncover the cord, meanwhile the vertebræ are locked over each other in front, and compression is still going on in front. I do not say it is not justifiable to make these attempts sometimes; but the latest statistics I have seen seem to show, on the whole, that up to this date, the percentage of recoveries was better in cases that were not interfered with, than in cases that were. The encouragement to interfere; to trephine the spine is very small. If we cut away considerable, we may relieve the symptoms; but the

patient will be, in the future, dependent on an apparatus to hold up his head.

Is there anything else we can do? Efforts have been made with occasional success to pull the fractured and dislocated vertebræ into place by traction; and once in a while, there has been a brilliant case; just as you read, once in a while, of that romantic and typical case, where a man has a piece of bone driven into the brain while in the midst of a conversation; loses consciousness; the bone is removed, and he rouses up and resumes conversation where he had left off; so you read occasionally of cases where reduction of dislocated vertebræ has been accomplished. It is a fair thing to try. How shall it be tried? The most efficient way is to suspend the patient in a tripod just as if about to put on Sayre's plaster-jacket for caries of the spine. The objection to the suspension is that the agony inflicted on the patient, and the constitutional symptoms produced, are very severe. The patient can hardly undergo it without ether; and while he is etherized and hung up, extreme care has to be taken lest he stop breathing, and die in the apparatus. In the child, young person, person not weighing very heavily, it is fair to try it; but in the heavy man, the chances of inflicting terrible suffering, and perhaps killing the patient, are something. On the other hand, it is claimed that efficient extension and counter-extension can be made with the body in the horizontal position, if you have plenty of assistants, and the body arranged on an angle; so that you can draw both ways, and draw the vertebra down into place.

We may trephine with a very limited chance of success and of recovery, probably followed by inability to walk, or move. We may extend by the tripod if the patient is not too heavy; we may extend more mercifully by doing it horizontally.

There remains only one other method of treatment, which should be applied to all cases, and can do no harm, and often does a good deal of good. After you have done what you can to draw down the parts; namely, to immobilize the spine; and that is done best by the plaster apparatus; the patient can be encased in plaster, and kept on a bed. One or two little precautions are very valuable. Turn the patient over often if you can, for otherwise he is sure to have a bed-sore. In the plaster-jacket you can turn him over; and it is a part of the nurse's business to turn him at least twice a day. Be very careful of the subsequent care of the bladder. Many of these patients die of subsequent cystitis; and if you can preserve the catheters and catheterization from sepsis, you may avert cystitis for a very long while.

Some of these patients live for months or years; and some of them waste away and die from affections of the bladder, and degeneration of the kidneys, and other organs.

INJURIES OF NERVES, MUSCLES, BURSÆ, ETC.

You will be at a loss sometimes perhaps to explain why it is that a moderate blow, from which the consequent bruising, which appears under the skin, has long since passed off, remains so painful and disables the parts so much. That is the case where a nerve has been bruised, and where the inflammation in its sheath cannot show outside through the skin and tissues, and shows only in its effects.

The effect is long-continued pain, lameness and inability to use the part. The treatment is strictly local. In the first place, the limb must be put at rest on a splint. The bruised nerve at first must be treated by laudanum fomentations, and later by more active treatment. In the later stages the application of iodine, or a blister, does a great deal of good; and finally the trouble subsides, after a good while.

When an effusion has taken place in the sheath of the nerve, and it becomes compressed; or when a nerve is wounded and its transmission of nervous influence is impaired, then some other phenomena come on which are characteristic, that is, reddening, glazing and blistering of the skin, especially on the tips of the fingers, along the inside of the fingers, on the palm of the hand. In these patients you will find not only the hand cooler than natural; less sensitive than natural to the ordinary touch, but also the skin vesicating, rubbing off, the knuckles frequently of a bright cranberry color; and the part excessively painful, and very easily affected by cold. This peculiar condition of the skin is a pretty good diagnostic mark of a nerve injury.

In these cases rest on a splint, opiates, local applications, time, etc., will bring the part round in a very large proportion of cases so that it may recover. It is known, also, very well that nerves that are cut have recovered their function after a certain time; that is, nerves of moderate size. It is one of the commonest observations that the branches of the facial on the face, cut so frequently in small operations about the face, entail at the time a great deal of paralysis, but it is not a permanent one. It is finally recovered from. This takes a long while, — four, six, eight months. Even the smallest growth or wen, anything of that kind, cannot be cut from out the cheek, from the side of the face or about the jaw, without cutting off some half-a-dozen or more filaments of the facial nerve. The muscles of expression of the face are so minute, and the changes which they undergo from want of innervation are so marked, that even these little incisions, destroying a few branches of the nerve, will give rise to a visible paralysis, and change of expression in the features. It is then important to warn the patient, who is to have a slight operation about the face, that he will have a temporary paralysis about the face for a little while, but that it will eventually recover.

Now after large trunks are cut off, unless the parts can be held perfectly still in apposition, their reunion is not so hopeful; but in these antiseptic days the stitching of the nerves together has been done with great success. It is said that you must stitch the sheath, or the neurilemma. That is very easily said, but is very difficult to do with ordinary instruments and needles without involving some of the nerve filaments and cells in the sutures. In fact, I believe it is practically impossible to stitch the neurilemma of the nerve and sheath close to the other divided end without more or less mutilation. Apposition of the ends, however, is what is needed. They should be snugly stitched together by antiseptic sutures. Put the limb on a splint so as to relax the nerve a little; dress the wound antiseptically; hope for union by first intention, and for union of the nerve.

The sensibility will not usually return for some weeks; but comes back very gradually as the nerve gets healed; and the nervous influence is re-transmitted across the space.

Partial cuts, then, will heal. Cuts of small nerves will repair themselves. Cuts of large nerves, as a rule,

will not repair unless they are sewed together by the surgeon.

Another class of affections and injuries of the nerves which are very troublesome, is when the nerve has not been cut off itself, but happens to get tied down in a cicatrix. This is a very distressing class of cases. It may occur in the continuity of a nerve, in the brachial or sciatic, that cicatricial tissue gets formed around the nerve, binds it down, compresses it, makes strong and elastic adhesions, and the nerve is held in this way until it gradually loses its own nutrition, withers, becomes changed in tissue, and so finally loses its use and function permanently. Unfortunately this change is almost always accompanied with a great deal of pain; and, inasmuch as most of the nerves have sensation as well as motion as part of their function, the pinching of the cicatrix, while it destroys the motor power of the nerve, at the same time inflicts severe pain on the sensitive portion; so that the tying down of a nerve in the cicatrix is one of the commonest causes of persistent neuralgia, or pain in the nerves. This, of course, is all relieved by cutting open the cicatrix, relieving the pressure, and sometimes by stretching the nerves, which may be done with blunt forceps.

Unfortunately there is another class of cases where the relief given is very doubtful indeed, and that is in case of neuromata or nerve tumors. They are not nerve tumors in the strict sense of the word. They are rather fibrous growths from the sheath of the nerve, which expand into little fibromata, in and among whose elastic fibres the nerve fibres get entangled and squeezed, apparently; and, although it appears as if there was a growth from the nerve itself, it is really fibrous tissue entangling the nerve in it. These neuromata, if single and occurring on single nerves, are curable, but when they occur in stumps, on the ends of divided sets of nerves, and occur in clusters, they are frequently incurable. The difference I do not know how to explain; but such is the fact.

Of the first class of cases is what is called the painful subcutaneous tumor. This means nothing more than a little neuroma, which is small, subcutaneous, and always implanted upon some cutaneous nerve. A favorite site seems to be on the peroneal regions about the fibula; also the arm. Wherever the cutaneous nerves are stretched pretty well over the bone, there occasionally comes what is called the painful subcutaneous tumor, which is nothing more than a little neuroma upon a cutaneous nerve-filament.

These little tumors are peculiar. They can barely be felt beneath the skin. They are little larger than bird-shot; are sensitive to pressure; and they are the seat of terrible neuralgia. The patient walks about for a while, or labors for a while, and as the day goes on this particular point begins to ache, and continues to ache until the limb is put at rest; and next day recurs again.

Now these troubles once recognized are perfectly curable by excision. The cure is complete; and there is no probability of a recurrence.

On the other hand, the class of neuromata which form on the divided ends of nerves in stumps after amputations, are multiple, and not only very painful, but they are very difficult to extract without recurrence. This is a very peculiar condition, which, as I say, we are at a loss to explain. On the brachial plexus, for instance, after a high amputation of the humerus, in the stump there begin to be formed painful spots which grow worse and worse until the patient is driven to have the stump reopened, the diseased points sought for and removed. On opening the stump, there is found on the brachial plexus a bunch of neuromata looking much like a bunch of small grapes. They grow out from the terminal ends of the cut nerves in distinct little fibrous masses. Of course, the surgeon endeavors to remove them all. He cuts short all the stumps of the nerves as far as possible and allows them to retract into the tissues, and the part heals up; but unfortunately, although this cures sometimes, it does not always do so; and recurrent pain comes on. The same series of changes take place higher up in the brachial plexus; and I know one patient where the pain finally went to the suprascapular nerve and the infrascapular, although removed about the axilla. This is a form of nerve affection which is not curable.

We see another class of cases distinctly curable, and that is where the end has got pinched in the cicatrix of the stump. You may have the bone a little too long. The flesh and skin of the stump are drawn tightly over the end, and then at some little nerve end you may have an exquisitely sensitive point where, if you touch it with the finger, the patient will scream out with pain, and which is always the seat of neuralgia. That is the case of a nerve imprisoned in the cicatrix, and that is curable. Cut away the cicatrix; shorten up the stump of the nerve, let it retract among the tissues and the difficulty is removed. In view of this danger, it seems to be a very important point in amputating to make sure that the nerves are cut short; and that you should not allow them to appear in the stump. If they appear relaxed and hang out, you had better draw out the nerve as far as you can, snip it far up, and let it draw back among the soft tissues where it cannot come anywhere near the surface, or be exposed to irritating adhesions.

Chronic inflammations of the nerve itself in the form of multiple neuritis are sometimes operated on, and sometimes they are temporarily relieved, but not always permanently relieved. The trifacial nerve is especially the seat of these cases of great suffering; and special names are invented for the affection. The inferior dental branch and infraorbital branch are the most frequent; the supraorbital not so often.

These nerves have frequently been cut down upon, the jaw and bones trephined, nerves excised, and sometimes they have been excised and pursued even up to the foramina through which they escape from the skull.

Permanent relief has been given in a few cases; temporary relief in all cases, pretty much. But the trouble is apt to recur; and sometimes operation after operation is done without procuring final relief. In this case, of course, we must conclude that the trouble finally becomes central: is in the central nervous system; and that the seat of the neuralgia is beyond the reach of surgical interference.

Now, the most practical points about all this — the most practical points surgically — are these: when a patient has had a blow, and, although the part looks well, when he insists upon it that it is always painful; that he is not comfortable; that the arm aches all the time, although nothing can be seen, you may conclude with great reason that a nerve has been bruised, and that he is having an effusion into its sheath that will not get well without treatment: that the treatment should be total rest, application of opiates, etc., until the effu

sion has gone. When you see a patient with these peculiar cranberry-colored knuckles and scaling off of the skin, you may conclude that, whatever that injury has been, a nerve has been badly damaged in some way. Then you would be mistaken in directing the treatment at all to the extremity of the hand and fingers where the trouble appears, but seek for the tender points above, and apply rest, splints, fomentations, etc., until you get the inflammation subdued. When you cut a little nerve on the face in doing any little operation, you will have more paralysis produced than you expected. You will be rather dismayed at the appearance of the face afterwards. You may, however, reassure the patient that the nerve will reunite in six to eight months. When a large nerve is divided, it will not, as a rule, reunite unless stitched together; and it is not possible to stitch the neurilemma without bruising nerve fibres; and that practically makes no difference provided the operation is done antiseptically and the wound heals by first intention. Great relief can be given to nerves caught in cicatrices by dissecting them out, and shortening them. A single neuroma has only to be recognized to be treated successfully by cutting it out, and it always gets well. A painful nerve caught in the stump can be cured by cutting it out. It is a good practical rule in amputating to cut the nerves short and allow them to draw back. The multiple neuroma is frequently incurable. We cannot promise cures. We can give temporary relief. The excisions of nerves for neuralgia always give relief lasting for months or years; but occasionally the trouble comes back beyond the foramina in the skull; becomes central; and the patient is the victim of permanent neuralgia beyond surgical aid.

Injuries of Muscles. — Now we pass to the injuries of muscles which are very few in number. The principal one is rupture of the muscle. Bruises and hæmatoma, of course, we expect will absorb and get well without suppuration, as a rule. The rupture of a muscle is a very troublesome affair. The partial rupture is not of very great consequence, but a complete rupture entails entire loss of function of the part. The biceps humeri and quadriceps extensor femoris are frequent instances; the most common of all, probably, the plantaris. The plantaris is merely the analogue of the muscle which in the bear pulls upon the plantar fascia as he walks. It is practically of very little use in man; and yet, when it is ruptured, it gives rise to quite serious lameness for about ten to fourteen days. As you may remember, the muscle starts with a very fine muscular bundle at the condyle, then becomes developed into a thin, long tendon which runs along the sheath of the soleus and gastrocnemius by the side of the tendon of Achilles, and finally is inserted into the os calcis. This snaps and ruptures in violent efforts, sometimes. The patient is not aware of what has occurred; but is almost always convinced that he has been struck. Something has hit the calf from behind; is compared by him to the blow of a whip-lash, or sharp stick, and he feels lame; immediately begins to manipulate the calf, and expects he has been bruised. In a little while, if you see the case, you will find a minute extravasation of blood has taken place in the skin and is gravitating down along the sheath of the plantaris tendon. That may not come out until the following day, or longer, but shows itself plainly; and when you see it, it is quite diagnostic of the affection. Meanwhile, the calf swells, the ankle swells a little. The patient walks not at all, or with great difficulty. He preferably takes a cane or crutch; and the trouble lasts one to two weeks. Nothing can be done in the way of repair. The injury is irreparable. The extravasation of blood along the sheath of the tendon makes the diagnosis clear. The diagnosis is strengthened by the age of the patient. This accident rarely takes place before the age of forty-five to fifty; and preferably in women of lax fibre and rather fat; occasionally in men. It usually occurs in consequence of some sudden and unexpected exertion; such, for instance, as trying to get hastily on a horse-car; trying to get up on a very high step; missing the step; getting off a curb-stone and coming down into the gutter; and, as I say, it occurs only in a person whose muscular fibres have become degenerated, is fat and lax; and the sensation is attributed to a blow from behind.

It is a good plan to treat it, because it gets well quicker. In the first place, if the patient is willing, he should lie still and have the calf fomented a day or two; a flannel bandage from the foot to the thigh applied, and kept on about two weeks. In addition to this, the patient must use crutches, or a cane. After about two weeks the trouble gets well.

Tearing away of the muscular fibres of the quadriceps extensor femoris from the tendon of the patella above makes a complete disability, just as complete as rupture of the ligament below. The muscle goes up in a mass, and the patient is practically helpless with regard to standing, and especially with regard to extending the leg.

Rupture of the biceps humeri makes an equally great deformity; but is not so marked in the disability it entails, because we always have the other muscles, the brachialis anticus and coraco-brachialis, to assist, so that the function of the biceps is not so missed as the function of the quadriceps extensor femoris.

It is a question in my mind whether it is not justifiable in these cases, if seen early, to cut down upon the part antiseptically, and try to sew the fibres together, put the limb in a state of relaxation on a splint and endeavor to promote adhesion. As a rule, the trouble is not fully recognized; tearing takes place gradually. The patient does not seek the surgeon until some time has elapsed; then the contractility of the muscular fibres is so great that the muscle is drawn so far beyond its place that it cannot be got down, and the trouble is practically hopeless of remedy except by position and bandaging and time.

Tendons rupture occasionally, but not very often. The most familiar mode of rupture is when the patient gets caught by the fingers; generally children, boys, getting caught on a fence or pickets, and having the finger caught, are temporarily suspended by the fourth or third finger. That tears the muscle in the forearm, and out come the tendon and muscle, the whole thing sometimes many inches in length, from the lacerated wound on the finger. These long tears of the muscles, of which there are a number of instances in the museum, are irremediable, of course. There is nothing to do but to extract and cleanse the part, and try to make it heal antiseptically, having forever lost the use of that particular tendon. Repair is impossible.

Tendons slip out of place sometimes; slip off from attachments about the ankle, the peronei especially; and also occasionally, it is said, the long head of the

biceps. This, however, is difficult to prove anatomically when it occurs; and it is perhaps not worth while to waste much time over it, as its existence even has been doubted. But the peronei about the ankle, and occasionally one of the ham-strings, slip out of place and have to be treated by bandage and apparatus to hold them in place.

The *Bursæ* are developed outside of the joints as a rule, little synovial sacs intended to relieve friction; and, as you know, they become developed by the use and friction of the part, in so much that certain trades are marked by peculiar bursæ. The miner has a bursa over the olecranon due to picking with his elbow raised so much against side walls. The bursa over the patella is the common one, as you know, which becomes inflamed and aggravated by work upon the knees, as in the case of women who scrub floors; and also largely in these later times, when hard-wood floors are used so much, in carpenters who work planing and polishing. The carpenter has what used to be called the housemaid's knee by this development of the bursa over the patella.

The only point we have to speak of in this part of the subject, in regard to bursæ, is their injuries. When they are wounded they give exit to an albuminous-looking fluid like the synovial sacs. They, of course, should be treated by cleanliness and rest, antiseptics, etc., until they can heal.

There are certain ones, however, which, when wounded, are extremely dangerous. For instance, there is a bursa developed about the semi-membranous tendon at the back of the popliteal space. This bursa is not very uncommon. It occasionally gets wounded, and unless treated carefully, entails serious consequences, because it very frequently communicates with the synovial sac of the knee-joint; consequently double care must be taken to wash out all dirt, cleanse and bandage it, and employ rest a good while, to avoid ill consequences.

The other class of bursæ which sometimes get injured, and sometimes are operated on surgically, are what are called ganglia, an improper name; they are also called, sometimes, weeping sinew. They form as little synovial sacs on the sheaths of the tendons at the wrist, especially on the extensors, sometimes on the flexors.

It is of the last importance to recognize a wounded joint and especially any synovial sac. The joints most frequently injured are the knee and elbow, especially the knee. The synovial sac of the knee is very large, extending far up above the patella. The punctured wound driven in above the patella is sure to injure it, and that is the favorite location for wound of the knee-joint. It may be a minute puncture. Nothing may attract attention to it unless we observe carefully, and then we shall see a little clear white, opaque, albuminous-looking fluid is coming out, not like blood, not like anything else. This is synovial fluid, and indicates puncture of the synovial sac; and it is extremely dangerous unless treated antiseptically, and by rest, inasmuch as destructive synovitis is likely to come on, if any dirt gets into the sac.

"WHAT a pretty dimple that boy has," said a lady visitor, as she patted the doctor's hopeful. To which the infant replied: "You think that is a pretty dimple? Well, you dess ought to see the one on my tummick."

SIMULATION IN TRAUMATIC NERVOUS DISEASES.[1]

BY PHILIP COMBS KNAPP, A.M., M.D.,
Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System to Out-Patients, Boston City Hospital.

A HEBREW psalmist, in the days of the Maccabees, said in his haste that all men were liars. Two thousand years of further observation have led mankind to repeat the statement after due deliberation. The mysterious periodical illnesses that attack the school-boy at eight in the morning and are well by ten, the bronchial affections that render exposure to the air of the college chapel deadly to the student, the diseases of military life that have given "sogering" its special significance, the complaints that prevent our jurors from serving, and the many ills which are to be found in our prisons at sick-call, are examples of the psalmist's words, and show that man is ever ready to lie about his health, as well as about other things, if it be to his advantage. So also in cases where a claim for damages has arisen, a powerful motive for lying exists, and it can hardly be thought improbable, when the pension agent and the "coffee-boiler" league together to get a pension for corns or baldness, that the victim of a railway accident, the "shyster," and perhaps the physician should also form a triple alliance to divide the spoil of the railway company.

That there are men who are willing to do this I freely admit, and I grant that there may be a considerable percentage of them among those who present themselves before the claim agents of the railway corporations seeking for damages for personal injury. In litigation cases, however, there is a constant process of selection. Cases of gross fraud are detected at once, and either withdraw or content themselves with the pittance which the company may offer to avoid the expense of a suit. The "shyster," too, no matter what his morals may be, is averse to spending his time and strength for nothing on a hopeless case; or, if he be fully committed to a scheme to defraud a company, he will seldom risk calling upon a physician of good standing, fearing lest his fraud may be discovered. Consequently I believe that few cases of deliberate simulation are likely to reach the neurologist, and experience serves only to strengthen that belief.

Nevertheless "railway spine" has become a by-word; there is a widespread opinion, not only among the laity but among the medical profession, that a large percentage of litigation cases are fraudulent, and simulation is the stock defence in the majority of cases that come into court. Singularly enough, if simulation were as common as it has been maintained, the alleged fraudulent cases have been reported chiefly by surgeons and general practitioners, and it is only within the last three years that, so far as my knowledge of the literature goes, there has been any considerable support for this opinion coming from neurologists.

The chief discussion of the subject has been in Germany, although before that, Walton,[2] in this country, had decried the importance of many of the symptoms observed and maintained the possibility of successful

[1] Read before the American Neurological Association, July 27, 1893.

simulation, and Seguin [3] had in part assented to his views. In 1890, J. Hoffmann [4] reported a series of twenty-four cases, eight of which he claimed were fraudulent. Soon after, at the International Medical Congress in Berlin, a heated discussion took place, and Schultze,[5] Seeligmüller [6] and Mendel [7] took practically the same position, claiming that from one-fourth to one-third of all cases were fraudulent. Eisenlohr and Reinhard [8] have also held similar views. These views have been fiercely attacked by Oppenheim,[9] supported by Dubois,[10] Möbius,[11] Strümpell,[12] Bruns,[13] Wernicke [14] and others. The cases of alleged simulation published by Hoffmann and Seeligmüller have been subjected to destructive criticism by Dubois, Möbius and Oppenheim,[15] while Oppenheim and his supporters have not hesitated to assert that those who find simulation so common have not a thorough knowledge of nervous diseases, especially of hysteria, and to quote Kühn's [16] statement on the simulation of insanity, to the effect that the number of simulants seen by the physician is usually in inverse ratio to his psychiatric knowledge. It is, moreover, of some significance that, in a second series of cases, Schultze [17] has found only ten per cent. of simulants, instead of thirty-three as in his first series.

In the study of traumatic nervous affections we run great risk of error, and we are liable to decide incorrectly that the patient is simulating, if we are not governed by the same principles which we apply to cases not of traumatic origin. Even in this latter class of cases we often see harsh and unjust judgment pronounced. If the patient have a disease of the imagination or of the will, it does not mean that the disease itself is imaginary or voluntary; yet, unfortunately, the majority of neurasthenic and hysterical patients are exposed to this reproach. The opinion is almost universal among the laity that patients with these disorders are "merely nervous; if they would only exercise a little will power they would be all right." There is much to warrant such a slur. The neurologist knows that the patient's statement that she has not slept a wink all night means that she has been awake an hour and a half out of the nine hours in bed, but the friends and the family physician are too often unable to make the proper personal equation and call the patient a liar. Tender regions in a hysterical patient may lose their tenderness or become much less tender if the patient's attention be diverted; analgesia may be associated with exaggerated sensibility to touch, or exquisite tenderness to touch may be associated with comparative indifference to deep pressure. A woman who vows that she cannot set foot to the floor may be led, either by the vigorous personality of the physician or by the "patter" and passes of hypnotism, to walk across the room. In many cases we find that some profound stimulus will rouse the enfeebled will power and that under the influence of the stimulus, the patient can do many things which before were impossible. Moreover the condition of the patient varies remarkably from day to day, and many symptoms, such as the extent of anæsthesia or the degree of limitation of the visual field, undergo pronounced changes.

In hysteria especially, there are many curious conditions which, to a layman, would be conclusive proof of simulation. For example, hysterical amblyopia affecting one eye, as Pitres [18] has shown, may exist only in monocular vision. When, for example, the right eye was closed, one of his patients with the left eye could hardly tell light from darkness; but, with a prism over either eye, she saw two objects, and, with a screen vertically before the middle of her face, she read letters on both sides of the screen, but, with the right eye closed, she saw no letters at all, and with the left eye closed she saw only the letters on the right of the screen. In such a case it is no wonder that a distinguished oculist should have told Pitres that he believed all cases of hysterical amblyopia were fraudulent. Janet,[19] too, has shown, and I have observed it myself, that if, in hysterical anæsthesia we touch the affected part, and then tap the "hidden self," we find that the patient has actually felt the touch. With pronounced contraction of the visual field, moreover, it is probable that the patient sees in the alleged blind region, for such patients go about without difficulty, a thing which has been frequently observed in cases where there was no litigation or thought of simulation, yet a thing which to some seems proof of simulation. Again, a patient may not be able to walk, yet examination will show that the sensibility, the nutrition, the power of co-ordination, and the muscular strength in the legs are normal, and the same patient can hop about the room perfectly well on either foot, or get about on all fours or with a tragedian's stride — and yet astasia-abasia may be a genuine affection. Other movements may be possible as co-ordinated movements, which cannot be performed by a distinct voluntary effort; just as an aphasic may sometimes sing a song when he cannot repeat the individual words; the lower centres being able to perform their functions perfectly when the higher cortical centres are powerless.

Hysterical and neurasthenic patients, moreover, may be very suggestible. In some cases the manipulations of an examination may be of influence, and may lessen or increase a sensory disturbance; the manipulation of a paralyzed arm may lead to muscular contractions, and when it is raised to a horizontal plane it may stay there under the influence of suggestion instead of dropping as would naturally be the case.

We have not disproved the existence of paranoia when we have demonstrated that there are no wires carrying electrical influences into the walls of the patient's room, and, in like manner, when we prove that the patient, under a powerful stimulus, can do what she says she cannot, that her pain is most marked when her attention is called to it, that her condition varies from day to day, that many of her complaints are due to a perverted imagination, and that much of her disability is due to a weak will — even if we prove all this, we do not disprove the existence of hysteria or neurasthenia. Neurologists, of course, are familiar with all these conditions and they can judge of them correctly, but the profession at large are, unfortunately,

still ignorant of them, and hysterical or neurasthenic patients are often misjudged in consequence, while the laity often think them deserving of the dark house and the whip once used for the insane.

It is impossible, as I have already said, to judge correctly of traumatic nervous affections without a thorough knowledge of nervous diseases in general. No man can become an expert simply by reading Erichsen, or Page, or Charcot, or Oppenheim, or all together. All these seemingly fraudulent conditions which I have spoken of, and many more, may exist in traumatic cases, and the chances are ten to one that they will be set down as proof of simulation — yet they may be genuine and the demonstration that the symptoms are not what they are claimed may be no proof at all of fraud. Suppose, for example, that a case of astasia-abasia were to come into court. Hundreds of physicians capable of making a careful and fairly thorough examination would find no defect and would swear that the case was fraudulent, yet the few men familiar with the affection would admit the possibility of its genuineness. The proofs of simulation, therefore, are not absolute and cases that seem palpably fraudulent to the ordinary practitioner become genuine or, at least, doubtful, the wider our knowledge of hysteria and neurasthenia becomes.

Bearing these points in mind we will usually find, by a thorough examination, that there are various symptoms which put simulation pretty well out of the question. I have already [20] gone into the question of methods of examination at considerable length, so that I shall here touch upon only a few points.

Setting aside the question as to the frequency with which contraction of the visual field occurs, I believe it to be a sign of great value when it is found, and the few experiments which I have been able to make on healthy subjects have led me to believe that it is very difficult, if not impossible, to simulate successfully a definite limitation, especially if that limitation be slight. Wilbrand and Sänger [21] confirm this opinion, and show how, by certain variations in the method of testing, such as testing on the arc of a much larger circle, simulation can be readily detected. If Förster's shifting type (Verschiebungstypus) of contraction be present, the genuineness of the symptom, according to König,[22] becomes still more pronounced.

Anæsthesia I believe to be an important symptom. Where the boundary is definite it is safe to assume that the symptom is genuine. Some people can determine with considerable accuracy whether they are touched to the right or the left of the median line, but if the boundary be to one side or pass more horizontally about the body or limbs it becomes much more difficult to tell on which side of the line the touch is made. Where there is much anæsthesia an unexpected and severe painful stimulant will elicit an expression of pain. Pitres [23] gives an instructive case of a man who came to the hospital to get a place to live in. He had for years played the part of the anæsthetic man in a show who stuck needles all over himself, and hence he feigned anæsthesia as a part of his fictitious disease, but the unexpected application of painful stimuli at once exposed his pretensions. This I believe to be the rule. If the prick be expected, any man can control himself so as not to express any feeling, but, for reasons which I shall speak of later, no man can keep constantly on his guard to repress emotion from an unexpected painful stimulus.

A simulated tremor can readily be detected because voluntary trembling is always of unequal rhythm and the movements vary in extent. If a fairly regular voluntary tremor be produced in the way Walton has suggested, by resting the hands on a table, it will require but little acumen on the part of the examiner to detect it. Of other motor disturbances, paralysis and contracture, I will speak later on.

The condition of the reflexes is of much importance. A difference in the skin reflexes on the two sides in cases of hemianæsthesia will establish the existence of anæsthesia beyond dispute, and the exaggeration of the knee-jerks so often met with, although not beyond the normal limits, is often suggestive of neurasthenic conditions.

Finally the condition of the circulatory apparatus is often important. A rapid pulse when the patient first presents himself for examination is, as Walton has shown, a very common thing in all sorts of cases; but a persistent rapid pulse is of more significance. Evidences of defective circulation are also frequent. Mannkopf's test of the increased rapidity of the pulse from pressure on painful regions has justly been accepted by Schultze as positive evidence of absolute value, and I have proved its importance in many cases.

All these symptoms may fairly be regarded as objective evidence of morbid conditions, and careful examination will reveal some of them in almost every case.

Let us consider now the ordeal through which a simulator must pass in order to deceive a skilled neurologist.

Of course, it may be admitted that if he complain of one subjective symptom, such as headache, it will be a difficult matter to prove the truth of his statements; but, if he present the symptom-complex of hysteria, neurasthenia, or any of the forms of traumatic nervous disease which are now recognized, the case is different. Let us suppose him to be wise enough to describe his symptoms in a subdued tone, to complain of moderate pain, of partial paralysis, of slight limitation of the visual field, of slight anæsthesia, instead of painting everything in vivid colors the way the ordinary prison malingerer does. Let him study any approved monograph on the subject — and he must know a foreign language to get at the best — and let him have a fairly skilful medical coach to train him in his feigning. With all that he is at an enormous disadvantage. The chances are that no man of high professional attainment would become a partner in such a scheme, so that his coach must be inferior to the examiner. The examiner knows all the monographs he has studied and more besides; he has the foundation which the simulator has not of a thorough knowledge of nervous diseases, and he has had experience in examining hundreds of cases and familiarity with instruments of precision. Even if the simulator be well-trained it is no very difficult matter for an expert to find the flaws in his acting; but if the examiner, as is so often the case, be a man without special training in nervous diseases, the simulator may succeed and the examiner will be likely to fall into error. This condition, however, which I have just described, demands that the simulator have learning enough to profit by his study and wit enough to play the part. It is needless to say

[20] Boston Medical and Surgical Journal, December 19, 26, 1889.

[23] Op. cit., i, 79.

that in the majority of cases that we see such attributes are lacking. Simulation of mental symptoms is especially difficult.

Another point must be borne in mind, to which attention has seldom been called. Recent investigations in psychical research have shown that it is possible for a man to keep his attention steadily fixed on any one subject only for a very short time. This is the secret of the prestidigitator's success. In every trick there is some one movement necessary to its success, which is done in full sight of the audience. Even if they know what the movement must be, it is impossible for them to keep a continuous lookout for it, and when by the many needless flourishes and the continual "patter" their attention is diverted for half a second, the movement is made and not more than one in a hundred has seen it. If it be thus impossible to keep the attention fixed on one thing, it is much harder to keep it fixed on half-a-dozen things at once; just as a man who plays a fair game of chess may find it impossible to play half-a-dozen games at once. When, therefore, a man tries to feign paralysis, anæsthesia, tremor, hyperæsthesia, and contracted visual field, granting that he could feign each one fairly well for a few minutes, it becomes impossible for him to keep it up for an hour or two before a man who is watching to take him off his guard.

I believe, therefore, that the successful simulation of any of the more complex forms of traumatic nervous affections is practically impossible if the examining physician be a trained neurologist, familiar with nervous and mental disease and with the methods of special examination.

I will cite very briefly three cases where the plaintiff was alleged to have simulated disease in the hope of obtaining damages.

Mrs. R. was said by all her neighbors to be a fraud, and it was alleged that she and her husband were planning to swindle the railroad company, but no special evidence of their suspicions could be elicited. Two surgeons of high standing had examined her a year and a half before and found nothing to lead them to think she had any serious trouble. They reported that she would get well when the case was settled. One of the lawyers for the road was positive that she was a fraud. I found general diminution of sensibility, great muscular weakness, absence of knee-jerks and of the abdominal reflex on one side, diminished faradic reactions, and Mannkopf's symptom. Three days later she died.

M. H., a very stupid day laborer, was regarded as a fraud by three physicians of high standing. He was seen out of doors, but when the doctor came he hurried into the house and got into bed. Examination in the presence of the counsel for the defence, however, convinced him of the genuineness of the patient's complaints, and he settled the case. The man had hemianalgesia with normal tactile sense, exaggerated knee-jerks, and Mannkopf's symptom, and he was besides, very pale and wretched looking.

In the case of E. R., the charge of simulation was hotly maintained. The patient complained of complete paralysis and anæsthesia on the right side. About half the adult population of a little country town swore that they had seen him use repeatedly the paralyzed arm and leg; the other half swore they had never seen him do so. The visual field was slightly contracted, and the blue field was smaller than the red. There was complete and sharply defined hemianæsthesia, and the strongest faradic current conveyed through a needle-pointed electrode, when unexpectedly applied, did not cause a start. The pulse was not quickened by driving pins under the finger nail. The tendon reflexes of the paralyzed arm were exaggerated, and the plantar reflex was absent in the anæsthetic foot. The paralyzed hand was cold and congested, and there was a diminished growth of hair on it. The right arm was nearly three centimetres smaller round than the left, which the defence claimed was simply atrophy from disuse, but they attempted, in order to disprove the paralysis, to show that he had repeatedly used the arm. Finally electrical examination showed degenerative reaction in the arm.

In going over the records of fifty consecutive cases which I have examined with reference to determining the degree of injury and to giving an opinion to be used in settling the claim for damages, I find that the percentage of simulation is very small. The cases, it may be said, were of all sorts, from simple traumatic lumbago to fracture of the vertebræ with complete division of the cord.

Of these fifty cases, thirty-eight were undoubtedly genuine, and were due to the injury. In these cases there was little special exaggeration, not much more than the ordinary extreme statements of an invalid. In six there was old chronic disease, but in five of the cases I was able to convince myself that the injury had clearly produced certain symptoms which aggravated the disease. One of the five cases was a case of tabes who had a traumatic lumbago. He had previously had merely the initial pains of tabes which he called rheumatism, and the result of learning that he had tabes had a very bad mental effect. In the sixth case I could find no evidence of fresh disease on examination, and nothing to corroborate the patient's statements, which were vague and contradictory.

In five cases there was distinct exaggeration, usually, however, involuntary. One patient, in whom I found nothing on examination, admitted that she had nearly recovered, but her statement as to previous suffering seemed out of all relation to her present condition. Another man was seriously injured, but made a good recovery, yet, perhaps from hypochondriasis, perhaps from the continuance of litigation, he made no effort and complained a good deal, until, after a second examination, I assured him that he was well, when he promptly improved, before the litigation was ended. Two other cases thought they had received an electric shock, and they imagined all sorts of ills in consequence. In one case certainly the assurance that no harm had been done had a speedy beneficial effect. Such hypochondriacal conditions are very common in cases where there is neither traumatism nor litigation, and it is certainly unjust to regard their morbid fears as a mere pretence.

Two of the cases were in children. In Walton's series of eighty-two cases he found none in children under fifteen. I have seen five cases in children, three of which are included in this series, but one was a case of coarse mechanical injury — fracture of the spine. In one of the cases physical examination revealed nothing except a very apathetic condition, but the mother's statement as to the mental condition was confirmed by disinterested observers. In the second case the parents made extravagant claims, but no complaints could be elicited from the child, and examination revealed noth-

ing abnormal except a slight peculiarity in going up and down stairs. The child was only seven, so that the guilt of simulation must rest more upon his parents than upon him.

Out of fifty cases, therefore, I find only two where simulation seems at all probable — one case of pre-existing disease and this child — and in neither of these cases is deliberate, conscious simulation proven. Exaggeration is more common, but even in extreme cases it may be due to perfectly natural causes, and not to an attempt deliberately to deceive. Men will simulate if they can, but ignorance cannot contend against knowledge. The charge of simulation is a favorite defence in suits for damages, but I believe it can seldom be substantiated, and that it rests more upon the ignorance of the examining physician than upon any conscious volition of the patient.

THE STUDY OF THE ANATOMY OF THE CENTRAL NERVOUS SYSTEM.

BY EDWARD WYLLYS TAYLOR, M.D.,
Laboratory and Clinical Assistant to Dr. Hermann Oppenheim, Berlin.

IT is probable that no single province of scientific medicine is, at present, demanding more critical study from so large a number of skilled investigators, than is that of the finer anatomy of the central nervous system. The reasons are not far to seek. First, human anatomy, excluding the nervous system, is, generally speaking, a closed chapter. If certain details yet remain to be added, it may still be said that the finer histological structure of the organs and tissues of the body, as well as its grosser form, is adequately understood. The topography of the brain, spinal cord, and peripheral nervous system, at the beginning of this century had also been thoroughly studied, so that little remained to be added. The histological character, on the other hand, remained completely obscure, for the reason that no methods of preparation had, as yet, been found by whose aid the observer could distinguish its various elements. In the second place, the nervous system, corresponding to its dignity in the organism, stands at the head of the tissues in complexity of arrangement and therefore was naturally the last to demand scientific investigation. Finally, with the growth of the spirit of exact observation, the feeling has developed that the interests of physiology and psychology, as well as those of anatomy, demanded a most thorough-going investigation of the finer relations of the physical elements, which we recognize as inseparably associated with our mental life, in its broadest sense. To the physiologist, it is a matter of the utmost theoretical importance to determine the exact anatomical conditions under which sensory and motor conduction, for example, take place. For the psychologist, also, who has taken his place among empirical investigators, the physical substratum of the psychical processes, which are his main interest, is no longer a matter of indifference. In the psychologist's training, anatomical and physiological knowledge have, in great measure, taken the place of metaphysical speculation. For the anatomist, finally, the subject has become of absorbing interest on its purely scientific side — the facts, simply as facts, are interesting enough to demand his faithful study.

The fact, then, that the histology of the nervous system was not understood and the fact that in the interest of physiology and psychology, as well as in that of anatomy for its own sake, it demanded investigation, may be looked upon as ultimate reasons of the enthusiastic research of the last few years. If, however, such causes have been at work with peculiar force during the past two or three decades, it is equally true that the means of satisfying the scientific curiosity have grown as rapidly, until now, with the aid of the wonderfully improved methods of microscopic research, it is, at least, possible to look forward to the time when the anatomical relations of nervous tissue will stand in the same category of exact histology, as do the component elements of the lung or kidney or liver. How this change has been brought about, and how, step by step, our knowledge has grown, a glance at the history of the study of brain anatomy will show.

Aristotle's conception of the nervous system was, that the brain is without sensation and without blood, and that its function is to precipitate mucus. The spinal cord he regarded as different in character from the brain; the function of the nerves he failed utterly to understand. Galen, in the second century after Christ, was able to give a description of the cranial nerves, which, in some small details, corresponded with the facts. During the Scholastic period the study of anatomy remained as neglected as every other department of knowledge, but with the beginning of the Renaissance the interest revived, and Vesalius, Eustachio, Varoli, Fallopia stand as leaders in arousing an interest in the study of the central nervous system. In the seventeenth century appeared, for the time in which they were written, accurate descriptions of the topography of the brain in the writings of Willis, Vieussens, Sylvius and others. Toward the end of the last and the beginning of the present century the work of Sömmering, Vicq d'Azyr, Rolando, Spurzheim, Gall, Riel, Burdach and others had brought the descriptive anatomy of the brain practically to completion; the relation of fibre systems to each other and to the various ganglia, and in general the finer structure remained, however, almost completely uninvestigated. In 1819 appeared Burdach's book, entitled, "Vom Bau und Leben des Gehirns," which is to be regarded as the completest work on the subject up to that time.

It is interesting to note the methods of research employed. At first, hardened bits of the brain were roughly torn apart with forceps, until, in the third and fourth decades of the century, with the discovery of nerve fibres and ganglion cells, the necessity of a less crude procedure brought about the method which Stilling first regularly used, namely, of preparing thin sections serially, so that the brain might be again reconstructed from the separate pieces. The value and, in fact, necessity of such a method is being more and more recognized for an adequate understanding of the relations of the various parts of the brain. From its introduction dates a most decided advance in our knowledge. Stilling himself seems fully to have recognized the significance of his procedure. Of a section through the hardened spinal cord he, in substance, writes: "When I brought the section under the microscope, with a power of fifteen diameters, and saw the beautiful transverse fibres, I knew that I had found a key which would unlock the chambers of the marvellous structure of the spinal cord."

With the introduction of the microtome and the

improved means of hardening nervous tissue came a new step in advance, but it was not until 1858, when Gerlach introduced the method of staining with carmine, that a really adequate differentiation could be made between the nerve fibres of the white matter, and the cells and connective-tissue of the gray matter. This method, by which the medullary sheaths of the nerve fibres were left practically unstained, while the ganglion cells, axis-cylinders, and neuroglia tissue took on a red color, was for many years the only one used and even now must be looked upon, as, by all means, one of the most valuable we have, and one which should never be neglected in the investigation of pathological changes. From the introduction of carmine as a staining agent dates a new era in the study of the finer anatomy; relations of gray and white matter became at once evident, which in fresh preparations could, at best, be but imperfectly distinguished. Other methods of staining followed, as, for example, that with nigrosin, and much valuable work was done by their aid, both anatomical and pathological, but there was still need of a method, by means of which the medullary sheaths of the nerves might be stained and so the course of fibres be more adequately followed. This service Weigert, 1884, rendered in the development of his "hæmatoxylin method," a method which has been one of the most valuable and significant in its results in the whole field of nervous anatomy. By it, the finest medullated fibre is stained black or deep blue, its course is thus easy to follow, and relations of fibre systems are revealed, which carmine had failed to make evident. Through a combination of the two methods, "carmine" and "Weigert hæmatoxylin," the essential characteristics of nervous tissue were brought into clear light.

Space does not permit even an enumeration of the different methods which followed close upon Weigert's publication. Three of the more valuable are: Pal's modification of Weigert's method, again a medullary sheath stain; Freud and Flechsig's gold-chloride axis-cylinder stain; and Exner's osmium-acid stain, especially for peripheral nerves.

Much as these various methods revealed of histological structure the all-important questions still remained entirely obscure — of the relations of nerve cells to each other, the relations of nerve fibres to cells, and the ultimate origin and ending of nerve fibres in the central nervous system. This knowledge none of the methods heretofore mentioned were able adequately to disclose.

The view which excited most controversy and yet seemed to approach nearest to the facts was advanced by Gerlach in 1871, after a careful series of investigations with the gold-method. Six years before, Deiters had arrived at practically the same results. They were, however, worked out by Gerlach with improved methods and in greater detail. Gerlach's conclusions, in brief, were as follows: that, in addition to its axis-cylinder prolongation, each ganglion cell gives off a large number of so-called protoplasmic processes, which soon after leaving the cell-body divide, anastomose with similar offshoots from other ganglion cells, thus forming a dense network, so that finally all the nerve cells of the brain are brought into direct relations with each other, "per continuitatem." As an explanation of the origin of nerve fibres which do not spring from the axis-cylinder prolongation, it was maintained that by the reuniting of certain of the protoplasmic branches, other axis-cylinders were constituted, and that, finally, the nervous system, as a whole, might be regarded as a unit, made up of an infinite number of connected cells and fibres, the connections being, for the most part, effected by the protoplasmic processes.

Discussion arose, but in general the theory of Deiters and Gerlach remained unassailed until the appearance of Golgi's main work, Padua (1885–6). Golgi employed an entirely new method with silver, whose advantage over all previous ones lay in the fact that the stain was selective. The extreme complexity of the network of fibres described by Gerlach no longer obscured the destination of the finest endings of the protoplasmic processes, since in each section, for some as yet obscure reason, only certain cells or fibres took the stain. A simplicity was introduced into the microscopic picture, which evidently detracted nothing from its truth, and yet showed relations which the previous unselective stains had merely tended to obscure.

In the hands of Ramón y Cajal in Spain, the Golgi method received a new impetus, so that now it is certainly not too much to say that it has proved itself to be one of the most significant contributions to histological study of this century. Its teaching is little short of revolutionary, and necessitates a complete reconstruction of our conception of the histology of the nervous system. In its main features the theory advanced by Golgi and substantiated by all those investigators who have employed his method has received universal acceptance. It holds that the relations which Gerlach had supposed to be anastomatic and direct are, in reality, in every case, indirect, that no nerve ending or protoplasmic process connects "per continuitatem" with any other, and that the only relation which exists is one of contact, "per contiguitatem." From this it follows that the nervous system, instead of being a unity of connected elements, is rather a plurality of separate elements, so-called "Nerven-Einheiten" or "Neurone." Each "neuron" consists of a cell, an axis-cylinder (if it have one) and protoplasmic processes. Such a nervous element is a unity, absolutely complete in itself, and bearing no relation, excepting that of contiguity to other equally independent nervous elements. A multiplicity of such distinct units makes up the nervous system. This, in briefest outline, is the essence of the modern view.

The distinction between the old and the new idea is so far-reaching in consequences, that, at the risk of repetition we venture once more to compare them. The old view, represented by Gerlach, maintains — first, that each nervous element stands in *direct* relation to other nervous elements through anatomical continuity, and secondly that the nervous system represents a *closed* unity, each part of which is connected anatomically with every other part. The new theory (Golgi, Ramón y Cajal) holds, on the other hand, that each nervous element is *absolute, independent*, stands in *no* direct relation to any other nervous element, and that the nervous system, as a whole, is therefore made up of a plurality of anatomically *unconnected* elements.

The details of technique, the mass of interesting points of dispute which the new disclosures have revealed, the physiological question of nerve conduction by contact, instead of by continuity of structure, do not enter into the scope of the present article. Too much stress, however, cannot be laid upon the extreme signifi-

cance of a method of research, which has so far altered our preconceived conceptions, and which is likely, in the near future, to introduce clearness into a subject, which heretofore has eluded most conscientious investigation.

Lack of space prevents anything more than a passing allusion to the services of Henle, Meynert, Waller, Türk, Ehrlich, Flechsig, Charcot, Westphal, Gudden, Waldeyer, Lenhossék, His, Kölliker, Gowers, and many other investigators, all of whom have materially advanced the knowledge of the finer anatomy of the nervous system.

It is natural with the renewed interest which recent research has aroused, that special laboratories should have been established. The subject has already grown far beyond the scope of a general anatomical and pathological course; its literature is increasing almost daily, and the microscopic technique, required for the successful preparation of specimens, has developed into a special study. In view of these facts a number of laboratories have been opened, whose general object is to offer courses of instruction in the methods of hardening, imbedding, cutting, and finally staining and mounting of nervous tissue, according to the various more or less complicated processes, already alluded to. Of such laboratories the best known are those of Obersteiner in Vienna, of Weigert and Edinger, who work together in Frankfurt am Main, of Mendel and of Oppenheim in Berlin. Each of these laboratories is devoted solely to the study of the normal and pathological anatomy of the nervous system. With certain restrictions in the case of the Weigert-Edinger laboratory, they are all open to students. Original work with the publication of results is, in general, desired, but of course is in no sense compulsory, the main object being to provide adequate instruction in methods which are essential to a correct understanding of the finer anatomy of the nervous system. It is probable that, within a short time, a third laboratory will be opened n Berlin under the direction of Professors Jolly and Siemerling; a better indication than this of the enthusiasm which the work is arousing could hardly be given.

In addition to such practical instruction, Professors Waldeyer, Mendel and Siemerling each offered during the last winter "Semester" a course of lectures, extending through the entire term on the normal anatomy of the central nervous system. It goes without saying that the lectures were most amply illustrated by dissections of the fresh brain, by hardened preparations, diagrams, enlargements of microscopic specimens thrown on the screen, and the free use of sections that were taken serially in various directions and through various regions of the brain and cord; the finer anatomy, nuclei of the cranial nerves, and especially the course of fibres, in every case, receiving a large share of attention. To the special student the value of such courses of lectures supplementary to practical microscopic work is self-evident. The crowded lecture-rooms are, however, but another evidence of the widespread interest which the general medical student and physician, as well as the specialist, feel in a subject, which a few years ago they would have left almost completely out of their medical training.

Without drawing comparisons, or prying into causes, it is, at least, interesting to note the fact of the contrast between the English-speaking countries and the continent of Europe in this matter of the scientific investigation and teaching of brain anatomy. Reasons aside, it is evident that England and especially America are so much behind, as scarcely to be able to claim any recognition. Of 175 references to the literature in Lenhossék's latest publication ("Der feinere Bau des Nervensystems," Berne, 1893,) only four or five English names appear and but one American — a disparity which is, unfortunately, evident enough in many departments of scientific work, but which in this case is more than usually conspicuous. It is most earnestly to be hoped that the immediate future may see a change, and that a subject, which, on the face of it, is of the utmost scientific and practical importance to physiology and psychology, as well as to pathology, may have a small place, at least, in the optional laboratory training of the American medical student.

Clinical Department.

A CASE OF LITHOLAPAXY.

BY FRANK M. SHERMAN, M.D., NEWTON LOWER FALLS, MASS.

MRS. C., aged forty-seven, widow, mother of seven children, passed "sand" with the urine eighteen years ago. Eight years ago, soon after the birth of her youngest child, she began to have pain in the bladder region, especially during micturition, and then began to notice a deposit in the urine. These symptoms have steadily increased in severity. Eighteen months ago she began to have incontinence of urine, this also has continued.

June 17, 1893, I was called, and found her suffering with fever, chills, pain, frequent desire to micturate, tenesmus, incontinence of urine, and loss of appetite. The urine contained a large amount of pus and blood. Examination showed extreme tenderness of the bladder. The bladder cavity was small, and a stone was plainly felt. There was evident dilatation of the neck of the bladder and of the upper part of the urethra.

For the next three days the bladder was washed out with boric-acid solution and the same drug was administered internally.

The general and local conditions being much improved, with the assistance of Dr. W. B. Lancaster, of Wellesley Hills, litholapaxy was done on June 21st.

Using cocaine anæsthesia, the Bigelow lithotrite, and Newell's evacuator, and short, straight, open-end tubes (which worked perfectly in evacuating the *débris*), the only difficulty found in the operation was the trouble in keeping enough water in the bladder to easily manipulate the lithotrite.

The stone (phosphatic) was about one and one-half inches in diameter. The bladder was washed out daily for a week. The urine and the washings contained much muddy and sticky detritus for several days, then became clear.

Recovery was uneventful. There was no rise of temperature. Patient was up and about in eight days.

The incontinence still continued; and July 1st a soft "doughnut" pessary was introduced into the vagina, which effectually controlled it.

On August 3d the bladder was examined and washed out. The urine was found clear. No signs of re-formation of the stone. The pessary is still necessary to control the incontinence.

THE SUBCUTANEOUS INJECTION OF SALT SOLUTION A SUBSTITUTE FOR THE INTRAVENOUS METHOD; REPORT OF CASES AND A SIMPLE APPARATUS.

BY FARRAR COBB, A.M., M.D.,
House Surgeon, Massachusetts General Hospital.

In a number of cases of collapse seen during the past three months of my hospital service sterilized salt solution was used subcutaneously instead of intravenously. A large-sized trocar of the aspirator pattern with a stopcock and entrance on the side, about six to eight feet of rubber tubing, and a hard-rubber funnel was the apparatus. The funnel and tubing after being sterilized were kept in corrosive sublimate (1–1000). The trocar was kept sterilized in a tin-box. The sterilized salt solution was kept at a strength of twelve parts to the thousand, so that when needed the addition of an equal amount of boiling water made it of the proper strength and temperature for instant use.

The following cases were all grave emergencies from hæmorrhage or shock.

Case I. Brought to hospital with a stab wound through the popliteal vein. When first seen had no pulse, was blanched, with sighing respiration and cold extremities. Three pints of hot salt solution were injected under the skin of the abdomen and thighs. The time of preparation taken was only that needed to scrub the skin and add boiling water to the solution. The pulse responded almost at once, and twenty minutes after the injections was good. The case fully recovered.

Case II. Internal hæmorrhage from ruptured kidneys and spleen. Four hours after entrance unconscious, cold extremities, blanched and pulseless. Three pints of hot salt solution injected into inguinal regions and thighs, resulting in rapid improvement in the pulse. The man regained consciousness and talked with his friends for an hour, but after this slowly failed, and died during the day. In this case the improvement in the pulse and mental condition was surprisingly lasting.

Case III. Marked signs of internal hæmorrhage, pulse almost imperceptible, blanched, unconscious. A quart of hot salt solution injected, giving fairly good pulse and return to consciousness for half an hour; but after this he became again pulseless, and died.

Case IV. Railroad accident. Crush of lower leg, with evident marked loss of blood. Pulse very faint and rapid, cold extremities. A quart of hot salt solution was injected (after vigorous stimulation with digitalis, atropine and strychnine had failed to cause reaction), and resulted in rapid improvement; eventually he recovered sufficiently for a successful amputation.

Case V. Severe abdominal operation for fibroid with profuse hæmorrhage followed by collapse. A quart of hot salt solution caused rapid improvement, and the case ultimately recovered.

Case VI. Both legs crushed in railroad accident. Condition of extreme shock, not reacting to vigorous stimulation. Three pints of hot salt solution under the skin caused steady gain. Pulse became fairly strong, the face regained its color, and the improvement lasted for three hours, though ultimately the man died.

The advantages of this method are its simplicity and the rapidity with which it can be done. The pressure of from four to six feet is enough to make the fluid run freely. In the above cases the loose skin in the inguinal regions was selected and the assistant stood on a chair or table holding up the funnel which he kept filled with salt solution from a pitcher. The inguinal regions took from ten to twelve ounces and the outside of the thigh somewhat less. The fluid always ran readily and was absorbed with astonishing rapidity. The effect on the pulse was not quite as soon noticed as if the solution had been thrown directly into a vein, but improvement began in every case before six ounces had been injected, and was after that as marked and as lasting as in the intravenous method. The two or three minutes wait for a response was more than offset by the saving of time in the technique as compared to opening a vein.

Medical Progress.

REPORT ON DERMATOLOGY.

BY J. T. BOWEN, M.D., BOSTON.

(Concluded from No. 11, p. 276.)

CUTANEOUS SARCOMA.[4]

On the 3d of January, 1893, Kaposi exhibited at the Vienna Medical Society three patients suffering from different varieties of sarcoma of the skin. He passes over the cases of isolated sarcoma of the skin, which may appear spontaneously or after injuries, and which may not have recurred ten or fifteen years after extirpation. The forms in question are those that constitute a serious general disease, by the extension of the tumors.

The first case presented was that of a man of fifty-one, affected with multiple idiopathic pigmented sarcoma, the form first described by Kaposi, in 1869. In this form the nodules always appear at the same time upon the hands and feet, are of a bright red color, changing sometimes to a bluish or dark red in consequence of capillary hæmorrhages, and become confluent to such an extent as to form nodular tumefactions upon the hands, fingers and toes, and cause a painful sensation of burning and tension. Ulceration is rare, usually only after traumatism. After the lapse of months or years the oldest nodules disappear by absorption and leave a brown cicatricial atrophy of the skin, not unlike that seen in syphilis and leprosy. A long time afterward new papules and nodules of the same type appear upon the arms, legs, ears, nose and lips, many of which are absorbed, while others increase and form fungous tumors. Finally, after five to eight years, nodules appear on the mucous membranes, in the lungs and internal organs, and the autopsy reveals a great number of very vascular nodules in the liver, spleen, and on the mucous membrane of the large intestine.

The course of this form is, therefore, rather slow, but always fatal. No good results have been obtained by treatment with arsenic.

The case presented showed a deviation from this type. It developed four years previously, with excessive pain and swelling of the hands and feet. Eleven months previously, on entrance into the hospital, the dorsal aspect of the hands and feet was greatly tumefied, of a reddish-blue color at the centre of the swelling, while the margin alone presented some small reddish-blue papular elevations. The palms and soles were red, swollen and excessively painful. Kaposi had

[4] Wiener Klin. Wochenschrift.

never seen so great redness, induration, and tumefaction, except in the case of very confluent nodules. But in spite of the deviation from the usual type, the correctness of the diagnosis was proved by the appearances that were then seen — namely, characteristic papules and nodules upon the ears and pupils, and a plaque with atrophy in the centre upon the buttock,— appearances that are, it is true, not usually seen until numerous nodules have formed on the hands and feet. At first, there was an improvement under treatment, but of late numerous foci had appeared on the buttocks and limbs in the form of disks and irregular circles, with slight infiltration.

A second type, the true melanotic sarcoma, was shown in a man of fifty-one years, that had begun three years previously with a swelling of the left leg. It is now the seat of an elephantiasis, less pronounced upon the right leg, and extending upward toward the pelvis; on the left knee were numerous reddish-brown nodules, and on the thigh numerous hard, dark blue papules. This form frequently arises from a nævus, often of the toe, which degenerates into a sarcoma or is excised, and the affection then extends along the lymphatic channels reaching the pelvis and internal organs. This form often appears on the skin, also, as a metastasis of primary visceral sarcoma.

A third type of cutaneous sarcoma was illustrated by a woman of seventy-six years. This type is less sharply defined histologically, as its relation to certain constitutional conditions as leucæmia and pseudo-leucæmia are a matter of dispute at present. The case in question had begun three or four years previously, and presented now nearly one hundred tumors upon the two shoulders front and back, upon the upper part of the chest and scapular region. The nodules were hard and elastic, from the size of a pea to that of a nut, hemispherical in form, from bright to dark red, glistening, and painful to the touch. There were also plaques as large as the palm of the hand, with central depression, like those of mycosis fungoides. There were almost as many nodules on the dorsal and sacral regions, the thorax and abdomen, together with a few on the limbs. As two similar cases, of which drawings were shown, had been cured by arsenic, injections of the arseniate of soda were tried. After six or eight injections most of the nodules had diminished one-half or one-third, but later, in spite of persistence with the treatment, they had again increased in size. Kaposi pointed out that since arsenic was first recommended by Köbner, many cases had been reported as cured by arsenic, a part of which, however, had finally terminated fatally.

Histologically, the place of this form has not yet been settled. In many respects the microscopic appearances resemble those of a round-celled sarcoma, while some have classed them with the lympho-sarcomata. In some of the cases leucæmia has been determined, in others pseudo-leucæmia, in still others no such complication. In this case the blood was normal. The same is true of mycosis fungoides and of lymphoderma perniciosa, where leucæmia has been sometimes observed, sometimes not. Further careful examinations are necessary, and transitional forms between these types may be found. He proposes provisionally the name sarcomatosis for these varieties.

CIRCUMSCRIBED LYMPHANGIOMA OF THE SKIN.

A number of cases of this peculiar and rare disorder have been studied and described of late years. Francis,[5] in the article before us, notes several that have come under his own observation and then attempts to group the recorded cases, partially on an anatomical, partly on a clinical basis.

CASE I is that of a male fourteen years of age, a bricklayer's apprentice. He has suffered from the disease nearly all his life, but cannot say positively when it first appeared. For the last two or three years there have been illnesses connected with the disease, occurring about every six weeks, and lasting two or three days, and consisting of great tenderness in the affected parts, and usually severe headache and nausea. The right buttock is the seat of irregular growths of the skin, varying from a pin's head to a five-shilling piece in size, in clusters which appear confluent in places and of a warty appearance at a short distance. There were very few vesicular lesions found in this case, and these only in the youngest and smallest patches; in the older and larger growths the cuticle seems thicker and the papule more solid. There were no appearances of dilated capillary blood-vessels.

The larger patches were shaved off to the level of the skin and the base touched in different parts with the thermocautery, fuming nitric acid, and salicylic acid cream. The wounds healed, and he was discharged apparently cured. In four months he was readmitted to the hospital. The part that had been excised was the seat of a raised brawny growth, of a reddish-brown color and quite firm. Numerous new patches of disease had appeared beyond the area of the old growth, consisting of isolated vesicles and groups of vesicles, like those of herpes, situated on a slightly raised base; the vesicles are translucent, covered by a firm cuticle and not easily ruptured. There have been no fresh attacks of pain. Some of the larger patches were excised and the smaller ones treated with the thermocautery.

Microscopic examination of a small papule excised, showed a dilatation of the lymphatic channels and capillaries, and in the central part the septa had broken down between them to form small multilocular cysts. The epidermis was not involved. The contents of the cysts were lymph coagula with a few leucocytes. Occasionally, at the lower part of the growth, dilated blood capillaries were seen.

CASE II is that of a male child, three and one-half years old, upon whose right leg a rash was noticed for the first time on the third day after birth, which has persisted and spread ever since. No history of inflammatory attacks in this region. The eruption is limited to the right lower leg, groin and perineum, and is distributed as an elongated streak from the inner malleolus along the line of the internal saphenous vein to the region of the saphenous opening, where it divides into two branches, one passing outward to near the anterior iliac spine, the other passing backward to the perineum and ending near the anus. The growth is composed of clusters of papules and vesicles. There are no dilated capillaries to be seen.

CASE III. Female of fifty-five years. The patient is quite sure that the region affected was natural until three years ago, when she received a severe blow in this place. The left side of the face exhibits a thickened patch of skin, with poorly defined margins, the surface of which is studded with minute translucent vesicles, with tough walls, exuding a clear fluid when

[5] British Journal of Dermatology, February, 1893.

pricked. No isolated tubercles and no telangiectasis on the face.

Case IV. Female, sixteen years. Tuberculosis of lungs. On the left side of chest a streak of nævoid growths in the mid-axillary line. The largest growth was present at birth, and of a general reddish-blue color; it is now slightly raised, but contains no vesicles, while scattered about this are many little growths composed of a single vesicle or group of vesicles, with tough walls, containing a clear fluid. One patch is covered by dilated blood-vessels and small blood cysts. No history of inflammatory attacks. The patch was excised, and there had been no recurrence a year later.

Case V. A female of seventeen, the affection being seated in the left axilla. It had existed since the age of two months.

Case VI was a female adult, part of the growth being congenital, part having appeared since birth. It was situated in the right axilla and on the right arm.

Case VII. A female child of eight. Partially congenital and this portion an ordinary nævus. The remaining portion consisted of dilated lymphatics, presenting, clinically, grouped vesicles.

Lymphangiomata which affect the skin alone, are closely allied pathologically to similar processes in the subcutaneous and deeper tissues, and with congenital elephantiasis and congenital tumors of mesoblastic origin. The author, although regarding them as very closely allied, suggests that the circumscribed lymphangiomata of the skin be divided into groups and sub-groups as follows:

Group I. Lymphangioma simplex. Of this he has been able to find but one case. It may be defined as a dense plexus of normal-sized, normal-walled lymphatic vessels, with no alteration in the surrounding tissues.

Group II. Lymphangioma cavernosum. Numerous tumors are distributed over the whole body, compressible, sometimes associated with pachydermia.

Group IV. Hæmatolymphangioma. The lymphatic and capillary blood-vessels are so closely allied that we may assume that hæmangioma and lymphangioma may not only occur in the same patient, but also in the same growth. The appearance of the growths differs widely according to the varying proportions of lymphatic and blood-vessel growth.

Sub-group (*a*) includes cases where we have originally a mixed hæmatolymphangioma, and the hæmangiomatous part undergoes retrogression, while the lymphangiomatous part proceeds to further development.

Sub-group (*b*). In this group he places those cases in which the original growth is a well-defined hæmangioma, but is subsequently associated with lymphangioma, or in which well-defined hæmangioma co-exists with lymphangioma. Nine cases belonging to this sub-group are cited.

Sub-group (*c*). Those cases of lymphangioma in which the only naked-eye evidence of hæmangioma consists in dilated tufts or striæ of capillary blood-vessels.

Sub-group (*d*). Those cases, which microscopically are shown to be hæmatolymphangiomata, but which to the naked eye appear free from hæmangioma.

From twenty-eight cases which the writer was able to collect of the fourth group (the hæmatolymphangiomata, with which we are especially engaged) he finds that of twenty-six, fourteen were males and twelve females, the favorite location being the upper portions of both upper and lower limbs. The affection is congenital (two cases), or begins early in life, in the majority of instances. There is a tendency for the eruption to take the form of streaks, and there is sometimes a distinct distribution over the nerve trunks. The part played by the nerves in its etiology is obscure; but this distribution and some other facts would point to a *possible* influence. The affection dates probably from embryonic life and is only shown when the lymphatic vessels become enlarged subsequent to birth.

An interesting point is the frequency with which these lymphangiomata are developed upon points exposed to friction and irritation, and sometimes an injury has been regarded as provoking their development. The removal of the disease surgically, or of a pre-existing nævus, has often been shown to be the signal for an acute outburst, and the same result, it is to be noted, has also followed the removal of lymphangiomatous tumors of the tongue.

Recurrent attacks of inflammation, sometimes called erysipelas, are observed in many of the cases. These attacks are often accompanied by fever and malaise, and seem to bear a close relationship with the recurrent attacks of "erysipelas" which accompany or produce an elephantiasis. They differ somewhat from erysipelas in their close limitation to the affected area. The writer suggests that they may be part of an extensive lymphangioblastic process due to some deeplying cause acting through the vaso-motor nerves. There is no evidence of obstruction of the lymphatic channels in any of these cases.

Numerous cases present, in addition to the newly-formed and dilated lymph vessels, an increase in the amount of fibrous tissue formed, so that the picture of a localized elephantiasis is presented; and it is probable that some cases of dermatolysis and pachydermia may belong in this same class, although they present when seen, no sign of "vesicles" or of lymphatic enlargement. The increase in fibrous tissue is regarded as a secondary phenomenon.

DISTINCT SPECIES OF RINGWORM.

M. Sabouraud,[6] instigated by Besnier, has been investigating the question of the existence of different species of trichophytons and has arrived at conclusions of considerable importance. His results are based upon more than 600 cultures, 100 careful clinical examinations combined with microscopical studies, about 60 cultures in drop (to determine the botanical characteristics) and 20 inoculations on men and animals.

It has been noted that certain cases of ringworm show, upon examination, small spores, while certain others always contain large spores, but no attempt at a differentiation of species from these characteristics has ever before been made. The writer shows in the first place, that these differences are constant, that is, an individual never presents at the same time both the large and the small spore, and the members of a family when several are attacked, always exhibit the same sized spore. He has further been able to differentiate two chief species of the trichophyton. The first species is characterized by small spores without mycelium and he names it the *trichophyton microsporon*. The spores are always extremely small. This form is found in the majority of cases of tinea tonsurans as seen in

[6] Annales de Derm. et de Syph., November, 1892.

children. The spores fill the hair completely, and surround it even, so as to form a sort of sheath.

The second species he calls the *trichophyton macrosporon* and it is characterized by the large size of the spores and by the fact that the hair is never surrounded by the parasite. Almost all the long and rebellious cases of tinea belong to the type characterized by the small spores.

Bacteriological studies proved that different forms of culture could be obtained from the cases containing the different varieties of spores, and this was demonstrated upon several different culture media. Cultures upon potatoes were particularly characteristic. If the cultures of the trichophyton macrosporon are examined after fifteen to eighteen days, they have a dry, powdery, flour-like appearance, which is never pure white, while the trichophyton microsporon has assumed at once the appearance of a perfectly white down. The cultures of one type never merged into nor simulated those of the other. The clinical differences have yet to be more carefully studied. In general it may be said that if the affected hair is large and broken short off, the type will be that characterized by the large spores; while if the hair is fine and not broken near the surface of the skin, the type will be that of the small spores. He considers from his studies that it is probable that the trichophyton macrosporon is the cause of most cases of trichophytosis barbæ, as also of the greater number of cases of tinea circinata (of the non-hairy parts). He thinks, too, that the trichophyton macrosporon is a parasite of the epidermis rather than of the hair. It may invade the hair of the infant, but it is far less frequent here and less rebellious.

It was found, however, that very rarely other forms present themselves, and besides these two chief forms, four other new species were obtained. Further studies with regard to them will be awaited with interest.

A series of inoculations were made by the writer upon himself, with the different species that had been isolated. The inoculations that were successful did not, however, contrary to expectation, prove the existence of a lesion peculiar to each parasitic species. It is necessary for success to render the region of inoculation thoroughly aseptic, and to inoculate by pricking, not by scarifications, which serve to mask the lesion which is to appear in a few days. It is necessary also to take care that the sweat is not acid. It was found that the trichophyton microsporon when inoculated upon the epidermis never produced more than a desquamation upon an erythematous base, and without a pronounced circular form.

Sabouraud also asserts that the parasites of the trichophyton group belong to the genus Botrytis of the mucorini and may be designated as Botrytis trichophyton.

Later, Sabouraud has published accounts of his further studies in this direction, which tend to show that the subject is a very complicated one. He has succeeded in splitting up the trichophyton with large spores into a large number of varieties, as well as into two grand divisions, those of animals and those of men. A notice of these later studies will be included in the next review.

"PERITONEAL pirouettes" is what the Philadelphia *Press* calls the objectionable dances on the Midway Plaisance.

Reports of Societies.

THE PAN-AMERICAN MEDICAL CONGRESS. SECTION FOR MEDICAL PEDAGOGICS.

C. L. SCUDDER, M.D., SECRETARY.

THE Section in Medical Pedagogics devoted its attention, at the recent meeting of the Pan-American Medical Congress in Washington, D. C., to a consideration of methods of medical teaching, a history of medical education in this country and a series of discussions on preliminary medical education. The work of the Section extended through three days of the Congress.

ON Tuesday the President, DR. J. COLLINS WARREN, traced the development of medical education in the United States.[1]

PROF. R. H. CHITTENDEN, of the Sheffield Scientific School of Yale, Professor of Physiological Chemistry, presented a valuable paper on the claims of physiological chemistry to occupy a prominent place in the fundamental preparatory training for medical education. Under the head of biology in the courses offered the student in college, is included more or less zoölogy and botany, with a comparatively large amount of dissection of typical forms, together with histology and embryology. This constitutes a presentation of the morphological side of biology. The physiological side is less thoroughly presented, and if presented, consists of muscle and nerve physiology, illustrating the mechanical side of physiology purely. All this side of physiology Professor Chittenden admitted is of the highest importance, but he wished to emphasize the fact that there is another side of physiology not much cultivated in this country as yet, namely, the chemical side or physiological chemistry. He proceeded to describe the scope of such work and the important place which it holds in the medical curriculum.

DR. HAROLD C. ERNST, of Harvard, read a paper upon the importance of bacteriological study and its proper position in the medical school course as a branch by itself, divorced from pathology, either general or surgical.

ON Monday an extremely interesting demonstration was made by DR. ZINKE, of Cincinnati, of the Cæsarean section and Porro operation. This demonstration illustrated what it is possible to do in the way of making clear, difficult problems in teaching surgery. It illustrated a method of teaching.

DR. BAYARD HOLMES, of Chicago, discussed the methods of medical education in the United States and argued for more thorough scientific training at the outset for all medical men, and the obtaining of the B.A. and M.D. degrees at one time, after a definite course of study. He believes that the tendency toward more laboratory work and less clinical teaching is of the greatest importance.

Dr. Holmes's paper, which was in some respects radical, was discussed by DR. OSLER and DR. WELCH, of Johns Hopkins, and DR. FITZ, of Harvard.

Dr. Osler said: The plan to which Dr. Holmes refers is in successful operation at the medical school in Cambridge, Eng., and is in many respects an ideal one. The student is enabled to obtain the B.A. and M.B. degrees in a little more than five years. The greater part of the academical course is taken up with the subjects of chemistry, biology and anatomy, and

[1] See page 285 of the Journal.

the student takes his B.A. degree in the Natural Science subjects. He can in this way obtain the two degrees in a shorter period of time than in the more advanced schools in this country, in which the preliminary chemical and biological work takes from two to three years before the student enters the four years' course of the medical school. I regret I cannot share Dr. Holmes's faith in the State Universities, at any rate as they are at present constituted. New ones organized would be likely to perpetuate the anomaly seen at present of separate Homœopathic establishments, and the folly of duplicating chairs in the important subjects of anatomy, physiology, surgery and pathology, when in reality homœopaths differ from us in a single detail — the treatment of medical cases — the very point upon which we all hold the most varied, often most contrary, views.

DR. F. C. SHATTUCK'S paper on methods of teaching clinical medicine, traced the connection between medical schools and hospitals, and emphasized the importance of a school owning its own hospital or at least controlling it. The necessity of both primary as well as advanced clinical teaching was dwelt upon. The value of the clinical conference was set forth.

On Thursday much was accomplished.

DR. M. H. RICHARDSON, of Harvard, illustrated by blackboard drawings, methods of teaching in anatomy and surgery. This demonstration showed conclusively the value of this rapid, free-hand picture-making in surgical teaching.

DR. VICTOR C. VAUGHAN, of Ann Arbor, Mich., read a paper on the methods of medical education. These he grouped into (1) lectures; (2) recitations from text-books; (3) laboratory instruction; (4) amphitheatre clinics; (5) medical teaching.

W. C. DABNEY, M.D., of the University of Virginia, read a paper in which he described the things necessary to a student's thorough medical equipment. He had in mind, not the training all would like, could they afford it, but the best training which the average man can afford.

DR. J. P. SAWYER, of Cleveland, gave an interesting demonstration of the action of the valves of the heart. By a series of tubes and glass windows introduced at proper places into the heart of a bullock, and by means of an electric light within the heart, it was possible, on forcing water through the tubes and heart to watch the physiological action of the valves.

PROF. W. T. SEDGWICK, of the Massachusetts Institute of Technology, presented a paper on preliminary medical education in the United States, in which he discussed in a very fresh and interesting way, the problem of the relations of preliminary medical education to the professional school. He sees in the recent step of Johns Hopkins, reason to fear the practical difficulties which may arise from such advanced requirements.

In connection with Professor Welch's paper, June, 1893, it will be interesting to read Professor Sedgwick's valuable communication.

The meeting of this Section in Pedagogy was a success; and it has done pioneer work in advancing all along the line an appreciation of the importance of the new era in medical education. It has placed on a firm footing the initial step in the direction of the study of methods of medical teaching.

We have been hitherto in the medical school lectured to; we have heard subjects talked about; there has been comparatively little *real teaching done;* hard laboratory teaching in all branches. That an intimate connection between student and patient, through the assistance of the instructor, is important, is only just beginning to be realized. The question how a given subject may best be presented to the student, what method shall be used, is coming to be regarded as of some importance. Competition in teaching — and the better scholarship of medical students to-day as compared with fifteen years ago, demand greater definiteness and more method in teaching.

The practical gain from this great Congress of foreign physicians and surgeons will be that medical education in the United States will, in the minds of foreigners, stand for something real and tangible and valuable. European nations will come more keenly to realize that the United States possesses, in Harvard University, in Columbia College, in the University of Pennsylvania, and in Johns Hopkins University, medical educational plants such as no other nation possesses. That these medical centres will before long attract the attention of students abroad cannot be doubted. It will not be beyond the bounds of possibility if, in a few years, students come from Paris, London and Vienna to enjoy the advantages which once these places alone possessed.

Recent Literature.

Nuevo Concepto de la Histología de los Centros Nerviosos. Par el DR. D. SANTIAGO RAMON Y CAJAL.

Recent Views as to the Histology of the Nervous Centres. By DR. D. SANTIAGO RAMON Y CAJAL. 8vo, pp. 68. With twenty-three illustrations. Barcelona: Henrich & Co. 1893.

These lectures, delivered at the academy and laboratory of medical sciences at Cataluña, and reprinted from the "Revista de Ciencias Medicas de Barcelona," contain a summing up of the latest researches into the fine anatomy of the nervous system. No one could better set forth the results obtained by the use of Golgi's methods of staining than the man who has been the chief pupil of Golgi in carrying on research by his methods. These lectures give the results thus far obtained, not only by Golgi and the author, but by other observers on the Continent. It is needless to say that the methods of staining first introduced by Golgi, and employed with such success by the author, have revealed to us new wonders in the marvellous structure of the nervous system. The physiological bearings of these new discoveries are as yet unknown, and their pathological relations have not yet been investigated, but they open wide fields for research. They have shown that each nerve-cell sends out many protoplasmic branches dividing into a fine net-work, and that the axis-cylinders give out various collateral branches, entablishing, through numerous reticulations, the most complex relations with other parts of the nervous system.

In the very brief space allotted to this review, the details of these researches, so clearly set forth, cannot be given. The author's work, however, cannot be slighted by any one who is interested in the anatomy of the nervous system, and we trust that it may be translated into a language more familiar to the scientific world than Spanish now seems to be.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 28, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

REGISTRATION OF THE STILL-BORN.

IN the last number of the JOURNAL it was shown that serious defects in the system of registration of the causes of death had led to a Parliamentary inquiry and report upon the subject. A considerable portion of this class of deaths consists of still-born children.

Dr. Rentoul, of Liverpool, devoted a paper to this subject, at the meeting of the British Medical Association August 2, 1893. He states that while the laws of nearly every other country of Europe require careful registration of the still-born, at the time of their burial, the law upon this subject in England and in Russia is very loose. By correspondence, Dr. Rentoul learned that 6,321 such burials had been made in 71 cemeteries. This led to a Parliamentary investigation which resulted in returning the facts as to 17,335 interments of still-born children in England of which number 4,569 were buried without a medical certificate as to the cause or manner of death. It would have been a useful addition to this information if the facts as to legitimacy could have been obtained, but owing to the defective methods of registration, this point could not be learned.

A writer in the *British and Foreign Medical Review*, estimates from a very large number of births from different sources that the proportion of still-births to legitimate births is as 1 to 18 or 20 (in Massachusetts it was as 1 to 27 in 1890) while among the illegitimate births it is as 1 to 10. These estimates were made from a total of 8,000,000 births. Dr. Bertillon states that in Paris the chance of an illegitimate child being still-born, when compared with the legitimate, is as 193 to 100.

Coroner Hicks, of London, says: "Many children who are termed still-born are not really so, but have been born alive and died soon after, sometimes from natural causes, but also from suffocation, and other illegal means. In fact it is to be feared that many children *termed* still-born are disposed of in other ways."

Dr. Tidy says, in his "Legal Medicine": "So notorious is it that a large number of these cases could be averted, that some legislation is urgently needed."

A regular funeral for an infant costs two to three pounds (ten to fifteen dollars), while a still-born child can be buried for a shilling and six pence. Hence the inducement to register the deaths of infants born alive as still-births. One of the principal causes of criminal still-birth is illegitimacy.

The following figures show the number of illegitimate births registered, exclusive of still-births.

	Year.	Populat'n.	Total births.	Illegitimate births.	Ratio to total births per 1,000.
England	1889	29,015,413	885,944	40,627	45.9
Scotland	1891	4,033,180	125,965	9,537	75.7
Ireland	1890	4,688,426	105,254	2,827	26.9
Massachusetts . .	1890	2,238,943	57,777	1,206	20.9

As a remedy for this evil, Dr. Rentoul proposed the inspection of all still-born children by a medical practitioner before their burial. In England any body can be buried, even though there has been no medical certificate of the cause of death, or even though the death has not been registered. "A truly delightful paradise for criminals!"

Dr. Rentoul says further: "The time is surely ripe for a public protest against the gross indifference of women of all classes as shown to the infant in the womb. The present state of affairs is a public scandal. A class of political economists may say that the human animal is a glut in the market, and so, not having the money value of a pig, calf or sheep, it may be placed on that little list, from which, they hope, it never may be missed. On the other hand, our words and actions must be made to give a strong color to public thought, to instil the knowledge, that from the moment of conception there is life; that this life has a right to claim our protection; and that it is one of our first duties to bring about registration and inspection of still-born children. And if we can induce our law-makers to extend further official recognition to the child in the womb, then we, as medical practitioners, possessing the power of harmonizing law with medical science, will be able to say that we have not altogether failed in our duty in dealing with this important question."

JAUNDICE FROM MENTAL EMOTION.

THE existence of jaundice from mental perturbation was recognized by the older pathologists. Budd, in 1844, referred it to arrest of the secretion and retention of the bile in the blood.

The theory of arrested secretion was abandoned when more correct notions of the physiology of the bile were acquired, and subsequently jaundice by nervous influence was ascribed to spasm of the bile-ducts;

this, it was affirmed, might produce complete obstruction to the passage of the bile and consequent reabsorption. Frerichs, later on, recognized the occasional occurrence of this form of jaundice which may appear very suddenly or in the course of a few hours after a violent mental emotion, as vexation, anger, fright, and he thinks that it may come about in two ways:

(1) By interruptions to the circulation of the blood through the liver, arising from the influence exerted by the nerves over the calibre of the branches of the portal vein.

(2) By interruptions to the heart's action, the respiratory movements, and the renal secretion.

Talamon, in a recent number of the *Médicine Moderne* (August 23, 1893), takes up the subject in connection with a remarkable case which had lately come under his observation where a healthy woman, aged twenty-four years, having had a severe fright, became intensely jaundiced after five hours. The icterus lasted twenty-four days.

Talamon, in discussing the pathogeny of emotional jaundice, thinks that there are two objections to the current notion that it is due to spasm of the bile-ducts: (1) the suddenness of its production; and (2) its persistence.

With regard to the suddenness, there are cases on record where the jaundice has come on almost instantaneously. Villermé mentions a case where two young persons quarrelled and drew their swords; one of them suddenly became yellow, and the other, terrified at the change of color, dropped his weapon. The same writer relates another case of an abbé who suddenly became yellow on a mad dog rushing against him. Although statements of this nature may appear doubtful, still there are numerous observations which prove that under such circumstances as those alluded to, jaundice may be developed in a much shorter space of time than is wont to happen after the application of a ligature to the common bile-duct.[1] The experiments of Tiedmann and Gmelin show that bile pigment does not appear in the urine till forty-eight hours after the ligation of the choledochus; those of Audigé, that resorption of bile is not effected under thirty-six hours.

As to the persistence, it does not seem likely that a spasm of the bile-ducts can continue eight, ten, fifteen days without relaxation. In Talamon's patient the urine was loaded with bile pigment on the fifteenth day.

The theory of polycholia (Grisolle) does not alone explain the jaundice that follows mental perturbation, for the resorption is still to be accounted for.

Talamon thinks that the principal element in the pathogeny of this form of jaundice is the disturbance through nervous shock of the hepatic cell whose secretory function is augmented while at the same time it loses its property of retaining the bile which is formed, whence the immediate diffusion in the blood of the excess of bile secreted. This is, in fact, Liebermeister's explanation, who calls this emotional icterus a *cathectic* jaundice. In the normal state, he says, the liver cells retain in their protoplasm the formed bile, a property which they lose in certain morbid conditions, leaving their product of secretion to diffuse itself through the blood as lymph. There is at the same time augmentation of the absorbent surface by reason of sudden paralytic dilatation of the hepatic capillaries. This, however, only in part explains the retention of the bile, and here Talamon assumes the existence of disordered contractions of the bile-ducts extending to the choledochus. This only partially interrupts the passage of bile into the intestine, for the spasm is not continuous, and there are periods when the bile passes freely, as when the stools are deeply colored. In the case which he reports, this fact is strikingly apparent in the clinical record; the stools were clay-colored one day, and bilious the next, etc.

This is in accordance with the observations of Labadie-Lagrave, who has recently published a very complete treatise on "Diseases of the Liver." This kind of jaundice is clearly differentiated from most of the other varieties by the fact that the stools are not invariably and continuously decolorized. In a recent case of emotional icterus observed by Chauffard, the patient, after intense excitement, became jaundiced in the space of an hour; during the first five days, the choledochus remained permeable and the stools were colored and soft: the decolorization did not appear till subsequently. Labadie-Lagrave rejects the theory of spasm for these reasons, and also because histological investigation proves that the bile-ducts are very poorly provided with unstriped muscular fibres; faradization cannot efface the calibre of these ducts through their muscular fibres. He believes, with Chauffard, that if in this kind of jaundice there is any obstruction of the choledochus, this results from thickening of the bile, or from epithelial desquamation, as in simple catarrhal jaundice.

It must be admitted that the mechanism of emotional icterus is not yet completely elucidated.

[1] Frerichs: Diseases of the Liver, Am. Ed., vol. i, p. 112.

SALINES IN APPENDICITIS.

We wish to call attention to the letter from Dr. M. H. Richardson, which is printed on another page. The question of the use of saline cathartics in peritonitis has often been discussed in papers and the reports of societies in the Journal, but it is only for a short time that the importance of the appendix as the common cause of what is still often called idiopathic peritonitis has been appreciated. The diagnosis and treatment of appendicitis is still in its infancy and discussion from men who have seen much of the disease is desirable. The treatment of mild cases of colic or local tenderness, which now for the first time are recognized as pointing to the appendix, is a matter of importance to every practising physician. The number of such cases is very large, most of them recover speedily if left alone, or go to confirm the belief of the medical

attendant in his common method of treating them. But any of these cases may result in perforation. Whether the free use of salines will diminish or increase this risk will probably not be soon conclusively settled, but with a perforation existing, increased peristalsis, and fluidity of the intestinal contents can hardly fail to increase the extravasation into the peritoneal cavity, and fatal peritonitis. Dr. Richardson believes that in catarrhal appendicitis there is no hurry to produce catharsis. This might be combatted by those who believe that the presence of a fæcal accumulation favors perforation, and proof from them that this danger is greater than that arising from cathartics, should be brought forward more clearly than it has been in the past. The uselessness of treating general peritonitis by salines while a direct communication exists between the intestinal tract and the peritoneal cavity hardly admits of argument.

MEDICAL NOTES.

PROGRESS OF CREMATION. — There are in this country already thirty-two active cremation societies and fifteen crematories. In the last five years there have been over two thousand incinerations.

IMMIGRATION VIA CANADA. — As a result of Canada's refusal to allow official immigration inspection at her ports by our Government, a conference was held last week between the United States Government and the various Canadian steamship and railroad companies regarding the most efficient means of quarantine inspection of immigrants entering this country by Canadian ports. The result was an agreement by which the various companies are to provide the immigration inspectors of the United States with facilities for a rapid inspection of immigrants at the ports of landing before they are sent to their trains. Proper passengers will be given certificates entitling them to enter this country. This being a private arrangement will be allowed by the tacit consent of the Canadian authorities.

YELLOW FEVER. — On September 13th, three cases of yellow fever were discovered at Brunswick, Ga., which had not been duly reported. Examination showed that two fatal cases had already occurred in different parts of the city, but had been returned as "consumption." Two of the cases were returned refugees. A quarantine camp was at once established. On the 16th two new cases occurred, and on the 17th eleven more, and the fever was officially declared to be epidemic. On the 18th there were twenty cases and one death. Since then there have been but a few new cases each day. The usual shot-gun quarantine has been established and the greatest suffering among the inhabitants has resulted. The actual necessities of life in the way of food and clothing have been exhausted, and all communication with surrounding districts for the purpose of procuring supplies is prohibited, so that at present the people are in greater distress for want of food than from the yellow fever.

A NEW ILLUSTRATED DICTIONARY OF MEDICINE. — Dr. George M. Gould has about ready the new medical dictionary upon which he has been at work for several years. It is a new book in every way and not a revision of his older one, and in it he has adopted the new method of spelling medical and scientific words.

RECOVERY OF DAMAGES FOR MENTAL SUFFERING. — The supreme court of North Dakota has ruled that mental suffering is as properly considered in estimating damages as is physical pain. The impairment of mental powers, naturally a proper element when proved, is only to be considered by the jury when claimed in the suit and evidence.

NEW YORK.

SMALL-POX. — A considerable number of cases of small-pox have developed during the last ten days, and several deaths have occurred from it. Among those suffering from the disease are two physicians, Drs. Thomas L. Richards and Charles Norris, who are said to have contracted it from a patient at the Vanderbilt Clinic who was at first supposed to have chicken-pox. At the Clinic the case was examined by quite a number of students and young physicians. On September 21st there were thirty-two cases of small-pox under treatment at the hospital for contagious diseases, and the vaccinating corps of the Board of Health are carrying on an energetic campaign in all the tenement-house districts of the city.

ANOTHER BROKEN NECK. — A third case within three months of a patient living with a fracture of the cervical vertebræ has been reported. The patient is under treatment at the Manhattan Hospital, and more than a week has elapsed since he broke his neck in a fall of ten feet. The other two patients, whose cases have already been referred to in the JOURNAL are still both alive, and one of them has already been discharged from hospital, although still wearing an apparatus to relieve the injured vertebra of the weight of the head.

ELECTRIC CAR ACCIDENTS. — On a single day recently, September 17th, no less than three children were crushed to death by electric cars, one in New York, one in Brooklyn, and one in the neighboring city of Newark, New Jersey. On the 21st another child was killed in the same way in Brooklyn, where accidents of this kind are extremely frequent, and on the 22d the fifth death was caused by the new cable cars on Broadway, New York.

RECENT BEQUESTS. — By the will of the late Hamilton Fisk, Secretary of State during Gen. Grant's administration, $50,000 is left to Columbia College, $5,000 to St. Luke's Hospital, and $2,000 to the Bellevue Training School for Nurses.

MORTALITY. — The general health of the city still continues remarkably good, and in the week ending September 16th the lowest mortality thus far during the year 1893 was recorded. The number of deaths was only 697, which is 61 less than during the previ-

ous week, and also 61 less than in the corresponding week of last year. This mortality is 64 less than the average of the corresponding weeks of the past five years, and represents an annual death-rate of but 19.09 per thousand of the estimated population of the city. The largest decrease was in deaths from diarrhœal diseases, which numbered 83 against 138 during the previous week. Of deaths from this cause in children under five years of age there were 70, against 118 in the previous week.

Miscellany.

A PECULIAR CAUSE FOR URETHRAL HÆMORRHAGE.

A CURIOUS case of rupture of the urethra is reported by Herrick in an article on that subject in a recent number of the *Medical News*. The patient, a man of forty, accidentally swallowed an artificial tooth-plate. He was given proper diet and kept quiet for four days, when he was attacked with severe urethral hæmorrhage. On examing his rectum, the tooth-plate was found and with a little difficulty removed. The hæmorrhage from the urethra continued but no blood escaped from or into the rectum. Neither did any find its way into the bladder, as the urine passed after the first instant was clear. The introduction of a large soft catheter controlled the bleeding. There was no extravasation and the catheter was left in place for forty-eight hours. Once in the interval it was expelled by the patient, with a return of the hæmorrhage which was stopped by reintroduction of the catheter. The tooth-plate probably had punctured the urethra by one of its projecting points, making a valve-like slit which prevented the blood from passing toward the rectum, and also preserved the parts from extravasation.

THE EYE SYMPTOMS OF CEREBRO-SPINAL MENINGITIS.

THE involvement of the eye in cerebro-spinal meningitis has been long recognized, especially the conjunctival inflammation and the photophobia. Intraocular disease — choroiditis, suppurative cystitis and iritis — has been observed and reported more especially by German writers. A systematic examination of the fundus of the eyes has been but seldom carried out, however; the external conditions having alone been studied. In view of the close connection between the arachnoid space of the brain and cord, and the deeper structures of the eye along the intervaginal space, Randolph urges a systematic examination of the fundus, which he says will often reveal changes of deep significance in the choroid retina or optic nerve, though the patient has been unconscious of any eye symptoms. He reports the study of thirty-five cases of cerebro-spinal meningitis[1] of whom twenty died. Of the thirty-five cases, only seven showed a normal fundus; and of these seven one had divergent strabismus and dilated pupils, one marked nystagmus, and a third dilated pupils. There was one case of retinitis which was associated with thrombosis of the central vein. There was strabismus in eight cases, always of the right eye and divergent. Indeed the right eye showed abnormal conditions of all kinds oftener than the left. "Optic neuritis occurred in six cases, and the other nineteen cases were characterized, as regards the fundus of the eye, especially by great venous engorgement and tortuosity and more or less congestion of the optic disc." He considers the cases of neuritis to be of the descending variety involving the entire trunk of the nerve and its sheaths, and the numerous cases of congestion of the optic disk as possibly beginning stages of optic neuritis. The treatment of the consecutive atrophy was as unsatisfactory as in atrophy from other causes.

Of the value and importance of this examination in all cases, he says: "I regard the existence of eye symptoms, especially those where the fundus is involved, as indicating a particularly grave case. Wherever I found the condition which I have described very pronounced, I felt justified in speaking positively as regards the prognosis. I think that this type of eye symptoms is of more value as indicating the condition of the brain than the symptoms described by other writers, such as panophthalmitis, suppurative choroiditis and keratitis, affections which, in my opinion, would be likely to have their origin in a general infection and not likely to be the direct result of the purely cerebral changes."

[1] Bulletin of the Johns Hopkins Hospital, August, 1893.

CHARAKA-SAMHITA.

THE sixth part of this curious and interesting work contains a lesson upon emergencies which may arise in the administration of emetics and purgatives. As there are many things necessary for achieving success in giving dangerous remedies certain arrangements of the house and servants are advisable. These directions imply nothing less than the equipment of a hospital and are worth recording, as showing an early recognition of the importance of special hospital construction.

"In the first place a mansion must be constructed under the supervision of an engineer well conversant with the science of building houses. It should be spacious and roomy. The element of strength should not be wanting in it. Every part should not be exposed to strong winds. One portion, at least, should be open to currents of air. It should be such that one may move through it with ease. It should not be exposed to smoke, or the sun, or dust, or injurious sound and touch and taste and form and scent. It should be furnished with staircases, with pestles and mortars, privies and cook-rooms.

"After this should be secured a body of attendants of good behavior, distinguished for purity and cleanliness of habits, possessed of cleverness and skill, endued with kindness, skilled in every kind of service that a patient may require, competent to cook food and curries, clever in bathing or washing a patient, in rubbing or pressing the limbs, well skilled in making and cleaning beds, competent to pound drugs, patient and skilful in waiting upon one that is ailing and never unwilling to do any act they may be commanded to do. A number of men should be secured that are skilled in vocal and instrumental music, in hymning encomiums and eulogies, and in reciting verses and pleasant narratives and stories and legendary histories, clever in reading the face and understanding what is

wanted by the patient and possessed of such politeness as to become agreeable companions.

"The mansion should be stored with an adequate supply of game of all kinds. A cow should be kept, yielding copious milk, of a quiet disposition, healthy, well tended with food and drink and *kept in a fold that is properly cleaned.*

"So also should be kept little vessels and cups, larger vessels for washing the hands and face, water-jars, small jars, dishes, cauldrons, pans, hollow vessels for covering articles, ladles, mats, covers, vessels for boiling oils and glue, churning rods, beds and seats, flat vessels for holding spittle and evacuations, placed ready for use; good beds placed upon bedsteads and overlaid with white sheets and containing pillows. Articles necessary for the operations, plaster, fomentations, rubbing, vomiting, purging, application of oily or other enemata, etc. Smoking-tubes, brushes, brooms, balances and weights, oil, fat, marrow, honey, salt, fuel, water, sour gruels, whey, buttermilk, sour gruel of rice and the different varieties of animal urine should also be kept ready. . . . Having kept these articles ready for use the patient should be treated as the case may demand."

THE PROTEID POISON OF SCARLET FEVER.

MR. T. J. BOKENHAM and Mr. W. Soltau Fenwick publish, in the *British Medical Journal* for August 19th, a paper detailing their research on the pathological effects of certain substances derived from the spleen in cases of scarlatina. Their experiments were undertaken to find, if possible, some definite chemical poison in the organs of patients dying of scarlatina, which would give additional evidence as to the bacterial origin of the disease.

The spleens of fifteen patients were subjected to examination, with results of quite uniform character. From all cases there was obtained a proteid matter which may be classed among the proteoses, and is quite indistinguishable chemically from the proteoses formed during the process of digestion.

The injection experiments were upon rats, guinea-pigs, mice and rabbits. The actual injection seldom caused any local disturbance. The constitutional effects varied according to the nature of the case from which the material was derived, but each preparation exhibited a uniform action in the various animals used. The proteid was highly poisonous when extracted from an acute case which had proved fatal during the first few days with symptoms of toxæmia. If taken from the ordinary septic cases of a fortnight's duration, associated with throat suppuration, the proteid was less poisonous and uncertain in its action. When the solution of the albuminous extract from a case of scarlatina fatal in one to five days was introduced under the skin of a rat in the proportion of 0.1 gramme per kilo. of its body weight, no abnormal symptoms manifested themselves for a period of twenty-five to thirty minutes.

At the end of that time, the respirations became increased in frequency, and the animal's gait became tottering and extremely unsteady. Within a short time paresis of the hind limbs set in, the body being dragged along in an irregular and zigzag fashion by the sole action of the forelegs. With the development of this paresis the respiration became markedly slow and labored in character, the accessory muscles of the nose and mouth being called into requisition. Within half an hour from the onset of the symptoms the animal passed into a state of profound collapse. The heart's impulse was weak and its action quick, and the surface of the body was cold to the touch. After a varying period of time, gradual recovery took place.

The immediate temperature reaction varied, rats and guinea-pigs showing a brief period of subnormal temperature, rabbits a corresponding short pyrexia, with a return to normal in each case within eight or ten hours. During the few days immediately following the animals appeared to suffer no particular inconvenience, and the temperature remained at its normal level. About the seventh or eighth day, however, the appetite began to fail, the temperature rose slightly, and the body lost in weight. With only one exception (rabbit) death ensued within the fortnight, the rats exhibiting a uniform tendency to succumb about the tenth or eleventh day. The earliest period at which death occurred was the fifth day. When two injections were given on consecutive days the animal died on the fifth or sixth, and after three doses on the third or fourth. In every case where it was possible to obtain a specimen of urine the presence of albumen was easily demonstrated, and in some instances epithelial and granular casts were also found.

Post-mortem examination of the kidneys showed acute parenchymatous nephritis, with very slight interstitial changes.

The proteid obtained from the second class of cases caused much less disturbance and in no case death. In a majority of cases the kidneys showed some congestion and a granular condition of the cortex.

In order to control to some extent the foregoing experiments, two spleens derived from cases which had died from an accident were subjected to the same process, and the albuminous extract administered to animals. The material in question gave rise to no pathological effects. In like manner peptic albumoses, when injected into the circulation, never produced an inflammation of the kidney similar to that previously described.

They conclude, therefore, that in cases of rapidly fatal scarlatina a morbid product of a proteid nature is formed that can be extracted from the spleen in small quantities. This substance, when introduced into the circulation of an animal, is rapidly excreted by the kidneys, and acting as an irritant to the secreting structure, tends to produce a condition of acute parenchymatous inflammation.

THOMAS HEAZLE PARKE.

THE sudden death of Surgeon-Major Parke, which occurred September 10th, has closed the career of a man of unusual strength and gentleness of character. Few men have accomplished such arduous and varied service or acquired at so early an age such world-wide and deserved reputation.

He entered the Army Medical Department in 1880 after becoming a Licentiate of the Royal Colleges of Physicians and of Surgeons in Ireland. His first active service in the Egyptian War of 1882 gained him a medal and the Khedive's star. He served on the Nile Expedition in 1884–5, and won two distinctions for the gallantry of his work.

In 1887 he was selected by Mr. H. M. Stanley to accompany him in his expedition for the relief of Emin Pasha. The splendid character of his services during this expedition was fully recognized by Mr. Stanley, who often refers to Parke's services, and describes him as patient, cheerful and

gentle. In speaking of the events at Kavalli in March, 1889, he wrote: "This expedition possesses the rarest doctor in the world. No country in Europe can produce his equal, in my opinion. There may be many more learned, perhaps more skilful, older or younger as the case may be, but the best of them have something to learn from our doctor. He is such a combination of sweetness and simplicity. So unostentatious, so genuinely unobtrusive. We are all bound to him with cords of love. We have seen him do so much out of pure love for his 'cases' that human nature becomes ennobled by this gem. He is tenderness itself. He has saved many lives by his devoted nursing on the green sward of Kavalli, daily administering to these suffering blacks, unknowing and unheeding whether any regarded him." The unanimous testimony of every one connected with the expedition was that the great untiring cheerfulness of Surgeon Parke went far to relieve the dreary discouragements of the search for Emin. His very presence, quiet and unostentatious as it was, gave strength to the expedition.

On his return he received the full honor due him at the hands of the general public and his friends. He was given the medals of the British Medical Association, the Royal Geographical Societies of London and of Antwerp, and was made a Fellow of the Royal Geographical Society, a Fellow of the Royal College of Surgeons in Ireland, and an Honorary Member of the Geographical Societies of Belgium and Antwerp, and of the Order of St. John of Jerusalem. The British Government alone maintained a brutal inattention to his services. His work, to be sure, was not done at the bidding of the State or for the direct gain and interest of the Government; but other officers received special honors and promotions, while Parke received no thanks, no honors, no promotion from the Government, but remained a surgeon-captain until the termination of twelve years' full pay service; the only consideration shown him being that he was allowed to count his time in Africa with Stanley as full pay service. Although this was on a par with the usual contempt shown the medical profession in English military and army management, the slight was so studied and marked that Parke felt it most keenly. Too modest to desire honors for their own sake, the absence of any recognition or acknowledgment at such a time weighed upon his spirits, till he felt it almost as a degradation.

A more lasting tribute than any army honor could have been will remain for Parke, in the words of Stanley, written during the expedition, "His devotion was as perfect as human nature is capable of rendering."

Correspondence.

THE USE OF SALINES IN APPENDICITIS.

BOSTON, September 23, 1893.

MR. EDITOR: — I wish to say a word against the use of saline or other cathartics in the early stages of appendicitis, because you have recently published articles on appendicitis in which the use of cathartics, especially salines, has been advocated.

The theoretical action of cathartics in peritonitis, as given by various men, consists in an absorption and removal by intestinal drainage of the toxic products of certain micro-organisms which, multiplying in or near the peritoneal cavity, endanger life. I do not object to carrying out this theory after the appendix has been securely tied, or after it is clear that there is no danger of rapid extravasation; but in the first forty-eight hours of appendicitis I look upon the administration of salines as extremely dangerous, and as a not infrequent cause of general peritonitis and death. The reasons for this lie in the pathological conditions that exist in a very considerable percentage of cases. If in a given case there is a perforation in an appendix of large lumen, salines, by liquefying the fæces and increasing peristalsis *will cause an immediate and almost invariably fatal extravasation.* In such a pathological condition, which is not infrequent, the use of cathartics before removal and ligation of the appendix must be and is attended by most fatal consequences.

There is the same objection to the use of salines in gunshot wounds of the intestines, in perforations of typhoid fever, or in perforating ulcers of the intestinal tract generally.

In catarrhal appendicitis, without perforation — the mildest of diseases — there is no hurry to produce catharsis; should the perforation suddenly occur, by keeping the bowels quiet you avoid the danger of rapid extravasations, and give the surgeon a chance to remove the appendix before a general peritonitis makes the outlook hopeless. In a localized peritonitis, if no surgical interference has been made, the recent adhesions may be ruptured by fresh extravasations forced along by a stimulated peristaltic *vis-a-tergo*, and a general peritonitis quickly develop.

These objections to the administration of salines are based upon a very considerable experience. I may say that a majority of the fatal cases of appendicitis have been attended by extensive fæcal extravasations. I do not mean to assert that these extravasations have been caused in every instance by the administration of saline cathartics; but I do mean to state most unequivocally that they have been so caused in many cases, and that, furthermore, the existing conditions of general spreading peritonitis, far from being curable by salines, are, in my opinion and experience, beyond relief even by the most radical surgical measures, except in very rare instances. Moreover, in these extraordinary cases where, in a fully established peritonitis, recovery, with or without operation, takes place, I believe we shall find that only comparatively innocuous micro-organisms are present; on the other hand, the explanation of certain fulminating cases, even if apparently trivial at the outset, lies in the presence and rapid reproduction of germ colonies of great vitality and virulence. In either case, I am convinced, the action of saline cathartics has very little to do with the result; except in certain instances, for the reasons above given, to hasten the fatal end.

If the appendix has been tied off, or if the peritoneal cavity has been walled off with gauze, or if there is a firmly localized peritonitis, I do not object to cathartics, and I use the salines freely. I must say, however, that in a completely established general peritonitis, from whatever cause, with distention, vomiting and obstipation, in my experience, salines accomplish absolutely nothing.

To produce "intestinal drainage" after abdominal operations I think salines most excellent; and they have their use in the very beginning of a peritonitis in which there is no question of extravasation. I believe the future use of salines will be confined to these conditions.

Yours very truly, M. H. RICHARDSON.

METEOROLOGICAL RECORD,

For the week ending September 16, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,153: under five years of age 1,435; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 782, diarrhœal diseases 453, consumption 309, acute lung diseases 216, diphtheria and croup 107, typhoid fever 88, whooping-cough 32, cerebro-spinal meningitis 23, malarial fever 11, measles 8, small-pox 3.

From whooping-cough New York 6, Chicago, Philadelphia and Brooklyn 5 each, Pittsburg 4, Boston 2, Washington, Cleveland, Fall River, Lynn and Waltham 1 each. From cerebro-spinal meningitis Chicago 9, Brooklyn 4, New York and Cleveland 3 each, Worcester 2, Washington, Milwaukee and Somerville 1 each. From malarial fever Brooklyn 7, Philadelphia 2, New York and Nashville 1 each. From measles New York 4, Chicago 3, Boston 1. From small-pox New York 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending September 9th, the death-rate was 20.1. Deaths reported 3,980; diarrhœa 564, whooping-cough 96, diphtheria 86, scarlet fever 65, fever 62, measles 93, small-pox (West Ham and Bradford 2 each) 4.

The death-rates ranged from 13.0 in Halifax to 30.2 in Hull; Birmingham 17.3, Bradford 23.3, Croydon 14.4, Leeds 22.8, Leicester 18.1, Liverpool 23.1, London 18.9, Manchester 23.5, Newcastle-on-Tyne 21.7, Nottingham 17.5, Portsmouth 15.6.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 16, 1893, TO SEPTEMBER 22, 1893.

CAPTAIN CURTIS E. PRICE, assistant surgeon, relieved from duty at Fort Wadsworth, New York, and ordered to report to the commanding officer, Fort Porter, New York, for temporary duty at that post.

CAPTAIN WM. C. SHANNON, assistant surgeon, is relieved from duty in the office of the Surgeon-general of the Army and as assistant to the attending surgeon in Washington, and will proceed to New York City and report in person to the commanding general, Department of the East, for duty as attending surgeon and examiner of recruits in that city, relieving CAPTAIN GUY F. EDIE, assistant surgeon.

CAPTAIN GUY F. EDIE, assistant surgeon, upon being relieved from duty in New York City, by CAPTAIN WILLIAM C. SHANNON, assistant surgeon, will proceed to Washington, D. C., and report in person to the attending surgeon for duty in his office.

CAPTAIN WM. G. SPENCER, assistant surgeon, is granted six months' extension to sick leave of absence granted in Special Orders, No. 108, A. G. O., May 13, 1893.

CAPTAIN H. S. T. HARRIS, assistant surgeon, U. S. A., is relieved from duty at Fort Keogh, Montana, and assigned to duty at Fort Preble, Maine.

CAPTAIN M. W. WOOD, assistant surgeon, U. S. A., is relieved from duty at Fort Preble, Maine, and assigned to duty in Boston, Mass, as attending surgeon and examiner of recruits.

CAPTAIN FRANCIS J. IVES, assistant surgeon, ordered to proceed from Fort Sheridan, Illinois, to Chicago, Ill., and report to CAPTAIN LOUIS A. LAGARDE, assistant surgeon, in charge of the Medical Section of the War Department exhibit, World's Columbian Exposition, for temporary duty.

CAPTAIN LOUIS BRECHEMIN, assistant surgeon, is granted twenty-three days' leave, to take effect about September 17, 1893.

MAJOR HENRY MCELDERRY, surgeon, U. S. A., is granted leave of absence for one month, to take effect about October 1, 1893.

SOCIETY NOTICES.

NEW YORK STATE MEDICAL ASSOCIATION.—The tenth annual meeting will be held Monday, Tuesday, Wednesday and Thursday, October 9, 10, 11 and 12, 1893, at the Mott Memorial Hall, 64 Madison Avenue near 27th Street, New York City.

CHARLES E. DENNISON, *Secretary.*

THE AMERICAN PUBLIC HEALTH ASSOCIATION. — The next meeting will be in connection with the International Congress of Public Health, at the Art Institute Building, Chicago, Ill., October 9–14, 1893. First meeting of the Congress, October 9th, at 8 o'clock, P. M.

President of the Congress, Dr. Samuel H. Durgin, President of the American Public Health Association. Sir George Buchanan has promised to accept the position of Honorary President for Great Britain, and Sir Charles Cameron has accepted the Presidency of the Section on Municipal Health Service.

IRVING A. WATSON, *Secretary, American Pub. Health Ass'n.*

VERMONT STATE MEDICAL SOCIETY.— The eightieth annual meeting will be held in Rutland, October 12 and 13, 1893.

C. S. CAVERLY, M.D., }
G. H. FOX, M.D., } *Committee of*
E. M. POND, M.D., } *Arrangements.*

RECENT DEATHS.

WALTER VOUGHT, M.D., died in New York, September 25th, aged thirty-one years. He was in charge of the Fire Island Quarantine Station during the cholera quarantine last year.

HORATIO NELSON PAGE, M.D., M.M.S.S., died in Milwaukee, Wis., September 16th, aged eighty-seven years. He graduated from the Dartmouth Medical School in 1831.

WILLIAM B. TOWLES, M.D., died in Charlotte, Va., September 18th, aged fifty-three years. He was professor of anatomy in the University of Virginia.

SURGEON-MAJOR THOMAS HEAZLE PARKE, who was chief medical officer under Stanley in the search for Emin Pasha, died at Alt-na-Craig, Scotland, September 10th, aged thirty-six years.

SEVERIN WIELOBYCKI, M.D., died in St. John's Wood, London, September 7th, aged one hundred years and eight months. He was born in Poland and served as a cavalry officer in the long struggle for national freedom. He was offered an escape to Great Britain and went to Edinburgh, where, after great privation, he succeeded in obtaining his medical degree. Probably the only occasion when a University has officially congratulated a graduate on finishing a century of life was that of Wielobycki's birthday last January.

BOOKS AND PAMPHLETS RECEIVED.

Address before the Harvard Medical Alumni Association, June 27, 1893. By J. M. DaCosta, M.D., LL.D. Boston: Geo. H. Ellis. 1893.

A Lecture by Victoria Claflin Woodhull (Mrs. John Biddulph Martin), in the Boston Theatre, Boston, U. S. A., October 22, 1876, before 3,000 people, The Review of a Century; or, the Fruit of Five Thousand Years. Reprint. 1893.

Address.

PULMONARY TUBERCULOSIS WITH ESPECIAL REFERENCE TO ITS PROPHYLAXIS, HYGIENIC AND CLIMATIC TREATMENT.[1]

BY EDWARD O. OTIS, M.D., BOSTON.

"A sick man helped by thee, shall make thee strong." —*Browning.*

Fellows of the New Hampshire Medical Society: Do not think that I hold in light esteem the honor you have done me in inviting me to speak to you to-day, because I have chosen the old, and perhaps to many of you, uninteresting subject of Pulmonary Tuberculosis. I have chosen it with deliberation and for several reasons. As you are only too well aware, it is one of the most frequent diseases you have to contend with in this climate. Refer to the report of the State Board of Health for 1891, and you will find that of all the deaths occurring in this State from 1884 to 1890, pulmonary tuberculosis constituted 11.99 per cent of them, or 787 each year. If we take the minimum estimate put upon the economic value of a human life, we shall find that $3,935,000 are annually lost to this State by the ravages of this terrible disease. Of the loss in intellectual and moral influence, not only to this State but the whole country, who can estimate that, or measure the heart-breakings of the sorrowing friends who remain. None of us have forgotten the alarm and almost panic that ensued last summer when it was telegraphed abroad that cholera had arrived in New York; and yet, as the author of the "Causes of Death" in the report of the State Board of Health to which I have referred you, says, "Even the terrible epidemics of cholera and yellow fever that rage in some parts of the world are not so destructive to human life as consumption is in the aggregate." This fact, alone, is a sufficient reason why, not only at this meeting, but at every meeting, a portion of your time and your serious attention should be given to the consideration of this disease. Again, the attitude of physicians is slowly changing regarding the prognosis in this disease, and from a state of extreme pessimism, they have entered upon one of more hope. That phthisis can be and is cured, should ever be in the mind of the physician as he treats his cases of this disease. Further, the advances in successful treatment which have been made are rather, in my opinion, hygienic and climatic than medicinal; and to-day there is no drug or combination of drugs or any substance, animal, vegetable or mineral, which has been proved to exercise a curative influence upon the disease. Having devoted considerable time, and travelled somewhat extensively in the study of climate as applied to this disease, I may be in a position to say something of value to you upon this subject, or at least, I can give you my conclusions. Moreover, I have something to say to you regarding the matter of proper respiration, upon which I have been making some investigations the last winter; and I hope to make you share my conviction that the average civilized man does not know how to breathe properly, and that proper breathing is like proper eating, an acquired art. I am desirous, also, of impressing upon you, if I am able, the duty and responsibility of the practitioner in averting this disease by proper prophylactic measures. For these various reasons, then, I have chosen this subject, which for many years has been one of profound interest to me. And you, also, to whom I speak, have all, alas! had large experience in dealing with this dire disease. What New England physician has not?

There are certain general facts which I hold as true, regarding pulmonary tuberculosis; and it may be as well for me to present them axiomatically at the outset:

(1) Pulmonary tuberculosis is, in the greater number if not all cases, a disease of in-door life and impure air.

(2) The first downward step towards pulmonary tuberculosis is impaired general nutrition.

(3) Improper breathing and insufficient lung ventilation may finally result in pulmonary tuberculosis.

(4) Pulmonary tuberculosis is inheritable in the common acceptation of the term.

(5) Pulmonary tuberculosis can be cured or arrested in not an inconsiderable number of cases.

(6) There is no specific for the disease.

(7) The successful treatment is hygienic and climatic; and under hygienic I include lung gymnastics.

(8) Pulmonary tuberculosis is capable of being cured or arrested in any and all climates, but more readily and surely in some than in others.

As we proceed to discuss our subject, let us bear the above axioms in mind. Preventive medicine in the future must and will become a far greater part of our art than it is at present, until we finally arrive at the wisdom of the Chinese, and receive our meagre honorarium for keeping our patients well instead of fighting a too often losing battle with outraged nature. Now and here, however, I believe we can and ought to do far more than we are doing to prevent pulmonary tuberculosis. "Let us set an example," says Dr. von Ruck,[2] "for integrity of purpose to allow no opportunity to escape, which may aid in restricting and preventing the ravages of a disease which is, of all diseases, the most prolific cause of death, and claims its victims by the hundreds of thousands every year, respecting no one, not even our own persons or families."

Every general practitioner, particularly in the country, has his families, of which, as years go by, he grows to have a pretty thorough knowledge. He learns their inherited tendencies, and becomes familiar with their habits of life and environment. It is this kind of knowledge, in fact, which renders the family physician so much more valuable to his patients than the most skilled practitioner without it. To know the family, their power of resistance to perturbing causes, what they eat, how they breathe, sleep and work, what they wear, and the kind of air they feed their lungs upon, makes a sum total of knowledge which enables the physician to warn and advise with wisdom and effect. Moreover, it places a certain responsibility upon him to use this knowledge when he sees the laws of health disregarded through ignorance or wilfully. As he goes his rounds he will not infrequently see, in the families of his clients, those who, though they may not be conscious of any especial or great falling off in health, yet are perilously near the danger-line of pulmonary tuberculosis. In one, for example, he will observe that the nutrition is defective from insufficient or improperly prepared food. In another that lung ventilation and aeration is inadequately performed, and

[1] An Oration delivered before the New Hampshire Medical Society, June 20, 1893.

[2] The Prophylaxis of Tuberculosis. Reprint from the Therapeutic Gazette, April 15, 1890.

air deficient in pure oxygen is being breathed. In a third he will see that assimilation is imperfect and the circulation poor from a lack of physical exercise. These conditions will generally suggest the advice to be given, and it seems to me that the faithful physician should ever be on the alert to detect these deflections from the normal standard of health, and by timely advice and insistence upon change in habits or environments avert the impending danger. An open fireplace in the winter sitting-room; sufficient sunshine in both sitting-room and bedroom; better and more nutritious food; deep breathing and practice in chest expansion; physical exercise of various kinds, bicycling, swimming — a most excellent exercise for lung expansion—tennis, rowing, mountain climbing; change from a damp dwelling to one high and dry, may be the prophylactic remedies to be advised for one or the other condition. Perhaps I can as well emphasize here the great utility, in my opinion, of free-hand physical exercise. No apparatus is required; but a few minutes may be devoted to it daily, and yet the results are both substantial and striking.

Again the physician finds his opportunity for his prophylactic advice when the individual presents himself as a patient, complaining of a group of symptoms which go to make up that condition which has been aptly termed the pre-tubercular. He complains of general malaise, want of vigor, loss of appetite, digestive disturbances, irregular sleep; and the physician will note loss of weight, superficial breathing and a rapid heart — symptoms with which you are all familiar, and which are so often the vedettes of approaching tubercular trouble. If you examine the chest, the result will generally be negative, or at most only a little roughening of the respiration. If you watch the respiration, or better, measure the lung capacity by the spirometer — which I wish might be done in every examination of the lungs — you will find it below the average, and the respiratory muscles poorly doing their duty. The chest expansion will also be defective. This is, perhaps, a typical case of a large group with which you are all familiar in your daily experience. It is a pre-tubercular state; and, unless so recognized and proper prophylactic measures taken, will inevitably enter the active tubercular condition. It is, moreover, often readily respondent to proper management.

Let me now enumerate a set of interrogatories for the physician to put to himself in his prophylactic endeavors to avert this disease:

(1) Nutrition: Is proper food and of sufficient quantity taken? and is digestion and assimilation good?

(2) Respiration: Is the breathing full and free? and is there good action of the respiratory muscles?

(3) Air: Is pure air and of sufficient quantity supplied? This is of especial importance in sedentary indoor occupations.

(4) Physical exercise: Is sufficient and proper physical exercise taken to ensure good respiration and circulation and proper elimination of waste products?

(5) Situation of dwelling: As to character of soil (damp or dry) and drainage.

(6) Light and sunshine — with especial reference to in-door life: Do working-room, sitting-room and bedroom have sufficient light and sunshine?

(7) Clothing and bathing: Is the clothing sufficient and of proper texture? and is bathing sufficiently frequent, not only for cleanliness, but to give tone and vigor to the peripheral blood-vessels?

(8) Mental condition: Do worry and a depressed mental state exist?

Other points will suggest themselves to you, I dare say; but the above seem to me the most important ones to be taken into consideration, bearing in mind that a disregard of any one or a combination of them opens a possible avenue for the entrance of the dreaded bacillus. It is not my purpose to exhaustively discuss each one of them, and, indeed, it is quite unnecessary before an audience of intelligent physicians; but I do desire to consider, somewhat in detail, the matter of proper respiration, a subject upon which I have been making some investigations for the last year or two.

Nature when left to herself is a very wise mother, and generally sees to it that what she creates properly performs its functions, be it a plant or man. But civilization — so-called — sometimes woefully interferes with her and thwarts her evident intentions. The savage, obeying nature, lives out of doors, bathed in sunshine and fresh air. He is physically active, which compels him to breathe deeply and fully. He runs, swims, climbs; all of which exercises are excellent for producing large lung capacity and ample chest expansion. Not so, however, is it with the civilized man: he leads, more or less, an in-door life where the air is often impure and insufficient. He takes too little or no physical exercise, so that he almost forgets that he has muscles which need to be used for their own integrity and that of the rest of the body; and proper respiration has come to be a forgotten natural art, and must be an acquired one, if he possesses it at all. The civilized man has forgotten how to breathe properly, and the civilized doctor seems to have forgotten to teach him.

Few of us, I believe, thoroughly ventilate and inflate our lungs; and I am of the conviction that this defect is an important and frequently overlooked factor in the causation of pulmonary tuberculosis.

Let me call your attention to some measurements of chest dimensions and lung capacity:

CHEST MEASUREMENTS.

Girth of Chest (muscular).	*Repose.*	*Inflated.*	*Difference.*
Men: Average of E. O. Otis. 1,000 measurements between 16 and 40 years of age	34.0 in.	36.1 in.	2.1 in.
Average of Dr. Hitchcock of Amherst College, 8,000 meas.	34.6	36.5	1.9
Average of E. Hitchcock, Jr., of Cornell College, 15,000 meas.	34.5	36.3	1.8
Women: Mt. Holyoke and Wellesley students. Measurements of Miss Wood and Dr. Mary Colton	29.5	31.5	2.0
Respiratory Chest.			
Men: Average of E. O. Otis. 1,000 measurements	31.1	33.1	2.0
Women: 50 per cent. of 1,500 Wellesley students. Miss Wood	24.6	27.2	2.6
Depth of Chest.	1,000 m.	112 m.	
Men: Average of E. O. Otis	7.3	8.2	0.9
Breadth of Chest.			
Men: Average of E. O. Otis. 150 measurements	9.6	10.8	1.2
Depth of Chest.			
Women: Fifty per cent. of 1,500 Wellesley students, Miss Wood	6.9	..	..

CAPACITY OF LUNGS.

Men.	*Cubic Inches.*
Average of E. O. Otis, 1,000 measurements	240.6
Hitchcock, Sr., 8,000 measurements	230.0
Hitchcock, Jr., 15,000 measurements	236.6
Women.	
Mt. Holyoke and Wellesley students, measurements of Miss Wood and Dr. Mary Colton	145.8
Fifty per cent. of 1,500 Wellesley students, Miss Wood	150.3

COMPARISON OF THE VITAL OR LUNG CAPACITY AND THE AMOUNT OF AIR EXHALED AFTER AN ORDINARY QUIET INSPIRATION. AVERAGE OF E. O. OTIS, 150 MEASUREMENTS.

	Cubic Inches.
Vital capacity or amount of air exhaled after a full inspiration	230.5
Amount of air exhaled after an ordinary quiet inspiration	129.3
Difference (complemental reserve air)	101.2
As given by Hermann	97.6

The tables just given are the results of my own investigations and of the comparison of them with those of several other investigators. Let us now consider their significance. These measurements independently taken by different examiners are so nearly alike, that we can assume, I think, that they are approximately correct. The average man, then, should increase the circumference of his muscular chest, by full inspiration, from 1.8 to 2.1 inches, and of his respiratory chest 2 inches; and the average woman 2 to 2.6 inches and 2 inches respectively. Moreover, the average vital or lung capacity may be regarded as between 230 and 240.6 cubic inches for men, and between 145 and 150.3 cubic inches for women. Further, the depth of an average man's chest may be taken as 7.3 inches in repose, and of a woman's 6.9 inches; and the breadth in men 9.6 inches in repose and 10.8 in full inflation. Consequently the antero-posterior and the transverse diameters of an average man's chest ought to increase about an inch in full inspiration. You will also observe that the so-called "complemental" and "reserve" air is about 100 cubic inches.

In making a physical examination of the chest, I believe we shall often gain valuable information, as to the manner respiration is being performed, by taking these different measurements and comparing them with the averages. Moreover, long before we obtain signs of disease by percussion and auscultation, an examination of this kind may, if the measurements are much below the average, arouse a suspicion of future trouble and suggest prophylactic measures in the way of deep breathing and exercises in lung expansion. Again, so long as the lungs fall short of full expansion in ordinary quiet breathing by about 100 cubic inches, once or twice, at least every day, full, deep inspirations should be taken so as to thoroughly ventilate the lungs; and this is especially needful for those who lead sedentary lives. The performance of this act is easy, and requires but a few moments each day; indeed, it is accomplished unconsciously by any active exercise, such as running, swimming, tennis playing, and the like. With those, however, who take little or no active exercise and follow sedentary occupations, it must be a matter of conscious exertion. With the hands upon the hips and the shoulders thrown back, standing either out of doors or in a well-ventilated room, one should slowly fill the lungs to their utmost capacity, and, after a moment at rest in this condition, slowly exhale. It is also of assistance to gradually raise the out-stretched arms over the head while one is inhaling, thus aiding the intercostal muscles, and so, more thoroughly opening out the chest. It is a significant fact that, after deep, full breathing and chest expansion has been practiced for some time, the "complemental" air is reduced, and the difference in the two diameters, in repose and full inspiration, is lessened; indicating that a habit of constant and permanent chest expansion has been established; which means, other things being equal, a valuable safeguard against pulmonary tuberculosis. In examining young men of average health, but of sedentary occupations, I have frequently detected the crepitant râle on deep inspiration at the lung apex, indicating not a diseased condition but simply the pulling apart of agglutinated lung cells, which in the insufficient lung expansion have fallen into disuse. May not this be one of the reasons why the apices of the lungs are so frequently affected?

The importance of this subject of proper lung aeration and chest expansion has been overlooked, it seems to me, both by the general practitioner and the specialist. May I have sufficiently excited your interest in it to cause you to bear it in mind when you are making a physical examination of the lungs, as well as when you cast a professional eye upon those who fall under your observation.

Let me next call your attention to some points in the hygienic and climatic treatment of pulmonary tuberculosis; but first, however, let me say a word as to the curability of this disease, or more accurately, its arrest. Do not be sceptical upon this point, but approach your patient with the hope born of conviction.

"Dr. Coats,"[3] says Fowler, "as the result of the careful scrutiny of post-mortem examinations, has come to the conclusion that about 23 per cent. of the persons who die of disease unconnected with tuberculosis have been, at a former period of life, affected with some form of internal tuberculosis."

Professor Brouardel[4] found evidence of cured tubercle in the apex of the lung in 60 per cent. of those over thirty years of age whom he examined after death from violence.

"In 200 autopsies in which this point was especially examined, Harris found 38.8 per cent. in which there were relics of former active tuberculosis."[5]

Of 1,000 cases in the practice of Dr. Williams,[6] 198 died; and of the 802 alive, 285 or 35.5 per cent. were classed as well; 293 or 36.6 per cent. as tolerably well; the well and tolerably well thus comprising 72 per cent. In a private letter received from Dr. O. Peters, of Davos, Switzerland, which is the famous high climate sanatarium for the treatment of this disease, he says that after eleven years of practice, his experience shows that a perfect cure is obtained in 20 to 25 per cent. of the cases and great improvement in 60 per cent.

The pathology of arrested phthisis is fascinating, but I have not time to consider it here. I will only say in brief that it occurs by the formation of a barrier of fibroid tissue. Let me, however, refer you to the record of 177 autopsies for other diseases in which evidence of arrested pulmonary tuberculosis was found in Dr. Fowler's[7] paper upon arrested phthisis.

Given then a case in which we find evidence of pulmonary tuberculosis, bacilli in the sputum, percussion and auscultatory signs, and all the other confirmatory symptoms, how shall we treat it? Let us suppose, moreover, that it is an incipient or not far advanced case in which treatment is of most avail. Let me repeat what I said in the beginning, that there is no drug or medicinal remedy which, in my opinion, exercises more than a very secondary influence upon this disease, neither creosote nor tuberculin nor the hosts of

other remedies or combinations of remedies seem to me to have stood the test of extended experience in producing definite favorable results. Our treatment, then, must be hygienic and climatic; let us become thoroughly convinced of this.

Food, exercise, fresh air, sunlight, rest and peace of mind must be our reliance in successfully battling with this disease as indeed with so many others. "As I watch the better medical practice," says Dr. Mitchell,[8] "I see a tendency to rely less upon mere drugs and more and more sharply to question their value — you will be struck, as I have been, when you come to read the books of the great masters, dead or living, with the great stress laid upon habits of living, what shall be eaten, diets, exercise, clothing, hours of work and rest." Climatic treatment, to which I shall call your attention directly, is a potent factor and of invaluable aid in consummating the cure or arrest, yet in any climate, by utilizing all its capabilities, there is much hope of success.

With regard to the diet, you cannot exercise too much care. Prepare a dietary yourself, and be sure that your patient eats regularly good, well-cooked, nourishing food. All sorts of special and exclusive diets have at one time or another been recommended, but I believe a plain mixed one to be the best. See to it that the material and cooking are good and not that usually found in the New England country household. Often the meals can be multiplied to advantage. In Dr. Turban's sanitarium in Davos, which I had the pleasure of visiting, the patient obtained five meals a day, as follows: First, coffee, tea, chocolate or cocoa with bread, butter and honey. Next a lunch of bread, butter and milk. Third, dinner consisting of five or six courses. Later, afternoon coffee with bread, and finally an evening meal of three courses. Milk was also furnished whenever desired.

Of primary and vital importance is out-of-door life. "I am well satisfied," says Dr. Austin Flint, "that here is the foundation for the successful management of pulmonary tuberculosis." "Out-of-doors," "out-of-doors," "out-of-doors" should ever be the watchword of the tuberculous individual. He should establish a habit of out-door living, and whatever may be the climate and weather, he should go out every day. "Neither the cough, the fever, the night-sweats, nor the hæmoptysis contraindicates this rule," says Osler.[9] Says Lindsay:[10] "There is now a vast mass of evidence which conclusively proves that consumption is comparatively rare among those who follow an out-door life under normal and healthy conditions; that it is comparatively common among those who live habitually in-doors; that it attains its maximum incidence among those whose occupation involves prolonged confinement in a vitiated atmosphere." This statement he verifies with figures and statistics.

It is hardly necessary for me to give you illustrations of the happy effect of out-door life upon this disease; you all, no doubt, can recall many examples in your own experience; I will, however, call your attention — for you may not have seen it — to the charming account, narrated by the late Dr. Henry I. Bowditch, of the chaise ride of his father through New England for the cure of his tubercular trouble.[11] "The first day," he says, "after a drive of twenty-five miles he was so much exhausted and spat blood to such an extent, that the landlord of the hotel at which they put up, advised his friends to take him back home to die." He pluckily continued, however, and when he finally reached home after a journey of seven hundred and forty-eight miles, he was in much better health than when starting; and by means of walks of a mile and a half to two miles taken three times a day during thirty years of his life, all pulmonary troubles disappeared. One illustration coming under my own observation: a sea-captain, below middle life, apparently well and strong, gives up his profession and out-door life and enters upon business connected with a railroad in a large city. He attains a high position and accumulates wealth, but dies of phthisis at about middle life. His son, also in his father's business, dies of the same disease at an early age. Here we have a change from an out-door life in the pure sea air to in-door life in the vitiated city air — and the result, pulmonary tuberculosis.

Of course, some climates are much better adapted for out-of-door life than others; but here in our own severe and changeable climate, the chances of recovery or arrest of the disease are infinitely better, in my opinion, by the out-of-door treatment than by an in-door life with the dangers of impure and often overheated air. "I fully believe," says Dr. Bowditch, "that many patients now die from want of this open air treatment." "For years," he says, "I have directed every phthisical patient to walk daily from three to six miles; never to stay all day at home unless a violent storm be raging. When they are in doubt about going out, owing to bad weather, I direct them to solve the doubt not by staying in the house, but by going out." If the patient is too weak to walk, let him be well protected and placed out of doors whenever there is sunshine and the wind is from a dry quarter, whether it be summer or winter; and keep him out for hours at a time. Let him sleep and eat there. I well remember the row of couches with their little tables beside them, which I saw at Davos at the sanitarium I have before mentioned. If we are unable to send our phthisical patients to a more favorable climate, let us utilize to the utmost the weather we have at home, and harden them to endure its frequent and great variations. Out-of-door life in this climate has cured phthisis; let us not forget this. I have often thought that if the same insistence to an out-door life should be practised at home that prevails in the various health-resorts, we should obtain far better results than at present. I wish, indeed, we all could visit some model sanitarium for the treatment of pulmonary tuberculosis, such as the one of Dr. C. von Ruck's at Asheville, or Dr. Trudeau's in the Adirondacks, and then come home and apply the same painstaking care and methods in the treatment of our own phthisical patients, not only as regards out-door life, but in all the detail of their management.

THE value of negative information was well stated by a famous French savant, of whom a lady asked an apparently simple question in science. He replied: "Madame, I do not know." "Well, what is the use of all your scientific education if you cannot tell that?" said she. "Madame, to be able to say I do not know."

INTUBATION OF THE LARYNX IN PRIVATE PRACTICE: RESULTS IN SEVENTY-EIGHT CASES.[1]

BY CHARLES M. WHITNEY, M.D.

During the seven years that intubation has been before the medical profession, evidence has been slowly accumulating as to its value in the treatment of membranous obstruction in the larynx. It was but natural that an operation of such apparent simplicity and freedom from danger should be received with enthusiasm as a substitute for the older and severer operation of tracheotomy.

The experience of many observers in different parts of the world has placed us in a position to-day to calmly judge of its merits as an operative procedure.

The frequency and fatality of laryngeal obstruction in children is so great that a clear understanding of the elements which guide us in a selection of one or the other operation is of the greatest consequence.

The majority of the reported cases of this operation have been performed in the large metropolitan hospitals, where the cases could be watched with the greatest care and where careful nursing was available. While this is of value it also follows that the children are usually taken to the hospital only after every method has been exhausted to expel the membrane and when suffocation is imminent.

The resulting weakened condition materially affects the outcome of either operation. Where one can watch the child from the onset of the symptoms, an earlier operation is possible, and the strength can be saved to fight the disease.

It is in this class of cases that I desire to present the result of five years' experience in the performance of laryngeal intubation.

Every practitioner of large experience has met with cases where a child suffering with membrane in the larynx, was growing steadily worse, and where the parents would not permit it to be removed to a hospital where an intelligent selection of one or the other method could be made, nor would they submit it to the cutting operation. In this class of cases, there was nothing for the physician to do but to watch the child slowly suffocate, until the originality and patient investigation of Dr. O'Dwyer placed at his disposal a method of relief.

It is here that intubation occupies a field peculiarly its own and no comparative statistical tables can show the number of lives which have been saved by it. My own experience has fully substantiated this statement.

Not the slightest objection has ever been made to the operation or to a re-intubation when the tube has been coughed out.

A case illustrating this fact came to my notice some three years ago through the kindness of Dr. Record, of Wollaston. A child of three years was attacked by diphtheria and rapidly developed symptoms of laryngeal obstruction. An operative relief was recommended and a surgeon was summoned to perform the operation. At the last moment the mother refused to permit the operation. As no tubes were available I was summoned to do an intubation. The operation was easily done and the child completely relieved. The relief continued for two days, when it perished from septic poisoning.

Intubation, then, has for its first advantage availability.

Any one who has watched a child with the disease in question, and has noted the labored breath, the restless tossing and gradual change in color, must agree that both exhaustion and carbonic-acid poisoning are very important elements in deciding the result of either operation.

In the beginning this change is so gradual that the parents are loth to believe that a little delay will not result in an amelioration of the symptoms, and thus postpone an operation which is so severe as tracheotomy. An operation so simple, so painless and bloodless as that under consideration is readily consented to and hours of suffering are saved the child and the strength is by just so much the greater.

This, then, is the second advantage of intubation that it can be done early. To safely perform a tracheotomy at the home of the patient, at least one trained assistant is needed and one man with steady nerves to manage the anæsthetic if one is used and to steady the head.

Intubation, on the other hand, can be performed by one moderately skilful with aid of two persons of ordinary intelligence, one to hold the child, the other to manage the gag. Several times I have inserted a tube with only the parents to help me, and in one instance the original operation was done on a child of thirteen months with the aid of two nervous women. In such a case the most ardent advocate of tracheotomy would find its performance rather difficult.

By these comparisons I do not desire to convey the impression that tracheotomy is always extremely difficult and intubation extremely easy for it is far from being true. Any one who has intubed a young child, gasping for breath, whose small pharyngeal space prevents or prolongs free manipulation and in whom the attempt to enter the larynx produces an alarming degree of cyanosis, will soon realize that any operation to relieve the condition cannot be simple and easy, but is fraught with the gravest anxiety and responsibility. For this reason no operation should be done without a careful consideration of all the elements in the case. Neither should be done as a routine procedure, but each performed in suitable cases. Certain other self-evident advantages belong to intubation: freedom from shock and hæmorrhage, absence of new infecting surfaces and resulting cicatrices, rapidity of performance, the opportunity of breathing air warmed by the natural passages.

My own experience in this operation comprises its performance in 78 cases, all in children under ten years of age. Divided according to age there were:

	Cases.	Recoveries.
Under 1 year	2	0
1 to 2 years	12	3
2 to 3 years	18	6
3 to 5 years	20	5
5 to 10 years	26	12

As regards sex, 48 were males, 30 females; of these, 26, or 33 per cent., recovered.

As these cases were nearly all seen in consultation with various physicians, they have presented a wide variation as to the time the operation was done. In some it was done early, in others very late, and taken altogether they represent a fair average of cases which

[1] Read before the Surgical Section of the Suffolk District Medical Society, April 5, 1893.

one meets both as regards severity and time of operative relief. Earlier operative relief would have saved even more lives.

These cases have been of the greatest interest on account of their occurrence in such varying surroundings. In some the most skilful nursing was available, in others only the simplest attentions were given. In all, the result was so relatively satisfactory that I desire to consider somewhat in detail the elements which have a great deal to do with the success of this operation.

The first important question which arises is, When has the proper moment arrived for operative interference in these cases? I am sure there can be no difference of opinion as to the advantage of early relief. When a child suffering with diphtheria develops a croupy cough with hoarse voice and harsh respiration, and when in spite of the usual treatment has obtained no relief, but is gradually growing worse, the intercostal, supra-sternal and supra-clavicular spaces are beginning to retract, then no advantage is to be gained by longer waiting.

This may take a longer or shorter time, but the persistent and increasing retraction is one of the most important symptoms, and longer waiting is at the cost of the child's strength. The steady progression of the disease with no intervals of relief, together with its gradual onset serve to distinguish it from catarrhal laryngitis, or spasmodic croup, especially in those cases where no exudation is present upon the fauces.

The instruments which are familiar to nearly every one to-day, consist of the introducer, the extractor and gag, varying sizes of tubes with their obturators.

It has been a matter of surprise and regret to me, as doubtless it has to many others, to find the instruments so carelessly made that they are often unsafe for both operator and patient. The original gag devised by Dr. O'Dwyer is difficult to manipulate, and has been replaced in most of the cases, sold now, by a straight one which works with a spring and ratchet. This, for example, is too light, the blades are made of soft iron, the spring and ratchet too weak, which allow the blades to be forced together, or to be snapped quickly when touched by the nervous hand of an untrained assistant. Twice, with the gag furnished in my first set, were the blades forced together while in the mouths of three-year-old children. In these cases the ratchet held well enough but the soft iron of the blades permitted their closure from the strong pressure of the jaws. The danger of diphtheritic infection from a wound in the finger is too great to allow us to consider such a matter lightly. The shank in the introducer is not strong enough, and frequently a bend is produced which interferes with the sliding of the fork which pushes the tube from the obturator.

The thread which unites the obturator to the introducer wears away so rapidly that after a short time the tube turns half-way round when screwed on tightly. Experience at the City Hospital has shown that this part may even break — a very undesirable accident.

I have considered the tubes to be fairly well made, aside from occasional deviations from the correct shape, but a recent experience has taught me that they, too, have the same faults of careless and poor workmanship.

In one of my most recent cases, after removing a five-year-old tube from a dead child, a matter of no difficulty whatever, I was surprised to find an opening had been made in the posterior wall of the tube just below the collar, which was produced by the moderate pressure of the jaws of the extractor. What the effect of the accident would be in extracting from a living child is at once apparent. The walls of this tube were as thin as paper.

I have attempted to overcome some of the disadvantages of these instruments by certain slight modifications. The obdurator is so easily removed from the tube when the latter is held in position by the finger, after introduction, that I have omitted the apparatus for removing it and have had the shank made larger and stiffer, and the thread hardened to prevent wearing. As the sizes below two years will not admit a large thread I have two shanks which are easily interchanged. In the original introducer, the angle made by the shank and obturator is a trifle more obtuse than a right angle. As the larynx is directed slightly backward, with this instrument the handle must be elevated so that the tube will easily enter it.

I have made this angle a trifle more acute than a right angle so that the tube will be directed forward and more easily enter the larynx. The joint in the obturator should be carefully oiled to prevent rusting and a possible breakage when removing it from the tube when in the larynx. To perform this operation quickly and with as little shock as possible, certain precautions are of value. The child's arms should be placed by its sides and a blanket should be firmly wrapped about it leaving the neck as free as possible. In young children two safety pins will make this secure, but in older ones a bandage should be added. If this is not thoroughly done, the child will seize the thread and pull the tube out in the struggle immediately following the introduction. A firm, straight-back chair should be placed so that there is plenty of space about it. The person who is to hold the child should be seated squarely on this chair, and the child placed in his arms, and firmly held. The position which I have found most convenient and which gives the most working space in the pharynx is one midway between the upright and reclining, the head resting on the bend of the elbow of the person who holds the child. Displacement of the gag by the shoulders striking it, or the hand of the assistant, is thus avoided.

The gag is then inserted far back in the mouth, taking care to open it widely or it may slip out, The assistant then holds this, and also steadies the head if no other person is available to do this. The operator, standing opposite the child, passes the left index finger well back into the pharynx and on bringing it forward the epiglottis is quickly seized and retained.

The finger and metacarpal joint of the operator should be well covered with adhesive plaster to prevent injury in case the gag slips. The threaded tube is then introduced precisely on the median line, the handle being at first depressed and then quickly elevated so that upon entering the larynx the tube is directed slightly forward. If the case is an easy one the tube slips quickly into the larynx, and as it is nearly in position the finger is pressed firmly upon the collar of the tube and the obturator removed.

It frequently happens, however, that after the tube enters the larynx it meets with some obstruction, the child stops breathing, gives a gasp and the tube slips in easily. This is caused, I imagine, by the approximation of the vocal cords, which upon separation permit the entrance of the tube.

The presence of the tube in its proper position is determined by two facts: first, the peculiar dry cough, which if once heard is sufficient to make one fairly sure; and second, by the presence of a septum between the finger passed into the œsophagus and the tube in the larynx. If this is felt its position is assured. With finger resting on the collar of tube the thread, which should be waxed to prevent sticking together, can be quickly removed and the operation is completed.

The relief in most cases is immediate. The child, after coughing a short time, breathes quietly, the face loses its drawn and anxious look, and for the first time in many hours goes quietly to sleep. This quick transition from the sufferings of severe dyspnœa to peaceful slumber is one of the pleasantest features of this operation, and it is one not so constantly seen after tracheotomy in my experience. While this is by far the most common result after this operation, it must not be forgotten that frequently certain variations are found, and (rarely, fortunately,) other grave emergencies arise, which one should always be prepared to meet. Among the former we find introduction difficult from enlarged tonsils, from swollen epiglottis and ary-epiglottic folds, and from a larynx small and deeply placed. In all these the first attempt may fail, but it rarely fails to dislodge a considerable quantity of tenacious mucus, or even membrane, which clears the way for the second attempt.

Not more than eight to twelve seconds should be allowed for any one attempt and frequent short attempts are far less productive of shock than a single prolonged one which should never be made.

Among the latter, we have the one possible danger of this operation, one fortunately so rare that it does not deter us in the least from performing it. That is, the danger of the membrane blocking the end of the tube, either by being pushed down and folded up, or by its presence below the lower end of the tube. In these cases the operation gives no relief, and the child may stop breathing.

The tube should be instantly removed and the cough which follows the procedure may dislodge the membrane, and render a second attempt possible. When this does not occur an immediate tracheotomy is the only alternative and it must be done quickly.

The outcome of these cases is usually fatal. The more strictly the tube is kept in the median line the less liable is it to dislodge membrane from the sides of the larynx and carry it before it into the trachea. As the tube reaches to within a half-inch of the bifurcation, it is not often that membrane is present in large enough amount below this to cause trouble.

In contrast to the number of deaths which occur from shock and hæmorrhage during tracheotomy, intubation has nothing to fear from a comparison of possible accidents.

It not infrequently happens that during the coughing which follows its introduction the tube may be ejected. One size larger should be selected and will usually be retained. If the tube is coughed out later in the progress of the case the same rule should be observed.

There is usually in these cases an interval of relief, long enough for the operator to reach the patient, and after the first twenty-four hours it occasionally happens that its re-introduction is unnecessary. In general, I have found that the tubes were a little small, and that the relative size of the child was the best guide in the original selection of the proper size of tube.

The after-treatment of these cases requires patient and unremitting care. Children have been, and will be, lost from lack of attention to certain essential details. Where it is possible, the care that a trained nurse can give, will greatly aid in carrying out these details.

To my mind the most important weapons we have to fight this dread disease are: abundant stimulation and nourishment; the free use of steam, and mercurial medication locally and internally.

The child must not be wakened from its sleep, however long it may be, for any purpose whatever. After wakening, however, if it is given some thin liquid and be allowed to take it in the usual upright posture, a violent attack of coughing ensues from lack of complete closure of the epiglottis over the tube. It does not take many such attacks to discourage a child from taking anything.

If, on the other hand, a semi-solid, like ice-cream, thick cream or the like be given the coughing is much less, or none at all, and the child soon adapts itself to its new condition and will soon attain a certain facility of swallowing which will permit even liquids to be swallowed with comparative ease.

The most important advance in the treatment of these children was made when Dr. Casselberry, of Chicago, showed us that a child lying down so that the pharynx was lower than the larynx could swallow with the greatest ease. When this position can be maintained the battle, so far as nutrition is concerned, is half won. This position, in my experience, is very difficult to get children to submit to, but by patience and firmness considerable can be done in this direction. In young children a nursing bottle is a great help and in older ones a tube through which they can take liquids when lying down. As a rule, the younger the child the more difficult is the swallowing.

Among the articles of food from which a selection can be made the following are of the most value — cream, ice-cream, egg-nog, bread and milk, blanc-mange, rennet, oysters raw or stewed, bananas and cream, shaved-ice, eggs in various forms, milk, milk-punches, beef-meal, peptonoids solid and liquid, Valentine's extract, bovinine, custard, Charlotte Russe, corn-starch pudding, sherbet, Roman punch, jellies of various sorts, thick gruels.

Rectal feeding has proved very disappointing, the rectum soon becomes intolerant of even the blandest injections, and there is more or less exhaustion resulting from the necessary manipulation. Before we understood the proper method of feeding it often became necessary, now, it is seldom required. If one wishes to use this method, peptonized milk, with the addition of peptonoids liquid or powdered, gives the most satisfactory results. Half-hourly administration of nourishment during the day is advisable unless the coughing is extremely troublesome when hourly administration may be substituted.

In obstinate cases where other means have failed, resort may be had to feeding through a tube. The child is held in the arms, a gag inserted, and a soft catheter

passed into the œsophagus and the milk poured into the stomach. The procedure is easily accomplished after a little practice and any nurse can quickly learn to do it. About four ounces should be used each time, with some form of stimulant.

The free use of alcoholic stimulants in these cases serves to most effectually fight the septic poisoning of the disease. It seems impossible to over-stimulate these cases, enormous amounts are taken without flushing or other evidences of too great an amount ingested. For a child of three years, from a half to a tablespoonful of whiskey or brandy can be safely given hourly to be increased or diminished as the case demands. By combining it with milk it is more easily taken and is less liable to cause coughing. When a child objects strongly to these two, champagne may be substituted.

In order to loosen the tenacious secretions steam is one of our most valuable agents. I have given up entirely the various steam atomizers, they are always untrustworthy, a cool vapor is produced and they are not available in all cases. I have found the most practical method was to utilize the ordinary tea-kettle which is always at hand. To the nose of this a rubber tube is attached and conducted to the bedside of the patient. The objection which I found to this was that so large a calibre of tube was required that much of the steam was lost by condensation. To obviate this I have availed myself of a device of steam fitters, which is shown in the diagram, called a "reducing coupling." By means of this a large tube may be used on one side and a small one on the other. They can be ordered from any plumber, by simply designating three-fourths inch and one-eighth inch nipples and a three-fourths-inch reducing coupling. The cost is slight, about thirty cents and the convenience great. If a large volume of steam is to be used, the child's bed or crib should be enclosed in a sheet-tent and the steam introduced beneath it.

Nipple (¾ in.). Reducing Coupling. Nipple (⅛ in.). Gas Tip.

Among the various medicinal agents which have been used to prevent the formation and extension of membrane in the larynx, mercury occupies the first place. Children suffering from diphtheria exhibit a remarkable tolerance to this drug. Doses which would salivate an adult are taken with perfect immunity by them. To accomplish anything, large doses must be used. In a child of three years it is well to begin with one-sixtieth of a grain of corrosive sublimate every hour, in Fairchild's essence of pepsin; and this should be increased to one-thirtieth of a grain every hour, if exudation on the pharynx is increasing, or if extension below the tube is taking place. I have occasionally, in severe cases, given one-sixteenth of a grain every hour, and no toxic symptoms were produced. In one case, which was treated under conditions particularly favorable for careful observation, being the child of a physician, during the eight days of the laryngeal invasion six grains of corrosive sublimate were taken in hourly doses of one-sixteenth of a grain. Absolutely no discomfort was noticed.

The symptoms of the toxic action are quickly detected by abdominal pain, nausea and vomiting, and by loose greenish stools. Even more remarkable is this tolerance as shown in the results of the method known as "calomel fumigation." A half-drachm of calomel is sublimed under a tent, and the child breathes this without injury, and with apparent benefit, while the nurses are usually mildly salivated by the slight amount of vapor which escapes from the tent. This method seems to promise good results in the treatment of this disease, but I have not as yet had a good opportunity to try it.

I have seen several cases of beginning laryngeal obstruction which have subsided without an operation where steam and mercury had been freely used, and in these cases the improvement seemed to be due to the mercury. In three cases, I have seen a fresh exudation form on the tonsils where it had disappeared after the use of this drug, and when from fear of poisoning its use had been discontinued. Upon again using it, the exudation promptly disappeared. If enough similar cases can be observed, it will materially aid us in deciding as to its value.

From my experience so far I should hesitate to treat diphtheritic croup without it. In addition to the drug internally, a spray of corrosive sublimate (1–2,000) is of service, used both in the nose and throat. I have given up the use of local applications if a child objects very strongly; for the exhaustion more than balances any benefit to be derived from their use.

Among other agents which are of service are digitalis, if there is defective action of heart or kidneys; also iron and peroxide of hydrogen in very septic cases, applied by spray or swab in the strength of one to four. The temperature of the room should be moderately elevated, 70° to 74°, and the air should be frequently changed to ensure plenty of fresh oxygen.

In favorable cases the child soon becomes reconciled to the presence of the tube, breathes quietly but rather more rapidly than normally, has now and then a severe paroxysm of coughing as it raises masses of tenacious mucous membrane through the tube, and often sits up in bed playing with its toys. More or less cough is constantly present, chiefly for the raising of the large quantities of secretion which come through the tube, but which being swallowed are not so easily noticed, and do not require the care that the secretion from a tracheotomy tube does. In fatal cases the child may gradually sink, the respiration becoming more frequent and the pulse weaker, and death may occur within the first ten hours. The shortest interval that I have observed has been eight hours. In many cases no unfavorable symptoms arise until the third day, when the temperature begins to rise, the respiration becomes rapid and somewhat labored, and the child dies from the resulting broncho-pneumonia in twenty-four to forty-eight hours. In the majority of fatal cases death occurs before the fourth day; and if they pass the third day without the development of these symptoms we can feel tolerably sure of a favorable outcome. The longest time that has elapsed in these cases which I have met with has been six days. If sudden occlusion of the tube occurs, a rare accident in the experience of those who have seen the largest number of these cases, the only resource is to use the method mentioned by Drs. Prescott and Goldthwaite, as used by a nurse at the City Hospital, which was to raise the child by its feet, when the tube may be moved enough to dislodge the obstructing membrane.

Dr. O'Dwyer suggests the value of firm pressure on the chest in cases of this kind, in the hope that the air thus compressed may force the tube out. It seems reasonable and deserves a trial.

The prognosis in these cases is a matter very difficult to estimate. Cases which look favorable will develop the most serious symptoms, and die; while those who have apparently no chance will pull through. In the cases which have come under my notice there were two well-marked classes:

The one, where there was or had been, little or no exudation upon the fauces, glandular enlargement or nasal discharge. This class of cases is often mistaken in the beginning for ordinary follicular tonsillitis, and I have in several cases noted the history of an attack of follicular tonsillitis perhaps a week before the onset of the laryngeal symptoms. Too great care cannot be taken in clearly establishing the diagnosis in such attacks; and in the present state of our knowledge I do not believe it can be done absolutely until a bacteriological examination has been made.

The other class has the ordinary symptoms of diphtheria; the fauces are more or less covered with membrane, the glands are enlarged, and more or less nasal discharge is present.

In fatal cases, the cause of death in the first class is from bronchial extension, and in the latter from septicæmia.

From the fourth to the sixth day the tube should be removed. It is often difficult to decide just when this should be done. In general the younger the child the longer the tube is required; and it is also true that the shorter time a tube is in the less the liability to to produce any ulceration from pressure, or to produce an irritation in the larynx which may be sufficient to require its insertion even in the absence of membrane. In cases where there is an exudate on the fauces, the disappearance of this is a valuable guide in deciding this point. If the temperature is normal or nearly so, the respiration easy and not increased in frequency, and if, in other words, the pathological process is at a standstill, the removal of the tube is advisable as soon as possible after the fourth day.

The operation of removal of the tube is far more difficult in my experience than its introduction. If any one doubts that it is difficult, let him attempt to localize the opening in a small tube, where the pharynx is small, and where every thing is covered with slippery mucus and feels alike, and after having done this successfully to attempt at the same time to hold the epiglottis out of the way while the point of the extractor is inserted into the tube. Far more practice is required and less is available (for removal from a dead child is quite another matter than from a living one), in the extraction of a tube than its introduction.

The instrument designed by Dr. O'Dwyer has the marked disadvantage that it does not hold the tube firmly enough, so that when partial removal is accomplished the tube slips off. Dr. Nichols of the City Hospital has skilfully worked out the mechanical problem, and has devised an extractor so excellent that any trouble in this direction will be avoided. Two points should be kept in mind in removing a tube: keeping the handle depressed as the tube is raised from the larynx, and also avoiding too great pressure downward in difficult cases. If there is much difficulty, it is safer to have an assistant place a thumb against the trachea where the lower end of the tube can often be easily felt, and by pressure upwards a greater firmness is given which renders a pushing into the trachea improbable.

If the tube is to be reinserted, the dyspnœa may at once recur, but in most cases not for four or five hours; after twelve hours they are usually safe. A most interesting exception to this was seen in a case which I saw with Dr. Francis Murphy, of Roxbury.

A child of eight and one-half years was intubed on November 27, 1890. The case progressed favorably, and the tube was removed on the sixth day. No recurrence took place until December 7th, when a second intubation was necessary. Removal was again accomplished on the fifth day, December 12th, and the case continued to perfect recovery. This is the only case of the kind I have ever seen, and the only one in which I have been obliged to reinsert a tube. After removal, the same treatment should be kept up for twelve hours. Children, from a stiffness of the epiglottis swallow little if any better for that length of time than when the tube is in position. Steam can usually be omitted on the second day, and the bichloride diminished rapidly till it is omitted on the fourth day.

From the foregoing considerations it will be seen that intubation is an operation especially adapted to private practice. It is always available, can be done early, is both painless and bloodless. In a majority of cases it relieves the dyspnœa perfectly and leaves no after-effects. It saves as many lives as tracheotomy, and many more where the latter could not be performed. On the other hand, it cannot be selected in all cases. It is not advisable where the tonsils are so large that they prevent the necessary manipulation, or where the fauces are full of putrid *débris* and the epiglottis immovable from the destructive action of the disease. Nor is it advisable in cases at a great distance on account of the possibility of the tube being coughed out and the dyspnœa recurring before the operator could reach the patient.

If one is called upon to operate upon his first case of croup, it would be wiser to select tracheotomy; but after a certain familiarity with the feel of the parts has been attained, which largely does away with the awkward and even brutal attempts seen in the beginner, I am sure that intubation would nearly always be selected. The operation is not and can never be an easy and simple one; extremely so at times, at others it is so difficult as to perplex the most skilful intubator. When its advantages have become thoroughly known, I am sure that many lives will be saved which now are lost, and that the profession will feel an increasing sense of gratitude to the skilful physician who devised it, Dr. Joseph O'Dwyer.

HORSE-HAIR IN MINOR SURGERY.[1]

BY C. O. THOMPSON, PH.G., M.D.

In calling attention to this subject it is not assumed that anything entirely new is to be presented, for horse-hair was probably used by surgeons in early times; but that its real usefulness is practically unknown to many is evident from the fact, that little has been written regarding its use, and it is found in the hands of very few at the present time.

The principal materials now in general use in suturing

[1] Read before the Surgical Section of the Suffolk District Medical Society, April 5, 1893.

ing wounds, are catgut, silk, and silver-wire. Catgut for stitching, has many disadvantages. When it is removed from the various liquids in which it is usually kept, it is harsh and kinky. When moistened with water or fluids from the tissues, it becomes slippery; and in either condition it is not easily handled, and is particularly difficult to tie. It is quite uncertain as to its retaining powers; and the fine gut cannot be used as it is too quickly absorbed. It is, therefore, often necessary to use a much larger needle than is desirable, as the eye of a smaller needle will not admit it, and its want of pliability causes it to form a shoulder at the eye, which is certainly objectionable.

Silk, although probably used more than any other material, is also open to several objections. It must be sterilized by immersion in antiseptic solution or moist heat; and when this is done it becomes swelled, so that it is difficult to get it through the eye of the needle. If threaded before it is sterilized, the needle will rust. When placed in the wound it imbibes the secretions of the tissues, and there forms a media for the invasion of bacteria, which have been proven to be present in the epidermis even after the most thorough disinfection. In this softened and soggy condition it becomes yielding and allows the opposed surfaces to move easily, which is unfavorable to union. If drawn sufficiently tight to hold the tissues in place, tension is apt to occur in the wound. Silver-wire, as a suture, offers fewer objections than any in common use, this being due largely to its non-absorbing property, but wire is not suited to all parts of the body. In its application to the lax and delicate integuments, it disposes the edges of the wound to twist and coil up far more readily than the wire itself. It is too stiff and unyielding, and therefore, its adjustment to these parts is difficult. After it has remained in the tissues for some time, it becomes so rigid that its removal is not only painful, but the parts are often torn, and the freshly united edges of the wound separated.

It was not until I had used horse-hair for three years, and had become thoroughly impressed with its practicability, that I had occasion to review the literature on the subject. The first mention of horse-hair found was in an article by Mr. T. Smith, of St. Bartholomew's Hospital, in the London *Lancet*, in 1862; in which he gives the results of a series of experiments with this material. In 1870, Dr. J. T. Darby published a monograph on "Hair as a Suture and Ligature"; a report of twenty cases was given in which hair was used in suturing with excellent results. In a paper entitled "Horse-hair Suture and Drainage," read before the New York Medical Society in 1884, Dr. Daniel Lewis relates his experience with horse-hair, and speaks highly of its utility.

Horse-hair is readily obtained by all surgeons, whether in city or country practice, and its preparation for use is perfectly simple.

The objection has been made that horse-hair, being cellular in structure, cannot be sterilized. This objection, however, is not well founded, as horse-hair is not materially injured by any of the methods used in the sterilization of dressings. Boiling in water is acceded to be one of the most practical methods; and according to the experiments of Drs. Stone, Dowd and others, all pyogenic bacteria are quickly destroyed, even the spores of these organisms cannot long resist this treatment. It is, therefore, an easy matter, should sutures not be at hand, for one to always readily prepare a practically sterilized suture, by removing a few hairs from the tail of a horse, placing them in boiling water for from three to five minutes, when they will be ready for use.

Although pus-producing micro-organisms are unquestionably destroyed by boiling, there are, however, certain forms of germ life whose spores are very resistant, as those of anthrax and tetanus; and as there is always a possibility of these being found in horse-hair, a series of experiments were performed with various disinfecting solutions. Dr. A. K. Stone kindly made the bacteriological tests for me. I will not here detail the various experiments; but it is enough to say that the simple immersion in ether, alcohol, solutions of carbolic acid and corrosive sublimate, for several hours, or days, and even repeated boiling in water was found not to render the hair *absolutely* sterile.

I have used the following method in preparing the hair for use: A bundle of carefully selected hair weighing from one to four drachms (the very fine and coarse hairs being discarded), is freed from dust as much as possible by shaking and combing. It is then washed in strong soap or soda solution, and when dry placed in a jar or bottle of the capacity of about one pint (a Mason fruit-jar answers the purpose admirably) which is then filled with benzine, the jar being agitated frequently. The treatment with benzine may be repeated several times; thus all fatty material is removed from the hair. It is next treated with a strong solution of bichloride of mercury, and finally immersed in bichloride of mercury solution, 1–1000. After this treatment the hair was found to be *absolutely* free from germ life.

If removed from the antiseptic solution it becomes stiff and wiry, and is not easily tied. It should, therefore, be kept in the solution until needed for use. A small bundle of hair can be folded and placed in antiseptic solution in a small vial, such as is carried in the ordinary medicine case, and is then ready for immediate use. Unlike catgut or silk, it does not swell when placed in aqueous solution, but, on the other hand, is rendered more suitable for use by its becoming more pliable, and its flexibility is retained so long as it is kept in a moist condition. It can be easily tied and holds a knot perfectly well. Its smoothness and uniformity of calibre, is such that it can be very easily passed through the eye of the needle, which is certainly a marked advantage over catgut or silk.

When a single hair only is required, a small needle or one with a small eye can be used. This is of decided advantage, notably in stitching about the eye and face, where one is particular not to leave stitch scars. How frequently we see in recently healed wounds, that have been closed with either catgut or silk sutures, stitch scars that are even more unsightly than the line of union itself. These scars after the use of the hair stitch, properly applied with a fine needle, are almost imperceptible. The sole disadvantage of horse-hair is its want of tensile strength, which makes it less useful than wire where several tissues are to be included and there is much tension in the wound; but by using two or more hairs together the strength is quite sufficient to readily overcome the tension of even large wounds. As a rule, a single hair is sufficient for closing a wound, unless it be large and much gaping is present.

The large, black tail-hairs are preferred for sutures, as they are more easily seen when you desire to

remove them, which is done by seizing the knot with forceps and snipping the hair to one side, when its smoothness and elasticity greatly facilitates its removal.

Horse-hair has all the advantage of the metallic suture, save that of strength, and is much more desirable to use where the tissues are lax and delicate, as of the eyelids, scrotum, penis and mucous membranes. It is equally unirritating, and so flexible as to readily accommodate itself to the folds of the integuments. Its pliability permits it to be easily passed through the tissues, and by its expansion it almost relieves itself from the tissues in which it is placed.

Its removal is accompanied with no pain or liability of injuring the parts. The hair suture produces so little irritation in the tissues that it can be allowed to remain for some time. I have removed these stitches that had been in the scalp from fifteen to eighteen days, and had apparently produced no disturbance. The fact of their being tolerated by the tissues for so long a period, makes it specially applicable to plastic surgery.

I have used this material for drainage, a small bundle being passed through the eye of a probe, and then the probe passed through the closed linear wound, drawing in the hair; or, if the wound be deep with narrow outlet, a bundle folded upon itself can be forced into the wound, and it certainly answers the purpose well. As the wound heals, the drainage can be gradually removed a few hairs at a time. It is not, of course, suited for draining large wounds.

My experience with horse-hair has been considerable, having employed it in the treatment of 296 incised and lacerated wounds during the past year. These have included nearly every part of the external body and its orifices, but principally of the face and scalp. The results in these cases have been so gratifying that I am convinced that the value of horse-hair renders it deserving of more general use.

I venture to call attention to the following cases:

Case I, January 11, 1892. Mr. C. D., age thirty-one years.

He came to office with incised wounds caused by broken glass. First wound on right eyelid three-fourths of an inch in length. Second, beginning at right eyebrow, extending upward and to the left, across the forehead, about two inches in length. Third, horizontally above left eye-brow, one inch long. The fourth, horizontally across the upper part of forehead, two inches long. First was closed with five single horse-hair sutures, second with eight, third with three, and fourth with seven, making in all twenty-three stitches in the face. Bichloride dressings were applied, the wounds healing promptly. In three days half of the sutures were removed, and the remainder on the fifth day.

Case II, October 2, 1892. Mr. C. L., age twenty-six years. Congenital phymosis; circumcision.

Elastic band placed about the penis. Forty minims of four-per-cent. solution of cocaine injected. About one inch of prepuce was removed, and frenum (which was short) was snipped. Elastic band removed. Small vessels seized and twisted. Fourteen interrupted sutures used to bring together edges of skin and mucous membrane. Dressed with sublimate gauze. Seven stitches removed on the sixth day and remainder on the eighth. Union by first intention. This is the tenth adult circumcision in which I have used horse-hair.

Case III, Mrs. C. R., age twenty-seven, primipara. Lacerated perineum.

Saw her on September 28, 1892. Had been in labor about six hours. Examination showed breech to be the presenting part. Labor was allowed to proceed without interference until breech was delivered. Patient was then anæsthetized, and feet and hands of child brought down. In haste to deliver the head I applied the forceps, and head was rapidly delivered. Child was resuscitated, and labor was concluded by expressing placenta. Upon examination, perineum was found to be lacerated for about three-fourths of its depth. This I determined to close immediately. Vagina was loosely packed with sublimate cotton, edges of laceration thoroughly cleansed, and wound closed with nine double horse-hair sutures. Packing was removed and no dressing was applied, and owing to circumstances and surroundings of patient, no special care was taken of wound. Patient made a good recovery. On the tenth day stitches were removed, the wound having closed by first intention.

The above is one of several perineal cases, in all of which I have closed laceration with horse-hair sutures with pleasing results.

Case IV, February 2, 1893. Mr. J. G., age twenty-seven years. Applied for treatment of swelling in left groin.

Examination and history lead to the diagnosis of syphilitic bubo. There were no signs of fluctuation. Solution of cocaine was injected, and an incision three inches long was made. Four large softened suppurating glands were removed, cavity curetted, and wound closed with five double horse-hair sutures, a drain being placed in lower end of incision. A large bichloride dressing was applied, and patient walked out of office. He returned again on the fourth day, and wound was again dressed. On the tenth day the stitches were removed, the wound having healed by primary union.

A SUMMARY OF THE ADVANTAGES OF HORSE-HAIR.

(1) Easily obtained and inexpensive.
(2) Soft, pliable, elastic and holds a knot well.
(3) Aseptic, non-absorbent and non-irritating.
(4) Can be used with a very small needle, and makes no shoulder at the eye.
(5) More easily removed than any other suture, without pain or injury to the tissues.
(6) Can be used for drainage.

Clinical Department.

SIMULTANEOUS FRACTURE (INTERARTICULAR) OF BOTH OLECRANON PROCESSES.[1]

BY E. S. BOLAND, M.D.

Finding only one similar case on record, and getting the consent of my patient to appear before us to-night, I have thought that there might be enough interest in it, to justify me in reporting this case.

August 16, 1891, Miss H. fell from the foot-board of an open horse-car, her dress drapery having caught on some projection of the seat or seat arm. She believes that she had both arms flexed in falling and struck both elbows on the pavement. The appearance of the elbows confirms this view. When she fell, she had but a single thickness of a summer garment on her arms.

[1] Read before the Surgical Section of the Suffolk District Medical Society, April 5, 1893.

When examined by me within twenty minutes of the accident, I found a simple transverse fracture of the right ulna in the depth of the sigmoid notch and a similar break on the left side with, in addition, a splitting of the detached olecranon at an angle to its long diameter. There was bruising and excoriation of the skin and soft parts over the back of both elbows, most marked on the left side; but although all three of the fractures extended into the joint, in neither case was the joint opened to the surface of the skin.

Realizing that there might be troublesome complications ahead, I asked Dr. M. F. Gavin to see the case with me. When he examined her the interarticular swelling was slight. He concurred in the diagnosis; and together we applied light, long wooden splints to the palmar side of both arms from the axilla to the ends of the fingers, disregarding the natural lack of parallelism between the arm and forearm and leaving a wide opening in the dressings over the elbows, to accommodate the now rapidly increasing size of the elbows from swelling of the soft parts and effusion into the joints. No attempt could be made to keep the distinctly separated fragments in contact at this time. Later, it was attempted on the right side; but the attempt was unfortunate, and, as I believe, responsible for the slower recovery of mobility in this joint than on the other side, where the conditions were much worse primarily on account of the comminuted fracture and greater injury to the soft parts. Indeed, so badly did the left joint look at this time that I feared its disorganization as the skin sloughed in places, rendering soothing applications necessary for several days.

Dr. M. F. Gavin kindly saw the case with me when the dressings were changed for the first time, and again to assure us both that the case was not so bad as it looked (which was certainly bad enough) with sloughing soft parts.

The patient was now, at the fourth day, getting very uncomfortable from the necessary confinement to bed on her back, as in no other way could the arms be supported; and she was as helpless as if she had no arms, not being able to turn or sit up.

Knowing that there would still be many days before flexing of the arms would be safe, I applied the principle of the Salter's cradle to her case. Erecting a light frame seven feet high, I slung two straight cradles by compensating cords and pulleys so as to admit lateral or front and back swing and adjustable to any elevation or angle. While sitting in a chair this could be used for some hours daily, with much relief from the irksomeness of the bed and dragging weight of the arms when motion was attempted.

As the swelling of the elbows went down, I began to fear anchylosis rather than non-union, to obviate which I began passive motion, stroking, kneading and, in short, general massage of the arms as early as the fourteenth day. At no time was pronation or supination seriously interfered with; but flexion of the right arm was most difficult and painful, although flexion of the left, from which at first there was most to fear, was less so.

About the twenty-fourth day the splints were removed except at night, and soon after entirely dispensed with, and special attention was given to daily massage. I am convinced that to this thorough daily massage, the patient owes the successful outcome of her case.

As soon as possible, gymnastic exercises were begun — at first only tossing a four-ounce bean-bag, then small dumb-bells, then light chest-weight exercises and finally Indian clubs, which she is now master of.

As mentioned above, the most seriously injured arm (the left) in which no coaptating measures were used, began to gain first, made more rapid progress, and its perfect use was regained long before the right, though Miss H had always been right-handed. I cannot explain this unless it was due to the attempt to coaptate the fragments of the right arm by pressure.

I was ready to report this case a year ago and show its results; but the Secretary of the Section had all dates filled for months ahead.

It is due to the patient to state that she has faithfully and intelligently persevered in every procedure attempted for her relief, in spite of the fact that an impending suit for damages put a premium on slow progress or permanent disability.

If you will examine the elbows, the lines of displacement can be distinctly felt, though less so now than formerly. The right hand covers the corresponding shoulder less perfectly than the left, but still as much so as in many who are uninjured. In sewing, when the weight of the arm comes on the shoulder, pain is still experienced. This is probably due to the severe jarring the shoulders received at the time of the accident, though no objective signs of injury could be found there at the time.

Miss H. will now swing the light Indian clubs, that you may see her perfect control of her arms. This exercise is one with which she was unfamiliar until after her accident.

AN ANOMALOUS EXTERNAL ILIAC ARTERY: AUTOPSY REPORT.[1]

BY PAUL THORNDIKE, M.D.,
Surgeon to Out-Patients, Carney Hospital, Boston.

A MAN, M., forty-eight years of age, entered the Carney Hospital on January 23, 1893, as a patient of Dr. W. N. Bullard, visiting physician to the hospital. The man was suffering from a chronic interstitial nephritis and died from this disease a few days later.

While examining the man, Dr. Bullard noticed a marked pulsation in each groin, and on palpating the areas, felt what he thought were large arteries pulsating directly under the skin and each apparently passing over Poupart's ligament and down into Scarpa's triangle. Two days later, January 25th, I saw the man with Dr. Bullard. As the patient lay on his back in bed, a pulsating area was to be seen in either groin. On palpating one of these pulsating areas there was no feeling of "thrill" or expansion, but the fingers felt what was evidently a large blood-vessel, which appeared close under the skin at a point about an inch above Poupart's ligament, passed over the ligament at a point midway between the anterior, superior spine of the ilium and the symphysis pubis, and then immediately became indistinguishable from the femoral artery, which could be felt pulsating in its normal position. The vessel felt like a somewhat atheromatous artery, and was about the size of a lead-pencil. On examining the other groin an exactly similar condition was found.

On the following day the man died; and I quote this extract from the autopsy report, furnished me by Dr. F. Coggeshall, pathologist to the hospital:

[1] Read before the Surgical Section of the Suffolk District Medical Society, April 5, 1893.

"The autopsy showed that the patient had suffered from chronic interstitial nephritis and arterio-sclerosis. At the end of the autopsy the following curious anomaly was observed: 'In both groins there could be felt passing over Poupart's ligament, and lying apparently just under the skin, a round, firm, somewhat movable, cord-like body about the size of the little finger. After removing the contents of the pelvic cavity, it was possible to trace distinctly the course of the abdominal blood-vessels, and it then became evident that what was felt under the skin was an unusually large external iliac artery which bent suddenly toward the surface when it had nearly reached Poupart's ligament and passed over it and just beneath the skin and superficial fascia. On continuing the abdominal incision into both thighs so as to lay open Scarpa's triangle, the whole course of the vessel was laid bare. It clearly passed over Poupart's ligament, rising abruptly from pelvic cavity and sinking again as abruptly to lie at the usual depth from the surface in Scarpa's triangle. The peculiarity was exactly the same in both thighs.'"

The vein accompanied the artery in both cases, while the nerves passed under Poupart's ligaments in their usual position. It was not possible at the autopsy to remove enough of a specimen to show all the relations of the artery and vein, so I am able to show you only the vessels themselves. The specimen includes about two inches of the right common iliac artery, the whole of the external iliac and the common femoral and about two inches each of the femoral and profunda femoris arteries.

In conclusion, I want to say that there can be no possible doubt of the anomalous course of these vessels, in spite of the well-known rarity of such anomalies. The dissection at the autopsy was most carefully and thoroughly made by Dr. Coggeshall, and was witnessed by Dr. Bullard and other members of the hospital staff. I have been unable to find a similar anomaly recorded in literature.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

C. L. SCUDDER, M.D., SECRETARY.

Regular Meeting, Wednesday, April 5, 1893, Dr. Abner Post in the chair.

Dr. E. S. Boland reported

TWO CASES OF SIMULTANEOUS FRACTURE OF BOTH ELBOWS.[1]

Dr. H. L. Smith showed two specimens, one a comminuted fracture of the olecranon taken from a man who had fallen from a height together with snow and ice, and had sustained internal injuries from which he died in a few days. Attention was called to the deep indentations upon the articular surface of the trochlea and the likelihood that adhesions might be formed at these points. The second was an elbow found in the dissecting-room, the history of which was not known. There was a Colles' fracture apparently impacted and firmly united. There was also fracture of the coronoid process, which was shown on section, and transverse fracture of the olecranon not united. It appeared that the accident must have occurred many months previous to death. The coronoid process was not at all displaced, the fact of there having been a fracture being shown only by a line running through the articular cartilage. On cross-section in a vertical plane, the fracture was seen to have included the bone. The olecranon process was fractured nearly transversely, about two centimetres from its extremity. There was absolutely no attempt at union of the broken surfaces, the fragments being held loosely together by dense fibrous bands connecting their posterior surfaces. The olecranon fossa was partially obliterated, so that extension was limited to an angle slightly more than a right angle. Flexion was nearly perfect, the fragments then becoming separated about half a centimetre. As far as could be judged the arm must have been a very useful one.

Dr. Smith said: An instance of simultaneous fracture of both olecranon processes has been reported by Fletcher.[2] The patient, a lad of sixteen fell over a piece of timber, striking on both palms. There was a separation of a finger's breadth in each bone. He was treated in "the usual way" by splints; and it was found after his death, which occurred ten months later from phthisis, that both processes were firmly united by bone.

Three reasons have been given for the frequent lack of bony union after fracture of the process:

(1) Insufficient blood-supply, due to the fact that the process is not covered by true periosteum but by an aponeurotic layer continuous with the tendon of the triceps.

(2) Imperfect contact between the broken surfaces, caused either by muscular spasm or effusion into the joint.

(3) Presence between the broken surfaces of foreign material, such as blood-clot or shreds of tissue.

All procedures, other than the commonly employed one of fixation of the joint with attempted replacement of fragments by various forms of external pressure, have been devised for the immediate purpose of overcoming one or the other of these supposed causes of non-union:

(1) We may safely say that the reason first given, namely, that of deficient blood-supply, is no longer tenable, since experience has shown that vertical fractures here and in the patella, where the conditions are very similar, always unite readily and firmly, and it has been abundantly proven that bony union does occur in the great majority of cases when the fragments have been wired.

(2) Probably far too great stress, here as well as in other fractures, has been laid upon muscular spasm. Mr. Macewen [3] has observed how easily the fragments of a transversely divided patella can be brought in contact after an incision has been made and other causes of separation have been eliminated.

To remove interarticular pressure due to effusion Grimm [4] has in one case employed early massage. In this instance there was a final separation of one-half cm. The injury in this case was a direct fall upon the elbow, a form of injury which ought, on theoretical grounds, to give the best result so far as a bony union is concerned. There have been reported three cases [5] in which the joint has been aspirated. Two

occurred in young men; one in a woman of sixty-eight. All were the result of direct violence, and all were aspirated immediately, with the removal of considerable quantities of blood and bloody serum. Very close union with good functional result occurred in all the cases. It is to be noted than no one of the above forms of treatment will insure bony union.

(3) The real reason for the frequent lack of union seems to have been arrived at by Mr. Macewen,[6] who made experimental fractures of patellæ, and who observed that where rupture occurred through indirect violence the bone was the first structure to give way and then the fibrous aponeurosis covering its anterior surface became overstretched, and finally ruptured, the ragged edges becoming folded over the fractured surface. When the rupture resulted from a direct blow on the patella the aponeurosis was itself torn across in the line of fracture. In the latter case there is no impediment to the direct contact of the broken surfaces, and bony union is more apt to follow. In the former case the fibrous masses cannot be dislodged and form an efficient barrier in preventing coaptation and bony union. Mr. Macewen thinks that he can demonstrate the presence of this aponeurotic tissue between the fragments by the soft elastic feeling, which he compares to that made by blood-clot obtained in attempts at producing crepitus. Although no experiments were made upon the olecranon, the writer referred to has observed a similar condition to that which obtained in broken patellæ in three cases where he had opportunity to cut down upon fractures of the process within a few hours after the injury. In these cases there was the same feeling of soft crepitation, and the explanation was found in the presence of the ends of the fibrous aponeurosis which had fallen in between the fragments.

To remedy such a condition nothing short of open incision seems to offer much certainty of success. I have found reports of fourteen cases where the olecranon has been wired. They are reported by Agnew,[7] Manley,[8] Mackay,[9] McCormack,[10] Rose,[11] Parker[12] and Macewen.[13]

Of the fourteen cases five were done within a few hours after the accident; six in consequence of non-union, after a lapse of from a few weeks to four months; and in three the reason is not stated. In four cases the result was noted as due to direct injury, and in three cases to indirect violence or to muscular action. In the others the point of injury was not distinctly stated. In two cases the arm was put up in a flexed position with good result.

It is interesting to observe that not a single bad result is recorded. The fragments have remained in perfect position, and in nearly all the cases the functional result was described as practically perfect after the lapse of from two to four months. In one case a bit of wire was removed from a sinus after fifteen months; with this exception no trouble was experienced with the wound.

While the result of these recorded cases may not justify a general resort to wiring in every case of olecranon fracture, they do give good assurance that excellent results may be expected to follow a secondary operation where lack of union or wide separation of the fragments produce diminished power of forearm extension.

DR. GAY: I should like to ask Dr. Boland if he made any experiments before he put on his splints, to see if the position of the arm had anything to do with the position of the fragments.

DR. BOLAND: I did not attempt it at all. In regard to soft crepitus, we did not get soft crepitus. Crepitus was distinct and so plain that there was no mistaking it. On the left side you could make out three pieces, and the crepitus was distinct between each.

DR. GAY: I asked the question because, while the classical way of treating those cases is with the arm in the extended position, I have seen a few cases where the position of the forearm seemed to have no effect upon the relative position of the fragments. It is easier to carry the arm in the right-angle position than in the straight position. I have always thought that the separation of the fragments was dependent upon the amount of laceration of the aponeurosis and the surrounding tissues. I remember one case I treated in the flexed position, and the result was good enough. In other cases where there was wide separation, of course I should not treat it in that way. I have never wired the bones. This case of Dr. Boland's is very interesting because the injuries were very severe and the functional results were admirable. Nothing could have been better.

DR. POST: I should like to ask Dr. Smith if anything was stated in regard to the indications for wiring the fragments in the cases he has referred to.

DR. SMITH: Dr. Agnew's case was a case of ununited fracture, and the wiring was undertaken on that account. In several other cases the operation was done for lack of union, with consequent disability.

DR. C. M. Whitney read a paper on

INTUBATION OF THE LARYNX. A RÉSUMÉ OF CASES IN PRIVATE PRACTICE.[14]

DR. GAY: I think Dr. Whitney has been particularly fortunate in his results, and is to be congratulated thereon. There is one point especially I want to speak of, and that is the way of estimating the value of the two operations. Heretofore it has been done, and I have been guilty of the same thing, by estimating the number of recoveries or deaths. It seems to me that is not the proper way. These operations are done for one specific object, and that is to relieve the laryngeal dyspnœa, not with the object of preventing or curing septicæmia, or preventing or curing bronchial croup, only to relieve the dyspnœa due to obstruction of the larynx. That being the case, we can very readily reconsider, I think, the value of the two operations. So far as my experience goes, intubation relieves the laryngeal dyspnœa about as well as tracheotomy. Once in a while a case of tracheotomy seems to do better than intubation; but I think in that case it is where the amount of thick gummy secretion is profuse, and there, I imagine, a little is pushed down ahead of the tube, and the child cannot clear the trachea and the tube, and relief is not as great. In only one or two instances have I been obliged to pull out the tube and do tracheotomy. The more I see of this operation the more I believe in it as the ordinary every-day operation in private practice. In the hospital I do not think the difference is so great.

[14] See page 341 of the Journal.

The other points in Dr. Whitney's paper I agree with very generally: especially is the point of stimulation well brought out. In septicæmia of all kinds it seems to me stimulants are the best agents with which to combat it; and as Dr. Whitney says, I do not believe, as a rule, you can give too much. My experience with the bichloride has not been as fortunate as Dr. Whitney's, perhaps, because the type of cases was different. But I do not know of anything else to take its place, and I think it is well to persist in its use.

Dr. Prescott: I think that if Dr. Gay had taken only the cases that he had in the hospital, and looked at the results which he obtained from mercurial treatment, he would find that his success had been similar to that of Dr. Whitney's, because he has been the one who, more than any other, has used the mercurial treatment, and has upheld it at all times when he has been on service; and the results in those cases which Dr. Goldthwaite and I reported were much more favorable when treated with mercury than in the cases not so treated. I think the difference was over seven per cent.

As regards the difficulties of the operation, I think it is quite a common thing for a person who for the first operation has an easy case to think that the operation is an easy one. I have had three men come to me and say they thought I put too much stress upon the difficulties of the operation, as it was so easy. They had never done the operation, and yet had put the tube in the first chance they had to try. I have always taken the ground that they would come to a case where they could not get the tube in; and that has been the case with every man who has spoken of it to me.

I think the point Dr. Whitney made about feeling the septum behind the tube is of very great importance in deciding whether the tube is in the larynx or not, for although the peculiar cough which comes when the tube is in the larynx is almost pathognomonic, yet even the practised ear is sometimes deceived.

In a meeting that was held here some months ago the question of drainage was dwelt upon, and the advantage of tracheotomy in giving good drainage to a case of diphtheria was presented as one of the advantages which tracheotomy had over intubation. I have looked up the cases of tracheotomy where there was no diphtheria, to see if there were not in such cases a great deal of discharge. In the last ten years at the hospital I could find twenty cases of tracheotomy done for other causes than diphtheria. In six of the cases no mention whatever is made of the discharge. One of the others died within twelve hours. There was a good deal of discharge, but I do not think it a fair case because the patient had large white kidneys and died with œdema of the lungs. In one case of tuberculosis there was little or no discharge from the tracheotomy tube, the patient doing well. In all the other cases mention was made of a profuse discharge, beginning with mucus tinged with blood and becoming purulent. In one case, a case of bullet wound, the man died of purulent bronchitis. In another case of cut-throat I could not decide where the pus came from. They said it was a cut-throat, and the tube was put through the wound and pus came from that. I threw it out as not being a fair case, but all the others seemed to me to be fair cases. In each there was a good deal of discharge from the simple introduction of the tracheotomy tube. In one of the cases where there was no mention made of the discharge, the house-officer who was on duty at that time remembered the case very well. It was a case of tracheotomy for paralysis of the vocal cords. In that case the man had to have a special nurse night and day on account of the extreme discharge from the tube necessitating its removal every two hours. There is nothing to show as yet that the intubation tube in the larynx causes the extreme discharge which comes in the tracheotomy tube: and it seemed to me possibly one explanation of the fact that cases get well after tracheotomy, where the discharge was free (and the percentage is nearly fifty in the cases reported by Lovett and Munroe where the discharge was free), was due to the fact that in those cases the membrane had not extended below the larynx, therefore the trachea was more nearly in the normal condition, and that the irritation set up in other cases was set up in these cases more easily than where the trachea was lined with membrane, as it is in the more fatal cases.

Dr. C. O. Thompson read a paper on

HORSE-HAIR IN MINOR SURGERY.[15]

Dr. Storer: I think the reader did not mention one suture which I regard as an ideal suture in almost all respects, that is silk-worm gut. It is sterilized without any trouble merely by immersion in steam for three or four minutes. It is absolutely unirritating. It has also the advantage which the reader spoke of as belonging to silver-wire the best of the other sutures, namely, strength. A medium sized silk-worm-gut strand will not be broken by all the strength you want to put upon it. It is said that three or four strands of horse-hair would be equally strong. It seems to me there are objections to suturing with a material of which you have to take several strands.

Dr. Thompson stated, in answer to questions, that horse-hair could be used to close almost any wound. He had under treatment a patient from whom he had removed a large tumor, and had used thirty-six sutures in the wound. In that case there had been a good deal of tension, but without any sign of cutting.

As to the tests by Dr. Stone, I have received only reports as to the presence or absence of bacteria. In all instances the organisms were present except when the horse-hair was sterilized by the treatment with benzine followed by bichloride. In some of the tests organisms were present after repeated boiling.

Dr. Thorndike showed a

PATHOLOGICAL SPECIMEN OF AN ANOMALOUS EXTERNAL ILIAC ARTERY.[16]

Dr. Munro: This certainly is a most unique case. It is difficult to understand how the artery could pass over Poupart's ligament. The ordinary anomalies of the femoral consist in its coming from the internal iliac (the branch corresponding to the external iliac being a very small vessel), or it splits in the pelvis or under the ligament; and there may be a vas aberrans. I can find no record of a case similar to the present.

A newspaper with a weakness for medical items published the following remarkable statement in a recent cable dispatch regarding the illness of Prince Bismarck: "The sciatica has now reached his arms and prevents him from using his hands, so that it is necessary for his attendants to feed him."

[15] See page 345 of the Journal.
[16] See page 348 of the Journal.

NEW HAMPSHIRE MEDICAL SOCIETY.

ANNUAL Meeting at Concord, N. H., June 19 and 20, 1893.

DR. EDWARD O. OTIS presented a lengthy paper on

PULMONARY TUBERCULOSIS, ITS PROPHYLAXIS, HYGIENIC AND CLIMATIC TREATMENT.[1]

DR. DAY: I have been interested to compute from the State Board of Health's Reports, the number of deaths from phthisis in the State of New Hampshire. As compared with the whole number of deaths in each county, the percentages of deaths from this disease are as follows:

Coos County	9.25%
Carroll County	10.76
Sullivan County	10.94
Grafton County	10.95
Merrimac County	10.99
Cheshire County	11.21
Hillsboro County	11.54
Rockingham County	12.63
Belknap County	12.98
Strafford County	13.80

Surely a marked difference. Now, if you will look on the map of New Hampshire, you will see that the countries which show the lowest mortality are in the more elevated portion of the State, while those which show the highest are along the sea-coast, or in the lower portion. So it seems to me that, as Dr. Otis says, we can take advantage of this fact and send our patients who cannot go South or West to higher altitudes nearer home.

DR. CONN: In order to have a dry climate we must have a dry soil. Mere altitude, though it be in a section of the country where but little rain falls, does not always make a dry climate, certainly not a dry soil. Places like the city of Mexico, where the rain falls during only two or three months of the year, would be uninhabitable, were it not for the fact that they have perfect sunlight all through the winter. It is a land of perfect sunshine during the winter months, and yet even there they have much consumption. Their most fatal diseases are phthisis and pneumonia. To those going from the States into that section it is folly to expose themselves after nightfall; and even in the day-time it is better to keep in the sunlight.

There are portions of Mexico which might be good places for consumptives, if they could get good food and shelter. In El Paso, Tex., I found physicians who thought it impossible to live in other climates. Dr. Jessup went from the States, going into other parts of Mexico, but found no place where he could breathe so comfortably as in El Paso. He gained in weight, and now considers himself quite well; and other physicians have had similar experience.

The County of Grant, in New Mexico, which is larger in area than the State of New Hampshire, the altitude being from 4,000 to 6,000 feet, with only an average of three inches of rain annually, would be an excellent climate; for there consumption among the natives is almost unknown, and whenever it can be made comfortable for people to go and stay in hotels and boarding-houses, it will become the sanitarium of this country.

Silver City, N. M., can be made comfortable for invalids, and may be a good place; but it is useless to send people who have had the refinements and luxuries of home into a wild country where they will have to rustle around like the natives of the country. They cannot do it, and they will sink faster than if they remained in their own land.

[1] See page 337 of the Journal.

SEQUELÆ OF LA GRIPPE.

DR. W. H. ALDRICH, of Marlboro: While the complications of *la grippe* have been many and varied, involving nearly all the organs of the body, most of the physicians have been particularly struck with the prominence of nervous and mental phenomena presented in individual cases.

One of the most common complications has been the so-called pneumonia following *la grippe*, which I am inclined to think is not pneumonia at all. A distinct difference can be made out between the true pneumonia lung and this grippe lung. In the latter there is a varying condition of blood stasis, unaccompanied by râles; and if resolution takes place within three or four days, as it is quite apt to do, it is accompanied by distinct mucous râles, giving no time for the slow bronchial breathing that characterizes the latter stage of true pneumonia. It is true that during the continuance of the blood stasis there is more or less of an exudation, which, as it increases, will give some bronchial breathing, which is never so complete as in true pneumonia, and which condition will pass off as gradually, or even more so, than it is formed.

Among the other disorders, resulting from an attack of influenza, which can be explained on this same theory of local vaso-motor paralysis, may be mentioned disorders of the liver, kidneys and pelvic organs. They suffer from forms of hyperæmia (subacute or chronic) which are more or less prolonged; and in patients suffering from chronic Bright's disease, uræmic convulsions have been precipitated. We also meet with various disorders of the extremities, such as flushed or pallid fingers, abscesses of the limbs, a sa result of this nervous disturbance.

The peculiar forms of pulse and perverted action of the heart, extending in some cases to cardiac paralysis, are really nervous phenomena which are due to paralysis, either partial or complete, of the inhibitory apparatus of the heart.

Any attempt to classify these nervous and mental phenomena must be attended with much difficulty, because there are, in the first place, affections occurring in nervous tissue and organs, although strictly speaking not nervous diseases, as in the articular pains and other so-called rheumatic manifestations, which are quite apt to follow after an attack of *la grippe*, as well as various forms of neuralgias, hyperæsthesia and paræsthesia which occasionally leads up to complete anæsthesia. Secondly, there are affections which would be recognized as properly referred to the nervous system, as in cases of neuritis, meningitis, cerebritis, and combinations of these inflammatory affections. Thirdly, there are symptoms which, although manifested in a non-nervous organ, are directly traceable to a nervous origin, as in the diseased condition of liver, kidneys, pelvic organs, etc., and as in the false pneumonia already mentioned.

In many cases, patients who suffered from the disease early during the epidemic are suffering to-day from the profound prostration attendant as a sequela. Undoubtedly to the cardiac debility may be largely attributed this weakness.

Cases of insanity are mentioned as a result of *la*

grippe. Fortunately they are rare; but undoubtedly, if facts were gathered, we should find more cases than are recorded, and a certain per cent. of our suicides might safely be attributed to the same cause, as a natural sequence from the generally depressed condition of the nervous system. There are cases of active insanity recorded, as occurring at the onset of influenza, and during its height. But the most of them occur during the decline of the disease and during convalescence, and the most common form is one of melancholia in the majority of cases.

DR. DINSMORE: We lay too much to *la grippe.* We used to have cases of nervous exhaustion, nervous prostration and insanity before we had *la grippe;* and they are not more common now than then. In treating *la grippe,* we were probably in the habit of using the coal-tar products — phenacetine, acetanilid, antipyrine, etc. Sometimes they are used in immense doses (ten, fifteen or twenty grains to a dose); and the thought has occurred to me that possibly some of those weak hearts that have been attributed to *la grippe* might be traced to too much medication on our part. We must take into account other causes, and not lay everything to the door of this disease.

DR. CONN: Dr. Aldrich spoke of the delirium as being rather of a mild form and not at all permanent. I have in mind one case in which the delirium lasted pretty much all winter, and there has been a recurrence of the insanity this season, the patient being still under treatment. The patient suffers from delusions, yet I have reason to hope it will not prove permanent.

DR. RUSSELL: I wish to mention another case of insanity parallel with the one just spoken of by Dr. Conn. The two cases presented almost precisely the same symptoms, and the terminations were about the same at first. While the insanity in the case mentioned by Dr. Conn has returned to a certain extent, probably as the result of overwork and anxiety, the mind of the other patient remains perfectly clear, and the general health is fairly good.

DR. PALMER: I have given doses of acetanilid, antipyrine, etc., and have regretted it. It is not my impression that I have injured my patients materially. I have had these sequalæ — nervous depression, etc.; but I think not from the treatment. I fully believe that depression of the nerve centres is occasioned by *la grippe.* I never considered that the nerve centres were primarily affected; perhaps they were.

DR. W. T. SMITH: It is a microbe that causes the disease; and the product of the microbe acts on nerves and nerve centres. The evidence is obvious. As the first and most prominent symptom we find pain — pain in the head, in the back, in the limbs. Patients say they "ache all over." They do not all suffer in the same degree, but all have pain. In many cases we find disorder of the stomach, perhaps with vomiting. This is due to the toxic action of the microbe on the sympathetic plexus of nerves supplying the stomach. We find congestion of the lungs very marked, at times simulating pneumonia; and true pneumonia sometimes occurs as a complication. This congestion may be ascribed to the paralyzing action of the virus on the vaso-motor nerves of the lungs.

Other various local disturbances — as cystitis, otitis, irregularity of the heart — may be best explained on this theory, that it is the nervous system which is attacked, and that the various organic troubles are essentially affection of the nerves and nerve centres.

DR. M. C. LATHROP: In the height of the epidemic of 1890, I saw two cases of well-marked hemiparesis, which proved to be merely prodromatous to *la grippe;* the paralysis wholly disappearing upon the fuller development of the main disease.

APPENDICITIS.

DR. GEORGE H. SANBORN, of Henniker, presented a lengthy paper. He concluded as follows:

(1) That in all cases the physician is concerned only in the early recognition of the disease, the subsequent treatment to be left to the surgeon.

(2) That the catarrhal or mild form of appendicitis may be considered the only medical form of the disease; and delay in operating may be encouraged to a reasonable extent.

(3) All cases of appendicitis which, at the end of thirty-six hours from the beginning of the attack, show signs of increasing disease should be operated on.

(4) That the majority of so-called recoveries, treated medically, are not recoveries in the full sense of the word, but simply a respite which enables one to settle worldly affairs, and take out a life-insurance policy, in anticipation of a fatal termination.

(5) The early surgical treatment of appendicitis enables us to avoid in every case uncertain results of a spontaneous cure, the danger of recurrent attacks, and the often fatal general peritonitis in apparently mild cases.

DR. IRA J. PROUTY, of Keene, reported twelve cases of appendicitis during the year ending May 18, 1893.

He said, in closing: From my limited experience in the treatment of appendicitis, I realize that it is a very grave disease; and we should not consider that any case is to be a mild one, as oftentimes the symptoms change very suddenly. The early treatment of cases of this kind should be rest in bed, liquid diet and judicious use of salines. There is a question about the use of hot applications, but there is one thing sure, that in many cases they will relieve the pain almost immediately.

I do not believe in the use of opium in inflammation about the cæcum any more than I do in hernia. In a paper read before this Society last year I said that the use of anodynes, especially morphia hypodermatically, in cases of strangulated hernia, often caused a fatal termination, as the most acute symptoms are blurred or blotted out entirely, and a false sense of security is felt by both physician and patient, and an operation is deferred until it is too late. If the case goes on and symptoms become more pronounced, the question of expediency of operation arises.

There is no one rule to govern us. Each symptom must be carefully weighed before deciding; but we should remember that early operations are advisable, rather than to wait for the formation of a large abscess, that no one can fail to detect on percussion or through the rectum. We must not rely on rise of temperature, for we have seen in Case VI that the temperature was normal for forty-eight hours before operation, and the pain had subsided a great deal.

The presence of a tumor is one of the most reliable guides, but not infallible, for we cannot be sure of fluctuation on account of the soft and yielding character of the contents of the abdominal cavity, and, moreover, muscular rigidity might be mistaken for the presence of a tumor.

As has been said, all the symptoms must be weighed carefully. The most marked cases there will be no doubt about, nor of the mild ones; but it is those of a medium nature that will cause the surgeon the most anxiety as to what manner of treatment is the most advisable.

The question of treatment of the stump, after removal of the appendix, has been much discussed. Some surgeons insist that the only safe way is to turn in the peritoneal edges and stitch with a Lembert suture; others always apply a ligature and cauterize close to the cæcum; while others merely apply a ligature and amputate a little distance from it, as has been the method used in all the cases herein reported. I believe it makes no material difference how it is accomplished, if the opening is only closed.

In the recurrent cases it is better to operate between the attacks, when the patient is in good condition and there is no inflammation, than to run the risk of waiting until there is suppuration and possibly septic poisoning, and until the patient is in poor condition to withstand an operation which must be done, perhaps hurriedly and with bad surroundings, in order to save life. After a patient has had two attacks of appendicitis, I advise the removal of the offending member, as I believe this is the only sure means of cure.

After operation for this disease, I always recommend the patient to wear an abdominal supporter in order to avoid ventral hernia; especially, if, like some of the cases here given, they are obliged to do heavy lifting. We should always insert three rows of sutures, instead of involving the peritoneum, muscles and integument in row.

By doing the operation under the strictest aseptic precautions, the mortality is growing less every year; and if a diagnosis is made early in the case, and operation (if found necessary) not put off too long, we can expect good results in nearly all these cases that formerly were invariably fatal.

COCAINE.

DR. HENRY DODGE, of Penacook, reports several cases of the use of cocaine in diseases of the bladder and stomach.

My theory of the method of its operation in diseases of the bladder is this, namely, that its local application to the mucous membrane with which the bladder is lined produces anæmia of this membrane in the same manner as we have all, no doubt, noticed its operation when applied to any inflamed conjunctiva, and that, by thus controlling the blood-supply to the inflamed part, it allows nature to assert itself and arrest the inflammation.

With regard to its use in diseases of the stomach, I believe it to have an indication in a wide range of diseases. I shall only endeavor to name a few of the more important. In cancer of the stomach, given in doses up to half a grain, many times it will control pain and stop vomiting; its great advantage over morphine in this class of cases being that it does not constipate the bowels. For vomiting of pregnancy, exhibited in minute doses at frequent intervals, as well as for obstinate vomiting from any other cause, it is of great value. I recall one patient with whom a great many prescriptions had been tried without success, who was almost instantly relieved by a dose of one-sixtieth of a grain given in water every fifteen minutes. For the relief of gas in the stomach, combined with bromide and codeine, I have found it to be of benefit in a large percentage of cases, also in gastralgia given in full doses every two to four hours. It is also of value as an ingredient of almost any combination for the relief of sick or nervous headache, being superior to the minute dose of morphine so often used. It is always well when using it in a new case to be exceedingly cautious, as a great many individuals, from an idiosyncrasy, are exceedingly susceptible to its effect.

DR. MEGRATH: I have not had any experience in the use of cocaine in diseases of the bladder, but in cases of pregnancy I have used it with marked success. I had one case in which the patient had not for some time been able to retain anything to speak of on the stomach. I recommended cocaine; after that she retained food. I have used a great deal of it with carbolic acid in extracting teeth. Patients say it does not hurt much; I never used enough to know that I got bad effects from its use. I have never used it in surgery, except in the removal of toe-nails and small growths. I should only advise its use for minor operations.

DR. LEET: I have used cocaine for more than eight years and for various operations. I have yet to see the first unpleasant result from its use.

DR. ALLEN: I am a thorough believer in cocaine; and if we leave the discussion where it is, I fear we shall leave a wrong impression. I have used it hundreds of times and for many things; for extracting teeth, amputation of fingers, removal of large wens, and in an operation on a large gland where an incision three and one-half inches deep was required; and I have never seen the first unpleasant result — I do not say *dangerous*, I say *unpleasant*. Now, am I wrong in using this? Am I careless in using it? I ask the result of the use of cocaine? Have you had any unfortunate results in its use? If so, for the sake of suffering humanity and your fellow practitioners tell us this afternoon. I have seen cocaine used many times, and I have seen ether used; and have seen more unpleasant results from the use of ether than from cocaine. Then why not caution each other to be careful in the use of ether as well as cocaine?

DR. DODGE: I have used cocaine in a great many cases and in a great many ways of which I have not spoken in my paper. I have used it, as others have, hundreds of times for the extraction of teeth; I have used it for opening abscesses; and, as has been said, I have not, in any of my cases, seen the first unpleasant result. I recall, however, that when I was in college, there was a student there who had a slight operation to be performed on his eye. He went to a physician, and a small quantity of a four per cent. solution, I believe, was injected. The operation was not performed, as violent symptoms of poisoning came on almost instantly. The physician immediately procured a hack and accompanied the young man to his boarding-place, remaining with him several hours, and to say the least, the symptoms were *decidedly unpleasant*. Therefore, I say we must be careful, as there are many cases of idiosyncrasy; and if we chance to find one of those cases we should be prepared for it. I have used it with caution even in so simple an operation as the extraction of teeth. I do not wish to be understood as regarding cocaine to be as dangerous as ether.

Other addresses and papers were the following: "Philanthropic Medicine," by Dr. E. F. McQuesten; "Use of Forceps," by Dr. Bradford Allen; "Report on Gynæcology," by Dr. D. M. W. Russell.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 5, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Edstor, and all books for review, should be addressed to the Edstor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TWENTY-FIRST ANNUAL REPORT OF THE LOCAL GOVERNMENT BOARD, 1891-1892: SUPPLEMENT CONTAINING THE REPORT OF THE MEDICAL OFFICER.[1]

In transmitting his Annual Report, Dr. Thorne Thorne recognizes the valuable services of his predecessor, Dr. George Buchanan, who had served the Government for thirty years as Medical Inspector, and as Chief Medical Officer of the Local Government Board. "Those alone," he says, "who have had the opportunity and pleasure of working under his direction, can appreciate to the full the important influence for good, which his labors have had; and they alone can realize how much the Medical Department owes to the example which he set as an earnest worker and director, who never ceased to claim that all true sanitary progress must be based upon accurate and scientific research into the etiology of disease."

The report shows that the vaccination returns for England for the year are not very satisfactory. After deducting from the total number of births in England and Wales for the year (885,909) those who had died unvaccinated, and those who were found to be insusceptible, and others whose vaccinations were postponed, there still remained 9.6 per cent. unaccounted for. For a period of twelve years (1872-1883) the percentage of children unaccounted for was quite uniformly, about 4.5 per cent. but it has steadily risen since 1883. The greatest delinquencies were in Leicestershire 43.9 per cent., Northamptonshire 31.8 per cent. and Bedfordshire 26.5 per cent. These figures "indicate a further increase in the amount of failure to comply with the law relating to vaccination, a circumstance which becomes serious in view of the growth of smallpox, which is in progress in many parts of the country." At the Animal Vaccine Station in Lamb's Conduit Street, London, 336 calves were vaccinated during the year, and from these 7,529 persons received primary vaccination.

[1] London: Eyre and Spottiswoode, 1893, pp. xvi, 212.

Among the local inquiries made by the medical inspectors during the year there is one which is worthy of notice as confirming a previous report of the same Board upon the origin of scarlet fever. This outbreak was traced to a milk-supply, and the Board concludes that, so far as it goes, the inquiry materially strengthens the conclusions arrived at by the Medical Department of the Board in the Hendon case, that there is a disease in the cow which is capable of being transmitted in the form of scarlatina to the consumers of milk.

A considerable part of the report is devoted to an inquiry by Dr. Parsons upon the subject of the transportation of town manures and their effect upon health.

That part of the report which is of most interest to the medical profession is the portion which embraces the auxiliary scientific investigations of Dr. Klein and others upon the bacteriology of diphtheria, and other allied subjects. He found that "so-called" scarlatinal diphtheritis occurring in the *early days* of scarlet fever attack, is not, judged from the bacteriological standpoint, diphtheria; and, on the other hand, that similar manifestations, whether of diphtheritic or croupy type, occurring in the *later stages* of, and during *convalescence* from scarlet fever, are almost invariably true diphtheria. But, he also finds, in the majority of cases examined by him, that membranous croup of the larynx or trachea, though altogether dissociated clinically from diphtheria, is to be regarded as essentially that disease; indeed, so far he has only met with a single instance of croup not related clinically to diphtheria or to scarlatina, in which he was unable, with the material at his disposal, to demonstrate the presence in the membrane of bacillus diphtheriæ.

Dr. Klein also reports the results of experiments in which he sought to induce erysipelas and vaccinia simultaneously in the calf. The vaccinia took and ran its course, while the microörganism of erysipelas failed entirely. He therefore concluded that calves were insusceptible to erysipelas. The practical bearing of this experiment upon the practice of animal vaccination is sufficiently plain.

Other simultaneous inoculations of the different microbes resulted variously.

Other important investigations are reported upon in this volume, as follows: "On the Products of Bacillus Pyocaneus as affecting the Development of Tubercle," by Dr. Klein; "On the Chemistry of Diphtheria," by Dr. Sidney Martin; "On the Chemistry of Susceptibility and Insusceptibility," by Dr. Hamer; and upon "The Effect of Pus upon the Vitality of Bacteria," by Dr. Andrewes.

INFANTILE INSURANCE.

The practice of insuring the lives of children has become so prevalent among the lower classes in England, that various official inquiries have been held and attempts made to restrict it. The National Society for the Prevention of Cruelty to Children brings many parents into court charged with maltreating or neglecting their children, and among these cases are many in

which it appears that the lives of the children are insured. In few is there a deliberate intention on the part of the parent or parents to direct murder, but in many the neglect is so outrageous that it is evident they follow Clough's decalogue, "Thou shalt not kill but needst not strive, officiously to keep alive." They consider the death of a child a good riddance; and if the child is likely to die any way, it seems only good business to make something out of its death. To what extent this infantile insurance is responsible for this cruelty and neglect it is very hard to determine. In some cases reported to the authorities the evidence is strong that children have been done to death as a business enterprise.

Is there anything at all similar to this with us? The lives of children, especially among our foreign born population, are not infrequently insured, but it is very uncommon to hear of a case in which a death has been hastened in order to get the insurance. Such insurance is generally for burial purposes only, and the whole amount goes to the undertaker. The children, or for that matter adults as well, are often not insured until they show signs of ill health. When they appear sick the parents or friends get a policy in some company not requiring a medical examination, but making some provision that the insured shall not die of phthisis or other long standing disease within a certain time. If the diagnostic or prognostic powers of the applicants were better, such companies would not make much money. Such insurance for burial purposes only, is entirely a different matter from the infantile insurance in England, where the fact that a child is insured increases the advantages of having it out of the way, and influences its treatment by its parents.

MEDICAL NOTES.

Harvard Medical School. — The Harvard Medical School has an entering class this year of somewhat over ninety — a falling off of about twenty from the number last year.

The Index Medicus. — According to a count made by the *Medical News* there are eleven hundred and nineteen medical journals and transactions regularly indexed in the Index Medicus. Besides these there are also the semi-scientific and commercial papers catalogued. Certainly medical ideas do not want for means of utterance.

The Cholera. — Cholera reports continue to be favorable. In England no new cases have been reported since September 20th. In Hamburg the epidemic is rapidly subsiding there being but two or three new cases each day. There have been one hundred and twenty cases with fifty-nine deaths so far. In Antwerp the disease is also declining, Palermo and Leghorn are still infected and eight or ten new cases occur daily. In Roumania and Russia the infection is still widespread and shows no marked subsidence, though the death-rate has not increased.

Faculty of the Army Medical School. — The following officers have been appointed as the faculty of the new Army Medical School established in Washington: Colonel Charles H. Alden, assistant surgeon general, U. S. A., president of the faculty, and lecturer on the duties of medical officers; Lieutenant-Colonel William H. Forwood, deputy surgeon-general, U. S. A., professor of military surgery; Major John S. Billings, surgeon, U. S. A., professor of military hygiene; Major Charles Smart, surgeon, U. S. A., professor of military medicine and director of the chemical laboratory; Captain Walter Reed, assistant surgeon, U. S. A., professor of clinical and sanitary microscopy and director of the pathological laboratory; Captain Julian M. Cabell, assistant surgeon, U. S. A., assistant to professor of military surgery and instructor in hospital corps drill. Instruction will be given in the Army Medical Museum, commencing on the first day of November.

Colorado Medical Library Association. — The physicians of Denver, Col., have formed a Medical Library Association for the advantage of physicians in that city and throughout the State. Owing to their remote position they have small opportunity to enlarge their collection of books, and request societies and physicians who may be so inclined to send copies of their publications to the Secretary, Henry Sewall, M.D., in care of the Public Library, Denver.

The Influence of Albinism on the Eye. — Dr. George M. Gould is investigating the extent and nature of the influence of albinism upon the eyes, and requests any physician who has had albinotic patients to send him as exact information as possible as to the condition of the eyes in those cases. Blank forms indicating the particular knowledge desired will be sent upon application and necessary expenses incurred by correspondents for postage, etc., will be paid.

Patent Medicines in England. — The sale of patent medicines in England has but few restrictions provided the vendor takes out a license for his trade. The annual receipts of the government from the issue of these licenses is nearly a million dollars.

The Persistence of the Contagion of Diphtheria. — At a recent meeting of the Medical Society of Lyon, Moncel reported the result of fifty cases of convalescence from diphtheria which were examined for the Löffler bacillus. In all cases of a lingering post-diphtheritic coryza there were bacilli found in the nasal mucous membrane, in some instances for as long as fifty-three days.

The Cranium of Sophocles. — A skull has been discovered at Deceleia which is believed to be the skull of Sophocles, but as several sceptics have doubted its genuineness, it has been referred to Professor Virchow, who will carefully examine it and decide if it is really Sophocles' or merely somebody that looked like him.

NEW YORK.

More Board of Health Physicians. — At a meeting of the Board of Estimate and Apportionment,

held September 28th, an appropriation of $3,000 was made to the Board of Health for the employment of fifteen extra physicians for the free vaccinating corps. At the same meeting $539,248 was voted for public-school improvements, and $50,000 for the further purification of the Croton water-shed.

Yellow Fever Relief. — The steamship *Algiers* has been fitted up to carry provisions and other supplies to the yellow fever sufferers at Brunswick, Ga., and Dr. A. N. Bell, editor of the *Sanitarian*, is to act as medical officer of the expedition.

Hereditary Polydactylia. — Charles Hodge, a lad thirteen years old, of Newark, N. J., who was born with twelve fingers and fourteen toes, was recently relieved of the extra members at St. Barnabas Hospital. It is stated that this superfluity of fingers and toes is a hereditary characteristic on the maternal side, running back for several generations, and that among the family relics is a bottle of alcohol in which are preserved a number of fingers and toes removed from various ancestors.

Mortality. — The bulletin of the State Board of Health for August, shows that during that month 11,037 deaths were reported in the State, which represents an annual death-rate of 21.20 per thousand of the estimated population. For 150 cities, villages and populous towns having a population of 4,785,000 it is 22.75, and for the rural portion of the State, 15.40. There was an increased mortality in the Mohawk Valley and in the western districts of the State, and this was chiefly due to diarrhœal diseases, which were less prevalent than usual in New York city and the eastern districts.

Miscellany.

MR. ERNEST HART ON THE "CODE."

The address of Mr. Ernest Hart at the Pan-American Congress was devoted chiefly to the consideration of the necessity for a code of ethics among physicians. Quoting Sir Astley Cooper's remark that success in the practice of medicine depended upon "the physician's knowledge, his continuous industry and his moral character," he said they might form a very adequate summary of the conduct, private dignity and etiquette of medical men in relation to public affairs.

"Just at present both in England and in this country the question is frequently asked whether it is necessary to add to the simple rules of ethics which direct the conduct of gentlemen a detailed code of medical etiquette and ethics. I think it is clear that never at any time, if there were a necessity for such a code, could that necessity be nearer or more apparent than at the present moment. Under the stress of a developing civilization, with the temptations induced by the enormous facilities for advertisement and the profit to tempt the medical man from the ancient bond of modesty and diffidence, there is now the strongest reason for fortifying every professional man against the inroads of modern temptations, by a code so precise, by deductions so exact, so comprehensive, and so far-reaching that he shall never be overcome by such temptations, but shall be able to know at once, and under all circumstances, what is his duty, what is the rule of his profession in any one particular case in which he may be tempted.

"Such a code as this does exist, and upon a logical and strong basis, for the benefit of the public as much if not more than for the benefit of the profession. It is not a trade-union business for the benefit of a private class interest, but is, on the contrary, a movement for the interests of the public in general far more than for the medical profession.

"We cannot in the face of past experience and medical precedents safely cast aside a code of ethics which has been carefully and deliberately reached regarding the especial application of ethical principles to medical life. For example, a medical man is prohibited from consultation with quacks. Now Dr. Johnson's definition of the word is, '*Quack—a boasted pretender to arts which he does not understand; a boasting pretender to physic; one who proclaims his own medical abilities in public places; an artful tricking practitioner in physics.*' Thus, there is no distinction between the quacks who have medical degrees and the quacks who have not. Moreover, no respectable physician should advertise. That is a method of the quack. Advertisments in any form, whether in the way of an interview by a representative of the secular press, or by published letter, by the description or criticism of some new alleged system of treatment, or by divulging the secrets of the sick-room are in direct contravention of medical etiquette, and deserve the scorn and reprobation of every honorable person as well as every honorable medical man. For a medical man to possess or profit by any secret remedy is not only an offence against professional morality, but is a source of public danger as well. The physician owes his knowledge as well as his capacity for practising medicine to the open communications of bygone practitioners, and a new treatment, drug, or medical dogma, is like a doctrine, dogma, or deduction in theology, both are alike the common birthright of humanity, and any man who for profit keeps as a secret a new treatment or a new doctrine is a traitor not only to his profession but to all humanity. The physician who trades in or palters with secret remedies is untrue to his obligations, unfaithful to the world, a shame to himself, and a dishonor to his calling. Nor can the alleged value of any so-called secret remedy be held to condone such an offence."

THE MADRID ACADEMY OF MEDICINE PRIZES.

The Academy of Medicine, of Madrid, has offered for the year 1894–5 two prizes open to public competition: The Academy Prize of three hundred dollars, a gold medal and the diploma of a corresponding member of the Academy, for the best essay on the "Treatment of the Different Clinical Forms, Accidents and Complications of Diabetes, based upon the Writer's Observations." The essay is to be written in Spanish or Latin. The Alvarez Alcala Prize of one hundred and fifty dollars, and corresponding membership in the Academy. Subject: "Surgical Intervention in Intestinal Obstruction." The essay to be written in Spanish, French or Latin.

The essays must be in the Secretary's possession by the first of May, 1894.

BAGDAD PHARMACY.

A CORRESPONDENT of the *Pacific Medical Journal* gives the following account of the attractive pharmacy of Bagdad: "The practice of medicine is in a degraded state, and patients are constantly bargaining with the physician for a cure, and refuse to pay for advice pure and simple or for an examination, no matter how much skill or time it may involve. When a wealthy person is taken ill all the doctors and magicians in the city are sent for an hour or two apart, and without each other's knowledge, and their advice is followed or not, as it suits the fancy of the women neighbors, who always try to pump the doctor by fair means and foul. If a prescription is sent to the drug store it will probably be put up in an old, unwashed cod-liver-oil bottle that has lain perhaps for months in some dirty corner, and then an old rag and some paper is made to do service as cork. This is not overdrawn. Sometimes the prescription may be put up in a cup without any cover at all. The percentage-on-prescription system has here been developed and refined as nowhere else. There are benevolent societies whose secretary receives as salary a certain amount on every prescription he has to settle for, and then he and the doctor agree that a new prescription shall be written for every dose!"

LIGATURE OF THE INTERNAL ILIAC ARTERIES FOR PROSTATIC ENLARGEMENT.

ACTING upon the analogy offered by the diminution in size of mammary and uterine myomata after diminishing their local blood-supply, Bier,[1] of Kiel, undertook a similar treatment in cases of enlarged prostates. By far the larger part of the blood-supply to the prostate gland comes from the internal iliac arteries. These are most successfully ligated just after they leave the common iliac trunks.

The extra-peritoneal method was found the surest, and in well-etherized patients no harder than the transperitoneal operation with its extra danger. Even in cases where both arteries are to be ligated, Bier advises bilateral incisions rather than the median laparotomy. His incision is made about two fingers' breadth above Poupart's ligament and extends in a curved direction upwards toward the ribs, the convexity being about three fingers' breadth inside of the anterior superior spine of the ileum. The parietes are divided to the peritoneum, and after all bleeding is stopped, this is peeled away from the wall of the pelvis till the artery is reached. It is essential to have the pelvis well elevated. Owing to the free anastamoses in this region no circulatory disturbance was noticed in any case.

The readiness with which such wounds as these heal, and the possibility of avoiding sepsis are greatly to the advantage of this treatment over direct operation upon the prostate. The cases reported certainly show that a measure of relief is to be expected. The patients, aged from sixty to sixty-nine, all presented typical cases of prostatic enlargement, frequent difficult micturition, residual urine, purulent cystitis and palpably enlarged glands. After the operation, the size of the prostate steadily diminished, in one case from the size of a hen's egg to the normal, inside of four months. Another case, in which catheterization had been necessary and the gland so large that in digital examination by the rectum the upper border could just be reached, presented the following condition sixty-four days later. "The patient passes all his urine himself and without delay at desire. The upper border of the prostate is now easily passed without ether. The urethra is now only twenty-two centimetres long. Although there is considerable enlargement still, and the patient is obliged to pass water several times each night, there is an undoubted diminution in size of the gland, and the residual urine has steadily diminished in amount from one hundred and fifty cubic centimetres to between thirty and forty." One case proved fatal from peritonitis, but had already shown an improvement in the urinary symptoms, not requiring catheterization as before. The autopsy showed a glandular hypertrophy of both halves, but less upon the left, the only side operated upon. Injection of the right hypo-gastric artery caused much less filling on the left side than on the right.

[1] Wiener Klinische Wochenschrift, No. 32, 1893.

OBITUARY.—DAVID SYLVESTER FOGG, M.D.

DR. DAVID SYLVESTER FOGG, who died of chronic myelitis, August 29th, aged seventy-two years and five months, was born in Meredith, N. H., March 30, 1821. His parents were well-to-do, energetic people, his father and grandfather patriotic, and identified with the military defence of the country. Dr. Fogg obtained his education in Holmes Plymouth Academy and in Dartmouth College. He studied medicine with Dr. Josiah Crosby, of Manchester, N. H., and obtained his degree of Doctor of Medicine from Dartmouth Medical School in 1845. In 1846 he located in South Dedham, and commenced the practice of medicine, which extended through the village and reached into the surrounding towns. He soon became noted for his skill, and was often called in consultation.

He was a member of the Norfolk County Medical Society and of the Massachusetts Medical Society and had been several times elected a councillor of the latter body. He was also a member of the American Medical Association.

In 1861 he was a volunteer surgeon in the Peninsular Campaign, under General McClellan. On the organization of the Board of Enrolment he was appointed by President Lincoln, a surgeon of the Board for the Seventh Massachusetts Division, head-quarters at Concord, Mass. After he had held that office for three years he then resumed his practice in Norwood. He was a friend to the public schools, and in 1878 was a member of the Dedham School Committee, which position he had occupied once before. He defended the schools in town meetings, and was always in favor of a liberal policy for their support, and an advocate of advanced methods of teaching. He was not a frequent speaker, but always spoke to the point, with practical good sense, supporting needed improvements and favoring municipal economy.

In 1847 he married Mary B., youngest daughter of Rev. Thomas W. Tucker, who was then stationed as pastor of the Methodist Episcopal Church, at Dorchester, Mass. Eight children were born of this marriage, six of whom, including his son Dr. Irving S. Fogg, with the widow, survive him.

Dr. Fogg was of a social disposition, a good neighbor, and during his long professional career made many warm friends. His stately form and commanding presence will long be missed. He was an early member of Orient Lodge, F. & A. M., and at his funeral that order took charge of the remains after the close of the services at the house. His professional brother Dr. John P. Maynard, of Dedham, attended Dr. Fogg in his last illness; and his friend Dr. A. P. Clarke, of Cambridge, also visited him.

A. P. C.

OBITUARY. — THOMAS F. SHERMAN, M.D.

DR. THOMAS F. SHERMAN died in Boston, September 26th, at the age of thirty-seven, after a long illness.

On leaving the Harvard Medical School he served for a year as house-physician at the Massachusetts General Hospital, and then immediately entered upon private practice. A man of great tact and kindly disposition with a keen sense of humor, quick to see through shams, patient in investigation and thoroughly loyal to patients and associates, his death was a loss to the community. He had ambition, but of a kind that was ready to push itself forward by means of work well done, and by that alone. Not a ready writer, and anxious to digest his work before giving it to the public, he had published little, but he had carefully collected notes which would in time have led to publication. A paper of his in the coming Report of the Children's Hospital is highly spoken of. In his capacity of assistant in the Harvard Medical School, he had proved himself capable of giving instruction, and he was much liked by the students. He had made an unusually efficient secretary for the Society for Medical Observation, and while not taking part in debate as often as some members, yet he was commonly present, and when he did speak it was generally to say something that he had well considered. Appreciation for his services was shown both by the Children's Hospital, and by the Hartford Life and Annuity Insurance Co., for which he was local examiner, by their declining to accept his resignation, preferring while his life lasted to allow his work to be done by substitutes.

Although in no sense a politician, his public spirit led him to take a warm interest in the political questions of the day and to have a reason for his vote. He was a Freemason and had held office in the order.

A hard worker, Dr Sherman made the mistake of doing seven years' continuous work, broken only by an annual week at the camp of the militia battalion of which he was hospital steward. To remonstrances from relatives, the answer was always that while he was young was the time for work. In later life he would have long vacations. By this unremitting labor he had secured some fine professional appointments, and the basis of a good practice. During the winter of 1891–92 some of his associates observed that his work was done with not quite the old vigor, but such was the man's persistence that when the break really came, it came once for all. During the last year and more he was making a gallant fight for life though himself of opinion that the end was inevitable. He was not married.

Dr. Sherman was so unassuming that it took one a long time to appreciate all the fine points of his character, but he was a man who will long be missed by those who were so fortunate as to know him well.

METEOROLOGICAL RECORD,

For the week ending September 23, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer.			Relative humidity.			Direction of wind.		Velocity of wind.		We'th'r. *		Rainfall in inches.

Deaths reported 2,973: under five years of age 1,400; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 711, diarrhœal diseases 393, consumption 298, acute lung diseases 206, diphtheria and croup 132, typhoid fever 86, whooping-cough 35, scarlet fever 28, cerebro-spinal meningitis 17, malarial fever 7, measles 6, erysipelas 3, small-pox 3.

From whooping-cough New York 10, Chicago, 7, Philadelphia 6, Pittsburg 4, Brooklyn 3, Washington, Cincinnati, Cleveland, Nashville and Lynn 1 each. From scarlet fever Pittsburg 10, New York and Chicago 4 each, Philadelphia and Lowell 2 each, Boston, Milwaukee, Cambridge, New Bedford, Everett and Woburn 1 each. From cerebro-spinal meningitis Chicago 6, New York and Washington 2 each, Philadelphia, Brooklyn, Boston, Cleveland, Cambridge, Lynn and Gloucester 1 each. From malarial fever New York, Brooklyn and Nashville 2 each, Philadelphia 1. From measles New York 3, Chicago, Washington and Pittsburg 1 each. From small-pox New York 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending September 16th, the death-rate was 19.8. Deaths reported 3,919; diarrhœa 518, whooping-cough 89, diphtheria 83, fever 79, scarlet fever 43, measles 32, small-pox (Birmingham and Bradford 2 each, London, Leicester and Oldham 1 each) 7.

The death-rates ranged from 11.2 in Derby to 30.1 in Burnley; Birmingham 21.7, Bradford 24.7, Bristol 19.2, Croydon 14.8, Hull 26.0, Leeds 25.7, Leicester 16.4, Liverpool 25.8, London 17.5, Manchester 20.8, Newcastle-on-Tyne 28.6, Nottingham 18.7, Portsmouth 20.3, Sheffield 23.3, Sunderland 19.8.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 23, 1893, TO SEPTEMBER 29, 1893.

By direction of the Secretary of War, leave of absence for four months, on surgeon's certificate of disability, is granted LIEUT.-COLONEL FRANCIS L. TOWN, deputy surgeon-general, U. S. A.

FIRST-LIEUT. CHARLES F. KIEFFER, assistant surgeon, is relieved from further duty at Fort Meade, South Dakota, and from temporary duty at Fort Yellowstone, Wyoming, and will report to commanding officer at Fort Assiniboine, Montana, for duty.

FIRST-LIEUT. WM. F. LEWIS, assistant surgeon, will, upon being relieved from duty at Fort Assinniboine, Montana, by FIRST-LIEUT. KIEFFER, report to commanding officer, Fort Apache, Arizona, for duty.

FIRST-LIEUT. BENJAMIN BROOKE, assistant surgeon, will proceed at once from Fort Leavenworth, Kansas, to Fort Brady, Michigan, for temporary duty during the absence on leave of Assistant Surgeon PAUL CLENDENIN, U. S. A.

Leave of absence for one month, to take effect upon the arrival of Assistant Surgeon BENJAMIN BROOKE, is granted CAPTAIN PAUL CLENDENIN, assistant surgeon, U. S. A.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SIX WEEKS ENDING SEPTEMBER 16, 1893.

MURRAY, R. D., surgeon. To proceed to Pensacola, Fla., for temporary duty. August 10, 1893. To rejoin station. August 18, 1893. To proceed to Brunswick, Ga., for temporary duty. September 14, 1893.

BAILHACHE, P. H., surgeon. To assume charge of inspection of immigrants. August 14, 1893. Detailed as chairman, Board for Physical Examination of keepers of Life Saving Stations August 18, 1893. Relieved from duty as inspector of immigrants. August 22, 1893. Detailed as chairman, Board for Physical Examination of Officers, Revenue Marine Service. September 12, 1893.

PURVIANCE, GEORGE, surgeon. To report at Bureau for temporary duty. August 6 and 10, 1893. Detailed as chairman, Board for Physical Examination of Surgeon John Vansant. August 28, 1893.

VANSANT, JOHN, surgeon. Ordered before Board for Physical Examination. August 31, 1893.

HUTTON, W. H. H., surgeon. To report at Brunswick. August 10, 1893. To proceed to Cape Charles Quarantine as inspector. August 12, 1893. To proceed to Brunswick, Ga., for temporary duty. August 12, 1893. To rejoin station, Detroit, Mich. September 10, 1893.

HAMILTON, JOHN B., surgeon. Granted leave of absence for four days. August 16, 1893. Granted leave of absence for ten days. August 29, 1893.

SAWTELLE, H. W., surgeon. Detailed as member, Board for Physical Examination, Life Saving Station. August 18, 1893. Detailed as member, Board for Physical Examination of Passed Assistant Surgeon H. T. Goodwin. August 22, 1893. Detailed as member, Board for Physical Examination, officer Revenue Marine Service. September 12, 1893.

AUSTEN, H. W., surgeon. Detailed as recorder, Board for Physical Examination of Surgeon John Vansant. August 28, 1893. To represent the Service at meeting, Pan-American Medical Congress. September 5, 1893.

GASSAWAY, J. M., surgeon. To inspect local quarantine at Pascagoula, Miss. August 23, 1893.

MEAD, F. W., surgeon. To proceed to Chicago, Ill., for temporary duty. August 9, 1893.

CARTER, H. R., surgeon. To proceed to Fernandina, Fla., to inspect quarantine and return to Bureau. August 7, 1893. To proceed to Pensacola, Fla. August 10, 1893. To proceed to Brunswick, Ga., for temporary duty. August 12, 1893. To report at Bureau. August 31, 1893. To represent the Service at Pan-American Medical Congress. September 5, 1893. To proceed to Philadelphia, Penn., and Reedy Island Quarantine. September 9, 1893. To proceed to Cape Charles Quarantine and assume command. September 11, 1893. To report at Bureau for temporary duty. September 15, 1893.

WHEELER, W. A., surgeon. Detailed for duty at Camp Loi. August 14, 1893. To rejoin station. August 22, 1893. Detailed as recorder, Board for Physical Examination, Passed Assistant Surgeon H. T. Goodwin. August 22, 1893.

CARMICHAEL, D. A., passed assistant surgeon. Granted leave of absence for thirty days. August 16, 1893.

PECKHAM, C. T., passed assistant surgeon. Granted leave of absence for twenty days. August 10, 1893.

GLENNAN, A. H., passed assistant surgeon. To proceed to Reedy Island Quarantine for temporary duty. August 30, 1893.

MAGRUDER, G. M., passed assistant surgeon. To proceed to Pensacola, Fla., as inspector. August 10, 1893. To proceed to Brunswick, Ga., for temporary duty. August 23, 1893. To proceed to Beaufort, S. C., as inspector. September 9, 1893.

KINYOUN, J. J., passed assistant surgeon. Detailed as inspector, New York Quarantine. August 12, 1893. Detailed as member, Board for Physical Examination of Passed Assistant Surgeon H. T. Goodwin. August 26, 1893.

GOODWIN, H. T., passed assistant surgeon. Granted leave of absence for thirty days. August 10, 1893. To proceed to Louisville, Ky., for duty. August 15, 1893. Ordered to appear for examination as to physical condition. August 22, 1893.

VAUGHAN, G. T., passed assistant surgeon. To represent Service at meeting of Pan-American Medical Congress. September 5, 1893.

GEDDINGS, H. D., passed assistant surgeon. To report at Bureau for temporary duty. September 13, 1893. To proceed to Brunswick, Ga., for temporary duty as inspector. September 15, 1893.

CAFER, L. E., assistant surgeon. To proceed to Savannah, Ga., for duty. August 25, 1893.

DECKER, C. E., assistant surgeon. To proceed to San Francisco Quarantine for temporary duty. September 3, 1893.

NYDEGGER, J. A., assistant surgeon. To proceed to Jersey City, N. J., for temporary duty. September 2, 1893. To rejoin station. September 9, 1893.

OAKLEY, J. H., assistant surgeon. To proceed to Quebec, Can., for duty. August 26, 1893.

NORMAN SEATON, assistant surgeon, To proceed to New York, N. Y., for temporary duty. August 18, 1893. To rejoin station. August 23, 1893. To proceed to Jersey City, N. J., for temporary duty. September 3, 1893. To rejoin station. September 9, 1893.

SPRAGUE, E. K., assistant surgeon. To proceed to Cairo, Ill., for temporary duty. August 26, 1893.

APPOINTMENTS.

WILLIAM STURGIS BIGELOW, M D., of Boston, has been appointed by Governor Russell, a trustee of the Massachusetts General Hospital, as a successor to the late Frederick L. Ames.

W. R. STOKES, M.D., has been appointed assistant to the Pathologist at the Boston City Hospital.

RESIGNATIONS.

G. H. TILDEN, M.D., has resigned the position of Physician for Diseases of the Skin to Out-Patients, and C. R. BURR. M.D., that of Assistant to the Physician for Diseases of the Nervous System at the Boston City Hospital.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, October 9, 1893, at 8 o'clock, P. M.

Dr. George Haven: "Some Cases of Laparotomy."

Dr. Joel E. Goldthwait: "The Treatment of Hallux Valgus." Pathological specimens.

JOHN T. BOWEN, M.D., *Secretary.*

RECENT DEATH.

THOMAS FOSTER SHERMAN, M.D., M.M.S.S., died in Boston, September 26th, aged thirty-seven years. He was a physician to the Boston Dispensary and to the Home for Little Wanderers, assistant physician to the Children's Hospital and assistant Instructor in Diseases of Children in the Harvard Medical School.

BOOKS AND PAMPHLETS RECEIVED.

The Era Key to the U. S. P., a Complete List of the Drugs and Preparations of the United States Pharmacopœia, Revision of 1890–3, giving official titles, common names and synonyms of the drugs, chemicals and preparations of the Pharmacopœia, with doses in apothecaries weights and measures with equivalents in metric terms. Compiled by the Pharmaceutical Era. Detroit, Mich.: D. O. Haynes & Co. 1893.

The Theory and Practice of Medicine Prepared for Students and Practitioners. By James T. Whittaker, M D., LL.D., Professor of the Theory and Practice of Medicine in the Medical College of Ohio; Lecturer on Clinical Medicine at the Good Samaritan Hospital; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians, of the American Academy of Medicine and of the American Medical Association. With a chromo-lithographic plate and three hundred engravings. New York: William Wood & Co.

A Dictionary of Medical Science; Containing a full explanation of the various subjects and terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Pathology, Surgery, Bacteriology, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Obstetrics, Pediatrics, Medical Jurisprudence and Dentistry, etc. By Robley Dunglison, M.D., LL.D., late Professor of Institutes of Medicine in the Jefferson Medical College of Philadelphia. Edited by Richard J. Dunglison, A.M., M.D. New (twenty-first) edition, thoroughly revised, greatly enlarged and improved, with the pronounciation, accentuation and derivation of the terms. In one magnificent imperial octavo volume of 1181 pages. Philadelphia: Lea Brothers & Co. 1893.

Lectures.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XVII.

FOREIGN SUBSTANCES IN THE THROAT.

Where do they go? Most likely to go into the alimentary canal. Occasionally they pass into the trachea. What different symptoms do they produce according to where they happen to lodge? In other words, what is the differentiated diagnosis between a suspicion of a foreign substance in the œsophagus or in the trachea?

If in the œsophagus, we naturally have great difficulty and reluctance in swallowing. Moreover, there is rapid increase in the secretion of all the fluids which assist in mastication and digestion in the mouth — great flow of saliva and mucus, that is quite common. These effects are not produced if the foreign substance has gone into the air-passages. If in the air-passages, there is no difficulty in swallowing. There is not an increase in salivation. If the foreign substance is in the œsophagus, it catches on one side or the other. The patient always inclines the head sideways and forwards to relieve the tension of the œsophagus; so that the characteristic position is a little like that of wry neck, where a foreign substance is in the œsophagus. Stabbing pain on swallowing, reluctance to swallow, soon followed by inability to swallow; if inability to swallow, the saliva constantly druling — that comes next in the stage. Soon after that, œdema of the throat, outside, under the skin; noticeable swelling and puffiness around the site of the foreign body. Peculiar position of carrying the head, salivation, inability to swallow and œdema — these seem to be the most marked symptoms when a foreign substance is in the œsophagus.

Now, on the other hand, if it has gone into the trachea, at first it produces intense symptoms of spasmodic croup. The foreign substance rides up and down beneath the vocal cords with each inspiration and expiration, strikes against the bottom of the glottis; produces irritation, spasmodic closure; and hence we have all the phenomena of spasmodic croup. The child appears to be suffocating. That passes off in a little while. The foreign substance drops to the bifurcation of the trachea, usually, and rests there; and beyond a sibilant, uneasy sort of breathing, there is not much indication of its presence. The characteristic position of the patient is rather upright and backwards, as they hold the head in croup, so as to lengthen the trachea, and give the best access of air. If there is any characteristic position, it is rather with the neck extended. There is no difficulty in swallowing; no salivation. If the foreign body remains, speedily bronchial secretion is excited, and necessity to expectorate comes on. That requires cough. Cough dislodges the foreign substance, drives it up and down against the vocal cords. There is then a repetition of the paroxysm of croup, which subsides again. I was once called to a case where a foreign substance was really the cause of the trouble, but the child was supposed to have the laryngeal stridor of spasmodic croup and nothing else, for several days and nights. Next positive bronchitis comes on; sometimes broncho-pneumonia. The child grows quite sick; goes through an attack of slight pulmonary inflammation, and then there is left chronic bronchitis, with frequent attacks of cough; every attack of cough bringing on an attack of spasm of the glottis. We have, then, if a foreign body has been some time in the trachea, the symptoms of chronic bronchitis added to those of spasm of the glottis; and the whole phenomena are somewhat like those of whooping cough, for which they may be mistaken unless a careful observation is made. Fortunately, the child, if old enough, almost always says that it has swallowed something; or if not old enough, the majority of them are watched and seen to swallow something.

Once in a while one sees a case where the symptoms are mixed, and where it was hard to say where the foreign body has lodged. Subsequently, however, after operating and extracting the foreign body its position explains why its phenomena were so varied. When the foreign substance happens to get caught in the gullet, just behind the arytenoid cartilages, it provokes the fibres of the pneumogastric, and brings on spasmodic symptoms and difficulty of breathing; but it very rarely catches there. If you see a bi-vertical section made of the head and alimentary canal, you will find that the pharynx is a funnel-shaped cavity tapering to a point near the œsophagus. This point is just behind the cricoid cartilages; and at this point the constrictor fibres cease and the circular fibres begin. At this point there is a sort of purse-like constriction; and that forms a little ledge; and it is on that ledge that the foreign substance, if swallowed into the alimentary canal, almost inevitably catches; consequently, if the foreign substance has got into the throat, passes beyond the voluntary control of the palatine arches and cannot pass down, in nine cases out of ten it will lodge on this little ledge, just opposite the cricoid cartilage, and preferably on the left side, because the œsophagus inclines to the left in its passage down into the thorax. In this particular case I spoke of, the foreign substance did not go so far; and irritating the back of the larynx and arytenoid cartilages produced the symptoms of difficulty of swallowing and difficulty of breathing; but ordinarily the substance that is lodged at the commencement of the œsophagus produces only the symptom of difficulty of swallowing.

There is another class of cases in which not only difficulty of breathing is produced by a foreign body in the air-passages or in the œsophagus, but even suffocation and death. Such is the case in which a bolus of soft food is swallowed hastily, drops through the pharynx, lodges on this ledge, and there is too big to pass, and necessarily compresses the back of the trachea. The back of the trachea is devoid of cartilage. It is quite conceivable that a foreign body may compress there and produce death by suffocation. This is the ordinary way in which deaths are occasionally reported as occurring while the patient is eating. The patient is eating carelessly some large mouthful of soft substance; jumps up; throws up the hands; falls to the floor; turns blue; ceases to breathe, and dies. It is due to a bolus lodged, not in the trachea, but in the œsophagus, and pressing in on the back of the trachea. If assistance can be efficiently rendered at the moment,

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

and a probang were at hand, so that the substance could be pushed down a little further, it would drop lower down into the œsophagus, and the patient would be saved.

The cases where foreign substances are inhaled, so to speak, into the air-passages, and are large enough to produce death by suffocation must be excessively rare, if they exist. In proof of that is the fact that so many foreign substances have been extracted from the trachea which have not caused death at the time of their first being drawn in; notably coins as large as the English sovereign, copper pieces and silver pieces have been carried into the trachea, producing spasm, but not immediate death.

So much for the essentials of diagnosis.

Now, in order to complete this part of the subject, we will follow up a substance supposed to have gone into the œsophagus, before taking the other class which have gone into the trachea. Most of them go down. A few of them lodge temporarily; and then after a few efforts, by swallowing a bolus of bread or drinking a draught of water, are swallowed.

Still another class are vomited up. The patient passes the finger down the throat and the tickling produces nausea, regurgitant action of the œsophagus comes on. The foreign substance is thrown up with the vomitus and the patient relieved. A considerable percentage of substances swallowed never get as far as the back of the cricoid cartilage, but lodge in the pharynx. Those are generally extracted through the mouth; many of them by the finger of the surgeon or physician when he arrives. The best way is to put a wedge between the teeth: put the finger in as far as possible to sweep around; and in very many cases bones, or fragments of meat containing bones in them, foreign substances like pins, hair-pins, shawl-pins put in the mouth by children, are readily detected, if they have not gone far beyond the palatine arch; and can generally be brought out by the finger, or reached by the finger, and extracted by the other hand with forceps. A large class of substances go into the œsophagus, lodge temporarily, but pass down and disappear from view; yet they give the patient the sensation and the belief that they are still in the œsophagus. That is the hysterical class of cases. They are more numerous, I think, than the real class of cases. Such a patient will come in and say he is quite sure he has a bone in the throat; that he got it in two to four days before, perhaps; and he is quite sure it is still there. You are quite sure that it is not there by the mildness of the symptoms; for no human being can tolerate a sharp substance in the œsophagus three days without producing intense local and constitutional symptoms. In such cases as these it is better, usually, to pass the bristle probang down gently, and then withdraw it. You find nothing. The moral effect is marked; and it needs only the effort of faith on their part to get them well.

Foreign substances which really lodge at the top of the œsophagus and do not become dislodged either upwards or downwards are then not very numerous; and when they are there they produce such a marked series of phenomena that there can be no mistake as to their presence. If then the patient with a history of having swallowed something he thinks has not passed, after two or three days presents the characteristic attitude, total inability to swallow, druling of saliva and especially commencing œdema of the neck, we feel that something must be done, at once, to relieve him.

Let us consider for a moment what takes place if they are not relieved. Numerous clinical histories have been collected, and quite a large series of experiments made on dogs, by inserting foreign substances into the throat and leaving them. These experiments have shown that the foreign substance which remains beyond the third day almost always, if it remains unmoved, provokes abscess and eventual perforation of the wall of the œsophagus, and the various consequences that may follow; and a periœsophageal abscess may be behind the œsophagus, may be at the sides, may be in front. You will remember from the arrangement of the cervical fascia and the looseness of the tissues on which the pharynx, larynx and trachea glide in the action of swallowing, that there is really no barrier stretched across between the mediastina and the spaces of the neck; and if an abscess forms, there is nothing to prevent its gravitating down into the thorax and eventually penetrating the pleura; sometimes perforating the large vessels, and leading to death from hæmorrhage; frequently penetrating the air-passages and causing death by suffocation; and, in some rare cases, where the patient lives long enough, and the abscess forms behind the œsophagus, leading to denudation of the tissues over the bodies of the vertebræ, and positive caries of the spine itself. Usually, however, where the foreign substance remains long enough to provoke abscess, the case goes on to a fatal termination in the course of a week, or ten days; and autopsies have proved that such is the usual result, and such the destination of the foreign bodies. A foreign substance left in, means abscess; sometimes coming on in three or four days; and death taking place in one or two weeks, in the majority of patients.

What then shall be done? Extraction through the natural passages, through the mouth, is of course the first and most natural idea which would occur to one, and it has often been practised with entire success. Loops, snares, forceps and various devices are used to slip down into the œsophagus and to catch the foreign body and bring it up. The snares and nets have often brought up coin; the loops and forceps have often brought up substances like bone or pins. Great care and gentleness of course have to be used in manipulating and in extracting; for otherwise we shall push the edge or point of the foreign substance, if it happens to be sharp, through the walls of the œsophagus, and make that perforation which we dread. It is quite possible, also, to make a retropharyngeal abscess and perforation by the rough use of even a simple probang. So that in that class of substances which we judge it is safe to push down into the stomach, where there is a bolus of soft food or some vegetable substance, something not sharp and hard, or even a coin, such substances as that, we may push down by a probang with a sponge on the end; but we must use care and gentleness especially in that point behind the arytenoid cartilages where the pharynx first enters the œsophagus and lies like the finger of a glove; we must be especially careful there, or we may perforate the back of the alimentary canal, and lead to the retropharyngeal abscess, which would not have been caused by the foreign substance. One or two instances of death have occurred in that way. Pushing down or extracting through the natural passages is to be attempted, if the substance has not been there too long; but if the sub-

stance has lodged there as long as the third day, and œdema of the throat and threatening abscess is already imminent; it is questionable whether other methods had not better be used.

A few years ago there was revived and brought back from India an instrument which has been of the greatest assistance in extracting foreign bodies, called the bristle probang; it has a little collar of bristles attached to an ordinary probang sliding in an elastic catheter; when you pull out the probang, it forms a circle of bristles, and sweeps the œsophagus, and frequently brings out the foreign substance. Care must be taken to see that the bristles are all perfect; that their rounded ends are turned in. All parts of the instrument must be thoroughly examined and felt, at first, for fear that something may break off in the œsophagus in the struggle of the patient, while withdrawing the instrument. It is passed down gently until you are sure that it is near the cardiac orifice of the stomach; then unfold the little bristles, and withdraw slowly and gradually; and in very many cases the foreign substance is brought out entangled in the bristles. Blood almost always follows, whether the foreign substance is brought up or not. There is a little scraping of the mucous membrane which makes it bleed. The patient is sore for a few days afterwards, whether a foreign substance is there or not; but that soreness soon passes off. Carefully used it is a harmless instrument; and it is so reliable, that it has probably diminished the chances of any one doing an operation for a foreign body in the œsophagus, very much.

A substance may go into the throat of such a nature that you do not dare to push it down; and having been there so long that there is œdema and fever and other evidences of commencing infiltration, you do not feel it is safe to manipulate; what is left to do in order to save the patient's life? Obviously to try to remove it by external incision in the neck. This course would seem to be so plain, that it is quite surprising that although it was done early in the eighteenth century, it fell totally into disuse, and it was not until about 1842 or 1843 that it was revived again; and then with timidity; and not until about 1868, that it was done with frequency.

Up to 1868 I could collect only twenty cases; but at the present time I can find one hundred and fifty-nine; so that in the last twenty years one hundred and thirty operations have been done; and previous to the last twenty years, twenty operations had been done. This shows the immense progress the operation of œsophagotomy has made since it was found that it could be done safely. What was the bugbear in the way? People were doing quite as dangerous operations about the throat long ago. The older surgeons back to the time of Velpeau and the elder Dr. Warren did the most terrible operations with safety, and without ether. The reason was the belief that, if the œsophagus was opened, it would never heal; and that a fistula would be established which would forever render the life of the patient miserable; that fluids of all kinds would be constantly regurgitating through the wound in the throat, that an œsophageal fistula would be a permanent thing; and that, if the œsophagus was opened by the passage of nutriment and the movements of deglutition, healing would never be brought about. It was then the fear of a fistula, more than anything else, that interfered with the progress of the operation. Now, however, we know that that fear is groundless; and experience has demonstrated that wounds there will heal, and without sewing also; will fall together and heal by granulation, without sewing, perhaps faster than when they are sewed up; and a good many operators, of whom I am one, prefer to do the operation without sewing; and it heals exactly as well. So, also, in a number of cases in which I have opened the pharynx and made large openings into the throat about the region of the tonsils, the back of the pharynx and the arches of the palate, for various purposes, in no case has there remained a fistula; in no case have they been sewed up; and in many cases there has been no leak of food from the first moment after the operation was done; the action of the muscles of the pharynx closing the orifice. In the œsophageal cases I have had healing take place, always, in about two or three weeks, and never longer than four weeks. You need not imagine if you happen to incise to remove a foreign body that you will not have a temporary fistula, for you will. If you open the passage as low down as this, the first efforts at deglutition will be followed by the spouting out of large quantities of fluid through the opening. Gradually, as the patient goes on day after day, the quantity grows less and less; and from being a stream it becomes drops, and presently ceases altogether.

The fear of a fistula being dismissed, there is really nothing which should render the operation for extraction of foreign substances through the œsophagus any more difficult or dangerous than the ordinary operations of surgery. I say any more dangerous, with good proof, because in the cases I collected myself, a good while ago, the mortality of operated cases was just about 25 per cent.; and in the table which I have just taken from Dr. Ashurst, where there are 159 cases, there are 24 deaths, or scarcely one-sixth; so that it may be safely said that in the cases of foreign substances, where it is necessary to operate, three-fourths get well, and one-fourth, at the most, die. On the other hand, if let alone, it is almost sure that 100 per cent. will perish. Moreover in the twenty cases I collected it is instructive to know, that the four or five which terminated fatally after operation, had been deferred until abscess had already formed, and secondary absorptions, as proved by the autopsies, had taken place. As in the case of strangulated hernia, after fair attempts have been made to remove the foreign body by the natural passages, the sooner such an operation is done the safer for the patient; and the quicker the healing.

The operation is done by an incision similar to that for tying the carotid artery; and the sheath of the vessels is found but not opened; the edge of the sterno-mastoid, of course, is found, and then the vessels in their sheath; with the pneumogastric; — the sterno-mastoid is drawn outward and the larynx, myolohyoid muscle, and the long muscles attached to the larynx are drawn inwards; and gradually we pick our way down to the œsophagus. There is a place left by nature, near the cricoid cartilage, through which we may pick our way down until we may go to the pre-vertebral fascia, if we wish. The superior and inferior thyroid arteries and superior laryngeal nerve, and the recurrent or inferior laryngeal nerve, are the things to be looked out for. The first three are easy to look out for; the other is not. It is important not to wound the recurrent laryngeal nerve. It controls the sensibility of the larynx; and any impairment of its fibres

is a certain injury to the vocal cords. If we avoid that wall of the œsophagus which lies near the trachea, we shall not wound the nerve; hence the incision should be made on the postero-lateral part of the œsophagus; that is, on the side and towards the rear of the œsophagus, and towards the vertebral column. It is very easy to get down there; then you put in the finger and see if you feel any foreign substance through the walls of the œsophagus. Usually you cannot. Then you find the only difficulty of the operation, and that is to open the œsophagus. The œsophagus is like the collapsed finger of a glove; lies in between the trachea and the vertebral column; nothing to stretch it. You are forced to introduce something as a guide. You pass a long catheter or stomach-tube into the mouth; into the pharynx and down past the point of incision. That brings the œsophagus up into view. You can then cut upon the posterior surface, upon the catheter, and make an opening, and then withdraw the catheter and enlarge the opening at your pleasure, and hold the sides open, and search for the foreign body. Sometimes it is opposite; sometimes below; sometimes above. It is extracted. There is no hæmorrhage. That is all, I think. There is nothing more to do, except that I should advise that the patient have absolutely nothing to eat for twenty-four hours; not a drop of any liquid or food. Thirst may be allayed by watery enemata thrown into the rectum; by allowing the patient to bathe his face and hands and wrists, which is a great comfort when feverish; and nothing should be given for the first twenty-four hours. Subsequently to that I have been in the habit of letting the patient swallow such liquids as were simple and homogenous; first water and then milk; or, if they wish it, strained beef-tea or broth. Iced milk is very grateful to the patient. The patient will sit up in bed and drink with perfect freedom and ease; get about one-third of the milk into the stomach, and the rest will pour out through the wound in a perfect jet. Why not give the nutriment the first twenty-four hours? To give the parts time to glue together a little, so that the fluids may not trickle down between the layers of the tissues and give rise to deep cervical abscess. Why not feed the patient with the stomach-tube instead of allowing anything to pass out through the wound? You may do so, if you wish. I have not thought it necessary. You must be aware, if you are going to feed the patient with the stomach-tube, that the tube has got to be passed below the level of the wound. Now this requires the stomach-tube to be passed a good ways. It requires you to steer it by the edges of the wound without irritating or making the parts bleed; and that has to be done three or four times in the twenty-four hours. I think this would interfere with the healing of the wound more than letting it alone. Some operators do one way, and some the other.

The essential thing is to make the diagnosis; do not wait too long. Get down to the œsophagus; stretch it, and cut in on the posterior side; extract the foreign substance; and, if the case has not been suffering too long, it will recover, almost certainly; at any rate, in three-fourths of the cases. The tolerance of nature in healing these cases is very remarkable. That was well instanced in a case of mine, which I always mention because it was very remarkable. The patient was a very stupid, drunken fellow, who, the first time, got a pin in the throat, and I did the operation; opened the œsophagus; removed the pin; kept him in the hospital three or four weeks, until he ceased to discharge any fluid through the sinus; and until the cut was a mere little line of granulations, almost healed; then I let him go home. He promptly improved the opportunity to get drunk again; and then tried to eat some rough meat with bones in it; and got a piece of it in his œsophagus, but coughed it out. It did not lodge there and he did not require any other operation. By this occurrence he burst open the whole wound and came into the hospital with a fistula thoroughly established. It looked discouraging with regard to healing; but after a month or six weeks it closed entirely. That shows the power of healing, contrary to the old idea that it was not safe to touch these cases at all.

FOREIGN BODIES IN THE AIR-PASSAGES.

The symptoms I have already described. They may be retained there a long while without killing the patient; many weeks; sometimes several months. Some substances, which are apparently innocuous when they are drawn into the trachea, afterwards change in a way to destroy life. It is very curiously the case with the vegetables like beans and peas. Beans and peas are favorite playthings with little children. They are apt to get them into the nose, or mouth; and if the child has a bean in his mouth and suddenly his attention is distracted, or it laughs or cries, and opens the mouth and inhales, the bean slips down past the guard of the epiglottis, and gets into the trachea, and lodges at the crossing of the bronchi; there produces the usual phenomena, but is not enough to obstruct respiration; but after twenty-four hours it excites secretion, swells, and leads to death from pneumonia, or atelectasis of the lung. Bear in mind that foreign substances always obey the law of gravity; and that any substance which has a large end and a small end will go down large end first. This is especially true of shawl-pins. The shawl-pin is an even pin all the length, with a wax or glass head. When coughed up and down the point is constantly cutting and pricking against the bottom of the larynx. Such a pin I removed from the trachea of a child after it had been in six weeks. This child had suffered a good deal from chronic bronchitis.

The symptoms are marked. What is the relief? The old remedy was to hold the child up by its legs, and to pound on its back, — occasionally, effectually. It was dangerous, however. The child is held upside-down, screams and cries, the substance drops on the glottis, spasm of the vocal cords is produced. Either it relaxes and the foreign substance comes out, or the child chokes to death in a very short time. The better way probably is not to attempt such a thing as that unless the means for doing tracheotomy are already at hand.

Opening the trachea is the only way to get at the foreign substance; and in this condition of things the child, not being in a state of profound dyspnœa except occasionally, it is perfectly proper and easy to give an anæsthetic — chloroform or ether. The child narcotized; the trachea opened in the usual manner; the sides are held open with hooks, and efforts made to find the foreign body. The foreign substance is sometimes thrown out in the gush of air that follows the opening of the trachea; and the substance occasionally is lost. If it is not expelled, it comes up into sight and disappears again. This cannot be the case with a substance which is impacted. Take a bean which has swelled. Symptoms would persist; no foreign substance would

be seen. Nothing would appear. Then we should search the trachea with delicate curved forceps; and we can generally make out whether the two halves of the bronchi are clear or not. This failing, the next resource is to leave the trachea open; but not to put in a trachea-tube which would interfere with the expulsion of the foreign substance. The trachea must be fastened open; say, put a stitch opposite on each side, with two elastics attached, and fasten about the neck of the child; and carefully watch in order that nothing bad takes place; because you will remember that the child can breathe with its trachea held open in that way perfectly well as long as it keeps the head straight and lies on the back; but when it turns on the side everything shuts; therefore it has always seemed to me not so philosophical to do tracheotomy, and have the child treated without a tube, as it is to put in the trachea-tube. Excessive care in nursing must be had afterwards to prevent the child from turning the neck to one side, and suffocating. For these foreign substances you may sew the trachea open, and have the child watched, day and night. Many cases have occurred in which the foreign substance has been expelled during the first few hours after this has been done. Finally the foreign substance has been found lying on the pillow, where it had been expelled. After this, what? It may be safer perhaps to leave the cut in the trachea open, or perhaps put in a tube, for a day or two, until any chance of œdema of the glottis has gone by; and then the wound is allowed to granulate and heal, which it always does with readiness.

The operation of tracheotomy itself. There is no need to describe it. You see it done. You probably will all have an opportunity to practise it, sooner or later. The important question is what are the symptoms in the patient; no matter what the disease is, what are the symptoms in the patient which make you think now is the time to do it? We all know it is safer to do it early than late; that prolonged difficulty of inspiration and expiration; prolonged croup; prolonged spasm of the glottis, lead to changes in the air cells of the lung which render the child less liable to recovery after tracheotomy is done, if done late, than it would be if done early. The air cells get distended and stretched, precisely as they do in the case of the man who is constantly blowing upon wind instruments; who fills his chest and lets the air out slowly through the holes of the wind instrument to produce certain notes. It is well known that pulmonary emphysema and dilatation of the air cells is a common affection in a person who spends his life in blowing the flute, or clarionet, or cornet. A similar condition seems to be produced, rapidly, in the delicate air cells of the young child, after they have been having this forced retention of air in the chest from imperfect respiration through the chink in the vocal cords; hence the importance of doing tracheotomy in membranous croup, or diphtheria, early, rather than late.

Now there are certain symptoms of what we call dyspnœa, or difficult breathing, that come on, that are very significant. I would not call your attention to those which are so marked that any one who looks at the child would say "it is suffocating and near its death," when its nails have become lead color; when the complexion is slate-colored and blue; when the respirations are sighing and irregular and very imperperfect; and when the child is in a state of stupor from carbonization of the blood; — any body could recognize that condition, and, generally, then it is too late to do any good at all. The symptoms which are significant are these, — great pallor; pasty look of the face; constant restlessness; extension of the head and neck backwards to lengthen the trachea; croupy breathing, of course; retraction in the space over the top of the lungs, behind the collar bone; still more marked retraction at the epigastrium. Uncover such a child gently, and see and watch his breathing. You will find the intercostal spaces drawn in at every attempt to inspire; the thorax thrown out with immense force; retraction then of the abdominal muscles; retraction of the supraclavicular spaces; throwing back of the head; restlessness; pallor; a croupy sound, are the most prominent signs. When this class of symptoms are persistent, after a little watching, if you look carefully at the history of the case and find that they have been developing slowly a few days; that the voice has gradually become indistinct; that membrane may or may not have been seen on the tonsils; that all the symptoms point to a permanent obstruction in the larynx from some cause; — then is the time to do tracheotomy, or intubation, if you prefer that method of operating.

PULMONARY TUBERCULOSIS WITH ESPECIAL REFERENCE TO ITS PROPHYLAXIS, HYGIENIC AND CLIMATIC TREATMENT.[1]

BY EDWARD O. OTIS, M.D., BOSTON.

"A sick man helped by thee, shall make thee strong." — *Browning.*

(Concluded from No. 14, page 340.)

Exercise. — We are all agreed, I suppose, that tuberculous patients with much fever or who suffer from hæmoptysis should be kept at rest. With these exceptions, however, more or less exercise is to be advised for all cases of phthisis and will naturally come with the out-door life. The variety will depend largely upon the taste of the patient; and the amount, which must be carefully determined, upon the stage and type of the disease and the strength. If one is dependent upon his own exertions for his support there are many light forms of out-door work; or if, of necessity, he must spend a part of the day at work in-doors, he may utilize the intervals in a variety of out-door sports or exercises. If he is strong enough he may ride horseback, or a bicycle, or hunt picturesque bits of scenery with his camera, or fish or shoot. In the winter, skating, snow-shoeing or tobogganing may be the form of exercise. To have the mind pleasantly occupied at the same time is of decided advantage, and fortunate the man who has a hobby in the form of some out-of-door sport. While spending the summer at Estes Park, Col., some years ago, there was a poor fellow there, I remember, with advanced pulmonary disease, whose distressing cough often kept the ranch awake at night. In spite, however, of his miserable condition, he would persist in his favorite amusement of trout fishing whenever he was able to drag his emaciated form to the streams. When I left the park, I expected that a few weeks would be the end of him; but what was my surprise to learn that he was still fishing there the following summer. Out-door life in a mountain climate, exercise, and a mind pleasantly occupied, were evidently the factors in prolonging a not altogether unhappy existence against such heavy odds.

[1] An Oration delivered before the New Hampshire Medical Society, June 20, 1893.

Whatever the form of exercise one thing must be insisted upon, namely: deep, full respiration and chest expansion. I have dwelt upon the importance of this as a prophylaxis of pulmonary tuberculosis; absolutely necessary is it in the treatment of the actual disease; and I believe it is one, if not the most effective factor in producing an arrest of the disease. Nature does this in the high altitude climate, which is, perhaps, the most important effect of altitude in climatic resorts. The rarified air of these regions stimulates one to take fuller and deeper respirations in order to obtain the requisite amount of oxygen, thus inducing greater chest expansion and more complete ventilation of the lungs. During the construction of the Oroya Railroad in the Andes of Peru, at an altitude of 15,640 feet,[12] some measurements were made of the native Peruvians employed at Yauliyacu with the following results:

Age.	Height.	Chest.
14 years	4 ft. 10 in.	36 in.
24 years	5 6½	36
21 years	5 4	36
16 years	5 0	34½
30 years	5 4½	34½

You notice the enormous chest circumference for the height. An American engineer increased the measurements of his chest four inches in two years by exposure to the rarefied air in these Andes. "The only explanation I can offer as to the nature of the influence of altitude," says an author quoted by Evans,[13] "and one to which I shall hold until something more satisfactory presents itself, is that people who have been born and brought up at great elevations have been always under the necessity of making frequent (or perhaps deep) inspirations, as a consequence of breathing a rarefied atmosphere: that they are continually practising a kind of pulmonary gymnastics, from which there proceeds a vigorous development of the breathing organs, and a greater power of resistance on their part to noxious influences from without."

There has recently been published an exceedingly interesting little book, written by an intelligent layman, narrating his experience in fighting pulmonary tuberculosis in his own person.[14] He attributes his cure largely to the habitual use of an inhaling tube. "To this instrument," he says, "I owe more than to all medicine, or to out-door exercise; and were I compelled to choose between the use of the tube for an hour and a half a day, and all other exercises and medicine without, for the removal of pulmonary tuberculosis, experience and observation would lead me to prefer the tube." If you will consider a moment the action of this little machine, you will observe that it is nothing more or less than a simple method of producing deep breathing and chest expansion, which is just what I have been contending for, and the extreme importance of which I have been trying to impress upon you. "To the use of the tube," continues Dr. Buckley, "the amount of time spent in walking and riding in the open air, and observance of certain additional hygienic methods together with the determination not to die, I owe my recovery." Merely to tell a patient to practice deep breathing is not sufficient. As a rule, he does not know how to do so, and often his respiratory muscles, especially the intercostals, are so weak that he cannot do it. Time and persistence and careful instruction will be required to accomplish this. In the beginning one should note, by measurement, the degree of chest expansion as well as the lung capacity, and these will serve as a basis of comparison with subsequent measurements, and indicate the effectiveness of the breathing exercise. I have already suggested the simple methods of accomplishing chest expansion; either with the arms at rest and the hands on the hip, or by an upward movement of the outstretched arms; slow, full inspirations are to be taken; or one may use the inhaling-tube, which is a useful device for accomplishing the same thing. If one has access to a well-appointed gymnasium, the different forms of lung-expanding apparatus can be used. It is hardly necessary for me to add that gentleness and moderation must govern the beginning, and the quantity of exercise should be adapted wisely to the patient's strength.

Habitation. — As pulmonary tuberculosis is a disease of in-door life, as little of this life should be lived as possible; all crowded halls and rooms, churches, closed vehicles of all kinds, street and steam cars should be avoided whenever possible. In the city, when one is obliged to ride upon a closed street-car, it is far safer to remain outside, even in cold weather than to undergo the risks of the generally impure air inside. The eloquent plea that the secretary of this society has recently made for better ventilation in railroad cars, and to which I call your attention with great pleasure, I trust will produce its results.[15] The church prayer-meeting, I am sorry to say, is often unmindful of the fact that holiness is more beautiful when given expression in a pure atmosphere. A country church in winter, and an unventilated vestry heated by a tight stove are prolific breeders of pulmonary tuberculosis; keep your patient out of them. When he is obliged to be in-doors, his room should be large and sunny and with but little furniture and that of the simplest kind. It should have painted floors that can frequently and easily be washed, and if possible walls without paper, but painted and varnished. Everything should be kept absolutely clean and well-aired. It is better to have a separate room for a bedroom, which should be large, sunny, and well ventilated, and neither gas nor a lamp should be used in it. It is well to bear in mind that an ordinary gas burner or lamp consumes as much oxygen as several adults. Both rooms should have an open fireplace; this must be insisted upon; it is the most ready and effective means of ventilation, and when heat is required, the air in the room can be kept cool and the patient warmed by radiation. Often, at not a large expense, a chimney can be added at the side of the house for the fireplaces, as is so frequently seen in the South. A large Franklin stove fulfils the purpose very satisfactorily. A damp cloth should be used for cleaning the furniture and the floor, instead of dusting and sweeping. The temperature of the rooms ought not to be above 65° F., or at the most 70° F.

Consider the condition of things in the average country house during the colder months of the year? The air is impure and stagnant; there is no ventilation; the temperature is perhaps 75 or 80, and the source of heat a tight stove. No daily thorough airing-out is ever thought of. Injurious enough to the most robust is this wretched atmosphere. What must be its effect upon the phthisical patient whom you so often find breathing it?

If the situation of the residence can be chosen, a dry, sandy soil should be selected — not a clayey one. Sometimes, if the patient is living in a damp place, he may have some friend or relative who is more favorably situated, and who will receive him into his house.

The drainage and purity of the water should also be investigated. Wherever the abode, let it have an abundance of fresh air, keep the windows open whenever the weather will allow. It is said to be the habit of the present Chief Justice of this State to remove every window from his residence at the advent of mild weather, and not to replace them until compelled to do so by the approach of colder weather in the autumn; an example well worthy imitating with our phthisical patients. Impress upon them the dangers of in-door life; it is for those of strong lungs — if for anybody — not for the weak chested. I remember an Irishman who came to my clinic with some kind of a bronchial trouble, and who asked me how much longer he should stay in the house. "In the house," I replied; "we should all be better if there were no houses." "Begorra, I think you are right, doctor," was his reply. At any rate, we must admit that living in houses is accompanied with much risk.

Clothing. — In this climate the phthisical patient should wear woollen underclothing throughout, both winter and summer. Differences in the thickness may be made according to the seasons, but woollen all the time. It matters not so much what the outer clothing is, only do not permit the patient to be too heavily clad, particularly about the chest: Chest-protectors and the various kind of jackets, I believe unnecessary, if not injurious. A daily bath I think essential, the temperature being regulated according to the season. Sea-salt is often a desirable addition to it. In winter it can be taken before the open fire. A word as to the care of the sputa, a most important matter. Under no condition should it be received upon a cloth, handkerchief, or paper, or deposited upon the floor or ground, where it will dry and be disseminated in the air. Experiments have shown that dried tubercular sputum may be kept for periods of from ninety-five to one hundred and twenty days, and yet when innoculated into guinea-pigs may produce tuberculosis. It is a good plan to do as Dr. von Ruck told me he was in the habit of doing at his sanitarium in Asheville; frighten the patient by making him understand that, unless he exercises every precaution in regard to this, he is in danger of reinfection, or of infecting the still healthy lung portions. I generally use the small paper receptacles made for this purpose, with absorbent cotton at the bottom impregnated with some reliable bacillicide, such as a five-per-cent. solution of carbolic acid or a solution of corrosive sublimate (1 to 500 or 600). The cotton is to be renewed every day or several times a day, and the receptacle itself is to be frequently destroyed. We must ever remember "that the sputum of subjects of pulmonary tuberculosis, is of all the excretions the greatest source of danger."[16]

The last subject of which I shall speak is that of climate, and I shall only be able to touch upon some of the salient points of such an extensive subject. Let me begin with a sentence from Osler,[17] which it will be well for us all to bear in mind. "When," he says, "the disease is limited to an apex, in a man of fairly good personal and family history, the chances are that he may fight a good winning battle, if he lives out-of-doors in any climate, whether high, dry and cold, or low, moist and warm." There is much encouragement in this for those of us who have to treat the majority of our phthisical patients at home. Bear in mind also another point, that change, *per se*, is often of great value, and sometimes, on the contrary, destroys the effect of the most favorable climate. I have visited many climatic resorts of pulmonary tuberculosis in this country and in Europe, and am tolerably familiar with the literature of the subject; and from what I have learned my conclusion is that there is no *one ideal* climate for the cure of this disease. Neither could there be, for varying conditions of the individual and the disease require varying conditions of climate. For example, one climate will promote good nutrition in one patient, another in another. There must be an adapability of the climate to the case. "Climatic treatment," says Jaccoud,[18] "is entirely a question of individual adaptation, and the problem is to determine which residence would be most appropriate to the patient in question."

Sometimes it will be necessary to change from one climatic resort to another, according to the changes in the disease or the individual. Furthermore, I do not think we are able yet to say what are the exact essentials of an ideal climate. Certain requirements, however, I think, we are sure of: first, a pure atmosphere; second, weather such that the patient can be out of doors most of the daytime during the whole year; third, as near eternal sunshine as possible. Most important, but possibly not always essential, is a dry soil and sub-soil. Dryness of the air and an equable temperature are also important, but it does not seem to me that they are always essential, especially equability, as it is generally associated with moisture.[19] The temperature of the air is a minor consideration, I think. Of all, *purity* of *air* is the most important point. In considering climate we must always keep in mind that "Climates which benefit consumption are found to fulfil one or both of the following indications: (*a*) The improvement of the local condition: (*b*) the improvement of nutrition and constitution vigor."[20] Increased experience and observation have taught me that a warm climate is not necessarily beneficial or a cold one injurious. Indeed the most successful curative climatic resorts at the present day are those of a cold or moderately cold climate, at least some portion of the year. I have no confidence in the warm and more or less moist climates, as for example, Florida and Havana, as curative. They may be used temporarily as a preliminary training for the higher attitudes, in cases where the vitality is low and one needs to exist with the least exertion; or they may be used as sedative and soothing, where there is no hope of cure. Whatever the climate selected, there are certain conditions which, in my opinion, must be fulfilled by the patient in order to gain the maximum of benefit from it. They are: (*a*) A long continuous residence; he should remain until he is cured, or it is proved that the climate does not agree with him. (*b*) Good sanitary and hygienic surroundings. (*c*) Nutritious well-cooked food. (*d*) An out-door life. (*e*)

Exercise, unless especial conditions temporarily prevent. (*f*) A comfortable mental condition, and freedom from worry and anxiety. (*g*) To be under the constant supervision of a reliable physician.

I am more and more convinced of the great advantage of well-conducted sanitaria in climatic resorts. In many, if not the majority, of cases far better results are obtained than where the patient is left to himself. Success in the treatment of phthisis depends so much upon constant care in the detail of one's life, and this can be so much more satisfactorily done when constantly under the eye of a skilful physician and with the aid of all the equipment of a sanitarium. Unfortunately, I know of but few good ones in this country.

With these general considerations, I will briefly refer to certain especial climates and the regions where they are found, in which, experience has proved that pulmonary tuberculosis has been most successful treated. First, however, let me remind you that all stages of phthisis are not benefited by the same climate, and some by no climatic change, however favorable. Of course, the incipient cases are the most amenable to any good climate.

The classes of climate which have given the best results are: (1) the high altitude; (2) the medium altitude; (3) dry aseptic climates without altitude; (4) the oceanic climate.

Thus far the best results have been obtained, in my opinion, in the high altitude climates as represented in Europe by the Alpine health resorts, in the region about Davos; and in this country by various places in Colorado, particularly Colorado Springs. Davos is situated in a narrow valley, is of about 5,000 feet elevation, and is admirably equipped for the care of the consumptive. In Colorado an altitude of about 7,000 feet would give us a climate approximating to that of Davos, but superior in the amount of sunshine and clear, pleasant days. Colorado Springs is the best known to you and the best provided with accommodations. I believe, however, that there are many other places in this great State as (or more) favorably situated, if only good accommodations existed. Dr. Ruedi, of Denver, has recently suggested [21] Estes Park, a mountain plateau of great beauty and of about 7,000 feet elevation, as offering excellent climatic conditions for the treatment of phthisis; and I trust his plan of erecting a sanitarium there may soon be accomplished. I can testify to the wonderful charm of the park both in climate and scenery from a summer spent there a few years ago. Manitou and Denver are also resorts for patients. In the great Rocky Mountain zone innumerable high altitude resorts could and will in time doubtless be discovered and developed. I have need only to mention the high altitude resorts of the Andes, such as Santa Fe de Bogota, Quito, Arequipa, etc. They are obviously too far away to be of use to us, and we know but little of the local conditions existing there.

It is generally conceded that cardiac weakness, senile change, a nervous diathesis and pyrexia are contra-indications to the high altitude treatment. Lindsay [22] also includes rheumatism. The characteristics of the high altitude are: great purity of air, dryness of the air and soil, the coolness of the air temperature and the great warmth of the sun temperature, the rarefaction and low pressure of the air, the intensity of the light, the stillness of the air, and the large amount of ozone.[23] The effects of such a climate are: increase of the appetite, promotion of greater expansion and ventilation of the lungs, improvement of nutrition and digestion, and increase of muscular and nervous energy.

The climate of the medium altitudes resembles that of the higher, with the difference due to the less elevation, and the geographical situation. It is represented in Europe by many of the lower Alpine stations; for example, Les Avants (in the neighborhood of Lake Geneva, and 2,000 ft. above it), Gorbesdorf (in Siberia, 1,740 ft.) and Falkenstein (in Germany, 1,500 ft.) might be included in this class, and are famous for the sanitaria of Brehmer and Dettweiller. In this country we have, in the mountains of North Carolina, Asheville, 2,350 ft. high, with the admirable sanitarium of Dr. Karl von Ruck; South Western Texas and Southern California, inland, of an elevation of about 2,000 ft.; New Mexico, somewhat higher; and the Adirondacks, with an elevation varying from 1,500 to 2,000 ft. Near Saranac Village in these mountains is situated the sanitarium known to many of you by the valuable investigations concerning pulmonary tuberculosis, conducted there by Dr. E. Trudeau. Although cold and snowy in winter, yet patients remain there the year through. There are many regions in this State (New Hampshire) of moderate elevation, which, I believe, offer a fairly good climate for the consumptive, particularly in summer; such as Bethlehem, Gilmanton, Dublin, and others which will occur to you. That they are cold in winter is necessarily no objection for a continuous residence; the number of sunny days in winter, however, is somewhat limited and the climate is moderately moist. There is much to be done, it seems to me, in the careful investigations of the climatic resources of this State; only by a series of accurate observations extending over a number of years can any definite and trustworthy results be obtained. The pains-taking paper of the late Dr. Geddings [24] upon Bethlehem and Maplewood is an illustration of the kind of work that ought to be done.

Of the dry, aseptic climates of low elevation, Egypt is perhaps the best illustration abroad; there, on the borders of the desert, the climate is very dry and warm, the sunshine abundant, and the air pure. In this country there are various regions where these conditions exist; portions of Texas and Southern California, and the pine-belt of South Carolina and Georgia. Aiken, in the former State, is perhaps the best known resort, and its meteorology has been carefully studied by Dr. Geddings, whose favorable results in the treatment of phthisis there are doubtless familiar to you. Marietta and Thomasville, in Georgia, are also well known. Lakewood, in New Jersey, has many favorable conditions to recommend it — its dry, porous soil, environment of pine forest, good accommodations and easy accessibility. Minnesota and Canada must also be mentioned. If for various reasons the higher altitudes are inapplicable, we have these resorts of low elevation, which have produced good results. Of the oceanic climate, as illustrated by long sea-voyages, I have little to say, for the obstacles to its use are obviously so great that it can but rarely be employed. Surely one obtains here the purest of air and an equable temperature. Very much the same conditions can be found

[24] The Climatologist, August, 1891.

upon mid-ocean islands, such as the Madeiras and Canaries. In the latter is situated the valley of Orotava, "which Humboldt thanked God he had lived to behold." "Here the invalid may live in the open air — the air of the ocean." "The temperature never falls below 50° F., nor rises above 82° F., and it rains but forty-five days in the course of the year."[25] Surely a delightful spot in which to enjoy the benefits of an ocean climate!

If I were asked which of these classes of climate I should select for a case of pulmonary tuberculosis of good or fair general condition and not extensive disease, I should unhesitatingly choose first the high altitudes, for, undoubtedly, the best results so far have been obtained there. "A consumptive," says Solly,[26] "treated in an open resort in an elevated climate has three times as good a chance of recovery as has one treated in an open resort in a low climate, and twice as good a chance as one treated in a sanitarium in a low climate." The residence, however, must be a continuous one and perhaps for a life-time. Next, my choice would be Southern California, inland, or if I possessed greater knowledge of the region, perhaps, South-western Texas. Third, I should select Asheville, in North Carolina; and lastly the Adirondacks, or some of the resorts in the pine-belt of South Carolina and Georgia. There is a wealth of sanitaria in this country, with an almost infinite variety of climate, as yet hardly known and not at all developed. It remains for our profession to investigate with pains-taking fidelity these regions, and to make them available for the poor consumptive.

A few years ago in the mellowed light of the afternoon, it was my privilege to visit the great cathedral of Winchester. I was impressed with its majestic size, its grand and beautiful architecture, and its noble tombs to heroes and valiant knights of the Crusades. The atmosphere seemed heavy with the invisible spirits of those who left home and friends and all the richness of their lives to uphold the Cross in a distant land, and be true to the highest ideal of their day. As I wandered about, my attention was attracted by a humble tablet on the wall, erected to the memory of a physician. I have forgotten his name — that matters not — but I have never forgotten the tribute there to his services to suffering mankind. It was this, "The blessing of him that was ready to perish came upon me." What finer or more God-like deed, I thought, could be done by hero or knight, than to rescue those perishing from disease, and restore them to health and usefulness!

Fellows of the New Hampshire Medical Society, you go forth to meet during your next year's practice a thousand or more poor unfortunates ready to perish with the awful scourge of pulmonary tuberculosis. If you shall approach these cases with a greater hopefulness and a more determined spirit to help and cure them, and reduce the frightful yearly mortality, then, likewise upon you will "the blessing of him that was ready to perish" come. And what greater satisfaction can any true physician ask for than this?

A new use has been found for aluminium. It is said that the metal is to be employed in making artificial limbs.

GUN-SHOT WOUNDS OF THE JOINT.[1]

BY HERBERT L. BURRELL, M.D.

Every surgeon knows that in the past there was a frightful mortality attending gun-shot wounds of the joints, and that these injuries usually meant amputation; exceptionally resection. Since the introduction of antiseptics, in the few instances in which its principles have been applied, there has been great improvement in the results, so far as life is concerned. With the introduction of small-bore rifles, which all the European nations (and at last our own government) have adopted, must come a reconsideration of the whole treatment of gun-shot injuries, and especially those of the joints.

I shall divide this paper into headings, and shall make broad statements in order to elicit discussion. It is written at best on insufficient data: hence the conclusions which I draw are advanced with considerable hesitancy. We can begin with this proposition, which will, I believe, be generally accepted, that we shall never know the full effects of the small calibre projectile until a war has taken place, and until such a calamity has occurred we must depend upon experimentation and theoretical reasoning.

The headings will be:

I. The effects of the new .30, jacketed projectile upon joints and individual joints.
II. The "firing-line" treatment of these injuries.
III. The field-hospital treatment.
IV. Complications and prognosis.

Under all these headings I shall consider the differences in the injuries inflicted between the .30 and .45 calibre projectiles.

I. — THE EFFECT OF THE NEW .30 JACKETED PROJECTILE UPON JOINTS.[2]

A most complete series of observations have been made by Capt. Louis A. LaGarde, of the United States Army upon "The Comparative Difference between Certain Wounds Inflicted by the Projectiles of the Large and Small Calibre Weapons." I am under the deepest obligations to Captain LaGarde for the privilege of seeing the specimens of bone injury by these projectiles, and for his permission to make abstracts from his paper, which has not yet been published. It would be more fitting if Captain LaGarde were to write this paper, as the specimens are unique and very valuable.

Our own government has finally adopted the Krag-Jorgensen rifle, and the experimentation of Captain LaGarde was carried out with what is known as the "experimental Springfield rifle of .30 calibre." Its ballistic qualities are quite equal to those of the new Mauser, Leble or Mannlicher rifle. The following is a description of the more important ballistic properties of these weapons as kindly furnished Captain LaGarde by authority of the Chief of Ordnance, United States Army:

"The Springfield rifle which has formed the armament of our foot troops since 1874 is a .45 calibre gun, the projectile of which has an initial velocity of

[1] Read before the Association of Military Surgeons of the United States, Chicago, Ill., August 9, 1893.
[2] When the term, .30 jacketed projectile is used, it is meant to include all the various makes of jacketed lead bullets of .30 calibre, whether covered by steel, nickel or copper.

1,301 f. s. Its projectile is made of compressed lead, cylindro-conoidal, cannelured and lubricated, weighing 500 grains, impressed by 70 grains of black rifle powder.

"The experimental Springfield rifle is a .30 calibre gun, the projectile of which has an initial velocity of 2,000 f. s. Its projectile weighs 220 grains, is made of a German silver jacket filled with a lead core, and it is neither canellured nor lubricated. It is impressed by 36 grains of smokeless powder."

The velocity and energy of the projectiles of the two weapons at different ranges are as follows:

VELOCITY OF THE PROJECTILES OF THE TWO GUNS.

Name and Calibre of Weapon.	Initial Velocity. f. s.	500 yds.	1000 yds.	1500 yds.	2000 yds.
Springfield, Calibre .45 .	1301	873	676	531	429
Experimental Spr'gfield, Calibre .30	2000	1103	804	627	495

ENERGY OF THE PROJECTILES IN FOOT POUNDS.

Name and Calibre of Weapon.	Initial Velocity.	Weight Grains.	Muzzle.	500 yds.	1000 yds.	1500 yds.	2000 yds.
Springfield, Calibre .45.	1301	500	1879	846	507	313	204
Experimental Springfield, Calibre .30,	2000	220	1954	594	315	192	120

It will be seen by the first table that the initial velocity of the small calibre projectile is far greater than that of the large calibre, and that the striking velocity at all the ranges is greater.

The penetration of bullets is proportional to the squares of their striking velocities. For equal velocities the penetration is proportional to the density of section. The form of the bullet and its power to resist deformation are also concerned in the penetration.

Considerable experimentation has been carried out by German and French observers upon the effect of small-calibre jacketed bullets as compared with the soft or hard lead bullets, and all agree in their conclusions. Bruns, Noel, Delorme, Chauvel and Nimier, Rogardik, Thurnwald and Reger are all men who have contributed to our knowledge. It is interesting to note that the calibre of fire-arms as used in European armies, which was formerly 18 mm. has been reduced to 7 and 5 and 8 mm., and in proportion the weight of the bullet has been reduced from 50 grammes to 15. The rapidity of the bullet has been increased from 400 to 600 metres a second. Experiments upon wood, iron, water and earth have been carried out, and it has been found that the force of the penetration exerted has been increased five or six times, but that the concussion of the bullet has been decreased, and that it causes a wound very like a cylinder, whereas the leaden produced a conically-shaped wound, the base of the cone being at the point of exit.

All writers agree upon dividing the effect of bullets into zones. In Zone 1, which extends up to 320 metres, the .30 calibre bullet has decided explosive [3] effects, but less than the .45 calibre.

Zone 2, which extends from 400 to 800 metres. The bullet produces a wound without any explosive effect. It is cylindrical, and not like the conoidal wound of Zone 1. Bones are perforated and splintered, but retain their form. The effect upon the soft parts is perforative and not especially destructive.

In Zone 3, from 800 to 1,200 metres, the wound is cylindrical. The wound of entrance is not larger than the projectile; the exit wound is only larger when bone has been traversed. The bones are perforated, but seldom shattered or splintered.

No particular study has been made of the effect of .30 calibre projectiles upon joints by European observers, but reasoning from the effect produced upon bone and the soft tissues and the increased penetrating power of the bullet, the effect upon joints at the various ranges will at times be complex, but usually less destructive than that of the .45 calibre. In a joint we have various densities of bone; we have a closed cavity filled with synovia, which is a capital culture medium for germs.

There will be a great deal of difference between a wound of the knee-joint and one of the wrist-joint, and it will be of great importance to decide at what range the bullet was fired. It can be readily understood that in a bullet wound of the knee-joint bits of the trousers and underclothing may be carried before the bullet, which may lodge within the joint and act as a foreign body. This would not be probable, for instance, in the elbow-joint or the ankle-joint. These considerations would naturally lead the surgeon to thoroughly explore the joint.

But a striking fact connected with the small-calibre projectiles is that in the mid-ranges their great velocity produces a perforative effect, and that not alone upon one man, but upon two or three. This was the experience in a number of instances in the Chilian War. Stitt, a United States naval surgeon, states that in the St. Augustine Hospital during the Chilian War, of 2,000 wounded, that those wounded with the .30 calibre projectile left the hospital a considerable period of time before some 300 of their fellows who had been wounded by the old projectile of over .40 calibre were convalescent. As an example of the conservatism which will undoubtedly be the rule in the treatment of joint injuries in a future war, Stitt relates two gunshot injuries of the elbow-joint in the San Juan de Dious Hospital; one received from a .45 calibre, the other from a .30 calibre. The injury which resulted from the .45 calibre demanded amputation, whereas that received from the .30 calibre resulted in a moderate synovitis of the joint, which required rest and passive motion a few weeks later.

It is interesting to note that Captain LaGarde's conclusions correspond with those of Continental observers, and he states that "the humane wound of the small bore rifle is especially observed in the joints and soft parts. Owing to the reduction in calibre the wounds in the latter partake more of the nature of subcutaneous wounds, and experience shows that they

[3] The term explosive effects should not be confounded with the action of explosive bullets, but it refers to the action of the bullet upon the tissues with which it comes in contact, especially resistant structures, like bone or tissues, containing much water, like the brain, enclosed in cavities with rigid walls.

LaGarde writes: "When a resistant bone has been hit the foyer of destruction will show great loss of substance; the bone will have been finely comminuted; the pulverized bone will have been driven not only in the direction in which the projectile was travelling, but in all directions, and the pulpification of the soft parts will not only be limited to the track of the bullet, but the utter destruction is noticed some distance into the tissues. The wound of exit appears like a bursting forth of the skin; the track leading to the bone is conical in shape; the base of the cone corresponding to the wound of exit in the skin, and the apex to the seat of fracture. These explosive effects correspond to the velocity of the projectile at the time of impact, and the resistance offered by the part hit."

heal very kindly under appropriate treatment. It is not necessary in this case to dwell upon the destructive effects of the larger leaden projectiles upon joints. Suffice it to say that the greater frontage which it naturally possesses is made greater still by deformation, and that these facts with velocity sufficient to penetrate a joint, serve to convert the .45 calibre projectile into a very destructive missile."

The following cases noted at Frankfort Arsenal will explain the marked difference in destructive effects by the two projectiles upon the spongy ends of bones:

"No. 1. Gun-shot injury of the lower part of the left femur; bullet marked No. 4, calibre .45, impressed by the velocity common at 100 yards, soft parts frozen. The wound of entrance is marked by a V-shaped tear, each side of the V being 2.5 inches in length; the wound of exit is round, 1.5 inches in diameter. It is funnel-shaped, the base of the funnel corresponding to the skin and the apex to the point of destruction in the bone. The soft parts adjacent to the track of the bullet are a pulpified mass mixed with finely pulverized bone. One and a half inches of the external half of the shaft immediately above the articular surface has been carried away; the remaining part of the shaft is separated from the articular surface by a transverse fissure, whilst an oblique fissure extends into the shaft above 2.5 inches in length. The upper and external quadrant of the patella was chipped. There was no fissuring into the joint. The projectile was not recovered.

"No. 2. Gun-shot injury of the lower end of the right femur; bullet marked No. 3, calibre .30, impressed by the velocity common at 100 yards. The soft parts were frozen, on account of which the explosive effects were enormous. The projectile entered the femur just above the epiphyseal junction of the internal condyle and emerged posteriorly in a horizontal line, making an orifice the diameter of the projectile upon entering, and five lines in diameter upon leaving the bone. The perforation is well marked. The track of the bullet in the bone and between the latter and the wound of exit is lined by bony sand. There is a fissure scarcely visible to the naked eye running downwards and from before backwards through the articular surface, separating the two condyles almost equally. There is also a subperiosteal fissure 1.5 inches long running upwards from the point of emergence in the bone; there are a few small splinters of bone near the wound of exit still attached to the periosteum. The projectile was not deformed.

"That we should find a perforation so well marked in the spongy end of a bone within the range of explosive effects, makes the latter case very remarkable. As it is the only recorded instance of a perforation by the small metallic jacketed bullet within the explosive zone, it is but natural to infer that the frozen condition of the soft parts contributed to the result."

The two following injuries illustrate the difference in destructive effects upon the spongy ends of the bones entering into the formation of the knee-joint at 350 yards:

"No. 4. Gun-shot injury of the left tibia and fibula near knee-joint; bullet marked No. 5, calibre .30, impressed by the velocity possessed at 350 yards. The wound of entrance is round, of the diameter of the projectile; the wound of exit is marked by a longitudinal slit measuring one-third of an inch. The projectile entered the anterior portion of the head of the tibia, one-third of an inch from the articular surface, in the middle line; passing obliquely toward the outer side it emerged from the posterior surface of the head of the fibula. The orifice of entrance in the bone is equivalent in diameter to the diameter of the projectile; the orifice of exit is irregular, and one-third of an inch in its greatest diameter. There is no comminution. The knee-joint was not perforated, but the articular surface adjacent to the tuberosity shows a fissure which was not apparent in the recent state. The projectile was lost.

"No. 5. Gun-shot injury of the lower shaft of the right femur, bullet marked No. 3, calibre .45, impressed by the velocity common at 350 yards. The wound of entrance is 1.5 inches above the outer condyle, round, and equals in diameter the diameter of the projectile. The wound of exit is in the upper part of the popliteal space, irregularly quadrilateral in shape, three-quarters of an inch in its greatest diameter. The bullet entered the lower shaft 1.5 inches above the margin of the articular surface, one-third of an inch outside the median line. Nine large splinters are detached measuring from three to five inches in length. There are a number of deep vertical fissures in the upper and lower fragments; those in the latter do not invade the joint. The projectile was very much set up."

Then Captain LaGarde states that "The tendency on the part of the smaller jacketed bullets to perforate the spongy ends of bones increases as the velocity diminishes. After the 500-yards range perforations of these structures are rather the rule than the exception. We made no notes of injury to blood-vessels."

So far as I have been able to ascertain there have been no observations upon the effect of the projectiles upon blood-vessels, and I fancy that this work should be done.

II. — THE "FIRING LINE" TREATMENT OF THESE INJURIES.

The theory of the asepticity of a rifle bullet has been exploded by the experimentation of Messner and LaGarde. Messner's experiments were made by shooting a bullet into a tin can filled with sterilized Koch meat peptone-gelatine. A full charge of powder was exploded. The range was 125 and 250 metres. The conditions were as follows: (1) A non-infected bullet, can sterile. (2) Bullet infected (pure culture), can sterile. (3) Bullet non-infected, can sterile, but covered with a flannel covering which was infected with a known coccus, pure culture.

The results are given thus:

"(1) The shot canal through the gelatine showed no change or more frequently a more or less vigorous growth of "scheinmelpilz" or those varieties more commonly found in the air.

"(2) Without exception did the gelatine contained in the can show the development of the specific germ with which the bullet was infected.

"(3) Here also the shot canal was infected with the same germ with which the flannel covering of the can was infected.

"Although the experiments in the third class are not wholly convincing, still enough data is furnished by the rest of the work to decide the question in the negative."

Perhaps the most conclusive proof was furnished by LaGarde, who fired a .45 calibre bullet through a rabbit's ear and infected it with erysipelas, the bullet

having been infected with the streptolococcus of erysipelas. He also communicated anthrax to three rabbits and one calf by shooting them with projectiles infected with anthrax bacilli. The wounds of entrance and exit in the .30 calibre in the mid and long ranges are slit-like, and have been compared to what would occur from the entrance of a knife. The skin of every subject of the reception of a gun-shot wound is, of course, septic. It is my belief that all that can be done for a patient receiving an injury at the "line of fire" will be:

(1) To check the primary hæmorrhage by means of tourniquets.

(2) To apply an antiseptic dressing (iodoform gauze) or some dry antiseptic. A cartridge shell of .45 calibre might be filled with iodoform and sealed up, and made a part of the permanent equipment of every soldier.

(3) To prevent further injury to the patient during his speedy removal to a field hospital.

To summarize, this means that every soldier should have an antiseptic dressing composed of some dry antiseptic, which will not need water to render it effective; and that he should have a tourniquet bandage, a suspender, that the company bearer may find his patient equipped for emergency treatment. This work will be done almost entirely by company bearers, under the direction of a medical officer. The ambulance corps will be busy in removing the wounded from the "line of fire" to the rear.

III. — THE FIELD OR BASE HOSPITAL TREATMENT.

Necessarily with this new projectile with its increased range of effectiveness field hospitals will have to be far in the rear. At this point a full equipment and a thorough system for immediate, rapid and accurate treatment of all injuries should exist. This will demand a corps of operating surgeons. The first thing to do in every case will be to wash, shave and sterilize the injured part. This will be done while the anæsthetic is being administered. The limb will then be rendered bloodless by an Esmarch bandage, and the surgeon with antiseptic precautions will explore the wound, and determine the amount of injury to the parts. He will take into consideration the character of the injury, the projectile producing it, the range at which it was fired, and the length of time that has elapsed since the injury was received. The best treatment of each case will be largely influenced by these considerations.

A gun-shot wound of the knee-joint from a .30 calibre jacketed projectile in Zone 1, 2 and possibly Zone 3, will require a thorough laying open of the joint, and its complete cleansing of dirt. A gun-shot wound with a .30 calibre in the shoulder-joint in Zone 1 will mean the mechanical cleansing of the entrance and exit wounds, the irrigating out the bullet track, and packing with iodoform gauze. The same injury occurring in Zone 3 may mean simply the washing of the external surface of the part, and excision of the wound of entrance and exit and no interference with the bullet track, but hermetically sealing it with a collodion and cotton (aseptic) or compound tincture of benzoin and iodoform dressing. A gun-shot wound of the hip-joint by a .30 calibre in Zone 1 means a thorough cleansing of the wound to its bottom, if possible, and tamponading it with iodoform gauze.

But I feel sure the rule will be to explore where there is any doubt of the cleanliness of the joint cavity. Plaster-of-Paris will enter largely into the treatment of joint injuries in future campaigns. Fenestra will be cut, and the wound dressed as often as circumstances demand.

IV. — COMPLICATIONS AND PROGNOSIS.

Complications in the treatment of these joint injuries will naturally arise, and they will have to be treated by the general rules of surgery. On the whole, there will probably be a greater mortality from the new .30 calibre than formerly; for not alone will a larger number of combatants be injured, but a greater number will die from primary hæmorrhage. But to speak of the prognosis of joint injuries from the new .30 calibre projectile it would seem as if not only would the ratio of mortality be greatly decreased, but the number of limbs saved and restored to usefulness would be very large. The simple cylindrical bored wound of the new .30 calibre projectile through the ankle-joint, if rendered clean, must be a far less serious affair than the conoidal smashing wound of the .45 calibre bullet.

The conclusions that may be formulated as regards gun-shot wounds of the joints with the new .30 calibre projectile are as follows:

(1) That joints having large synovial cavities will have to be thoroughly explored and cleansed, except possibly where the injury has been received at mid and long range.

(2) That small or superficial joints with small synovial areas will simply require cleansing and tamponading.

(3) That it will require a larger number of company bearers, Red Cross workers and surgeons than have ever been assigned for duty.

(4) That so far as joint injuries are concerned the new .30 calibre is more humane than the .45 calibre bullet.

RECURRENT TONSILLITIS.[1]

BY G. A. LELAND, M.D.

The subject of recurrent tonsillitis is one which is forced upon the attention of the general practitioner often with distressing frequency; and the young physician, perhaps also the older one, is often disgusted at his inability to prevent it, or to really palliate it. From month to month, or perhaps more frequently, these tonsils come under observation, with all their annoyance and distress, not to say danger; and the efforts put forth for relief are all but powerless. The onset of the exacerbation may be sudden, ushered in by a chill more or less marked, with high fever, followed by more or less formidable swelling, with exudation, white or yellow patches, etc., to subside after a week or two; or it may go on to abscess, intratonsillar or peritonsillar, with great distress, forced starvation, restless days, sleepless nights, extreme prostration and anxiety (both for patient and physician), requiring weeks or months for recovery. The mental state of the attendant is not an enviable one when he knows that he may have a sudden fatal termination from extreme faucial swelling, œdema glottidis, suffocation from sudden discharge of pus, or by involvement of the great vessels, the carotid and internal jugular, by extension of inflammation.

In general, there are two varieties of tonsils which are subject to such recurrence. First, is the tonsil which in an inflammatory attack simply rounds out an increase in size — smooth, red, shiny, the parenchymatous variety. The crypts or lacunæ are not markedly developed, but the lymphoid elements are increased in size and in number (Virchow). If the capsule is broken and the finger introduced, a soft, friable feeling is communicated to it, something like that of the normal spleen. After several inflammatory attacks, these tonsils are adherent to the pillars of the fauces, and especially when this adhesion has taken place, are they apt to be permanently enlarged, and even to close the faucial passage pushing forward the uvula, with every slight cold, or disturbance of the digestion, or from some other ill-defined cause, so that the voice and respiration of the sufferer are much affected.

The other variety is the chronic tonsil, which has a hard, rubbery feel, whose surface is full of crypts or lacunæ which run into its depth from one-quarter of an inch to one inch or more, which crypts usually contain inspissated secretion of a cheesy consistency and of a most offensive odor. This is the "lacunal" tonsillitis of Wagner or Brown. It may be large enough to just project beyond the pillars or it may reach even to the uvula. Because of the diseased condition of the interior of the crypts, it is especially liable to frequent inflammatory attacks from even the slightest cause. It acts as a foreign body in the fauces, producing a tickling, hacking cough, giving a malodorous breath; and doubtless keeps the general health of the patient down from the absorption of these decomposing cheesy masses through the tonsil itself, or from their being swallowed. It is said that attacks of indigestion light up inflammatory conditions in the tonsil. It is probably also true that the contents of the crypts excite or keep up a fermentative indigestion. This variety of tonsil is doubtless the result of repeated inflammatory attacks of the first variety.

[1] Read before the Boston Society for Medical Observation, May 1, 1893.

It has always seemed to the writer that the ordinary methods of treating these enlarged tonsils have been extremely futile; that advocates of sprays, washes, gargles and pigments applied to the surface of the tonsil have lost sight of the fact that the tonsil is an organ of considerable size covered by mucous membrane, and hence these applications can have scarcely any more effect than that of a counter-irritant, externally applied to have an influence over any internal organ. Brudenell Carter in his work on the eye, speaking of blepharitis, says, "When Sidney Smith saw a little girl patting the shell of a tortoise in order to please the animal, he told her that she might as well pat the dome of St. Paul's to please the dean and chapter." It seems just as rational and just as efficacious to apply remedies to the outside of these enlarged tonsils. Even excision of the tonsil except of the first variety, as usually practised, fails to reach the bottom of the crypts; and, although it is often done with great benefit, it may also be considered a sacrifice of science to expediency. The stumps will still contain more or less of the crypts in this diseased condition, and if the stumps do not atrophy, as they commonly do not, the pillars of the fauces are still widely separated impairing the flexibility of articulation. But if the crypts themselves can be treated so that their contents will not remain to excite frequent inflammation, the tonsils will subside into a quiescent state and shrink to a small size, provided the fibrous elements have not been so largely increased as to interfere with shrinking. Hence about ten or twelve years ago, a suggestion found, I think, in a French medical journal promised to be a step in the right direction. This suggestion was that a syringe with a long nozzle bent at right angles an inch from the extremity, could be used to remove the decomposing matter from the lacunæ, and that then the tonsil would shrink away having lost the exciting causes of inflammation. I, therefore, had this syringe made and used it for a couple of years assiduously; but as it did not seem to meet the indications satisfactorily, or quickly enough, it has been used less and less in favor of a method which I saw mentioned some eight years ago, and which McBride says was advocated by Hoffmann, namely, the tearing away of the partitions between the crypts, so as to connect the many small contracted mouths into a few large, wide open ones.

As is well known, a tonsil which has suffered many attacks may have a surface more or less reticulated by fibrous bands between which are small holes which lead into crypts which are often large enough to contain many cheesy pellets; or the mucous membrane of the surface may be fibrous and tough. It is probably true that the septic contents of a crypt, acting as a foreign body, may start up an inflammatory attack which will close the mouth and so produce an abscess cavity, and this seems to be a rational explanation of recurrent abscess of the tonsil. Or the septic matter may be absorbed into the lymph spaces in the connective-tissue outside of and around the tonsil, and produce the peritonsillar abscess. Now, in the chronic variety of these tonsils these crypts can be united so as to form large mouths which will readily allow their contents to pour into the throat before they have become diseased. The introduction of caustics or the actual cautery into the crypts does not seem, at least in my hands, to accomplish the same result. First, because the application is a good deal wasted upon the

contents of the crypts, since it is difficult and tedious to completely empty them; and, second, because it may not reach their farthest depth, and the inflammatory products produced by the application have the same small hole to get out of, or nearly the same, as before. Doubtless, however, good results are obtained in this way, although I think there is more discomfort to the patient, and less ease and facility on the part of the surgeon, than in Hoffmann's method. His blunt hook was used by the writer for a number of years, but cases were encountered where the tonsil was too tough to be easily torn by a blunt instrument. The idea then suggested itself that the inner edge might be made sharp, and that thus the instrument might be much more effectual and the operation more nearly painless. It was then that these knives were made by Goldthwaite & Co., at my suggestion, and I have treated this variety of tonsils for several years with them with the greatest comfort to myself and with the least discomfort to the patient. Gampert has lately called attention to this method, which he calls "decission of the tonsils." He also observes that many follicles communicate, and if the fistulous tracts be incised, the cicatrization occurs as in similar passages.

It is well known that the tonsil is not very sensitive, and I have often used this knife without the patient being aware that I was doing any cutting. The method is simply as follows: The olive-shaped tip of the knife is introduced into a crypt in the upper part of the tonsil, and then turned downward and inward and made to come out by another in the lower part. The substance of the organ between these two holes is then cut through. This can be repeated from three to ten times at a sitting until the surface of the tonsil presents the appearance of being full of slits. There is usually not much hæmorrhage, and this knife can be introduced oftentimes to its fullest extent without danger. As soon as the bleeding has ceased, the slits are painted with Monsel's solution, or with a mixture of glycerine and tincture of iodine in equal parts. These solutions may be put upon the end of the cotton-wrapped bent applicator and crowded down to the bottom of the tonsil. This is done for antisepsis, and to prevent the wounds from uniting immediately as they tend to do, thus rendering the operation futile. The patient is advised to gargle with hot water very frequently for three or four days, and to return in a week for another operation, if necessary. Dobell's or Seiler's solution, or a little borax, may be added to the hot water. It usually requires from four to eight sittings to cause a large tonsil to recede from the median line to a position almost out of sight behind the pillars of the fauces. If the tonsil is very fibrous and hard there will be left small projections upon the surface. These can be readily nipped off with adenoidal forceps or can be seized by long dressing-forceps and removed with a blunt-pointed bistoury. The patient is then instructed to return on the slightest symptom of the old trouble, that any crypt which has escaped treatment may be attended to. In adults this method can be carried out with the greatest facility and ease, and often in children as young as ten years of age. I have also been able to operate with satisfaction, although with a little more necessary persuasion, in children as young as five or six; and recurrent tonsillitis is not apt to occur younger than that, at least in my experience. The first variety of tonsillitis, in which the crypts are not so much developed or so fully diseased, is much benefited by this method if the capsule is torn or cut and the solution applied to its interior, and perhaps even if only adhesions between the tonsil and the pillars of the fauces are cut away by this method. It has been said by some one, whose name I have forgotten, that these adhesions can be removed by the galvano-cautery flat knife. I have tried this on one or two cases, only to give it up because of the pain of the application and the extreme soreness of the throat afterward. By the use of this knife, however, the pain of the operations is comparatively insignificant; and, although the tonsil may be sore for a day or two, it is not so sore as to give the patient great inconvenience. Oftentimes the patient returns, and says that the throat has not been sore at all; but, of course, in this, as in many other things, there are various degrees of complaining.

In Lennox Browne's third edition, in speaking of "Chronic Inflammation of Tonsils," he says: "Treatment of chronic lacunar disease is very tedious and unsatisfactory when the tonsils are not hypertrophied. It has been proposed to squeeze out the cheesy secretion from each diseased crypt, and then to apply solid nitrate of silver or other caustics — preferably the galvano-cautery if available — to the cavity. Such measures are, however, but too frequently only tentative, and not of permanent benefit. It is better to treat such cases on general principles, according to the diathesis and to give guiacum or chlorate-of-potash lozenges. Whenever (as is almost certain to occur in these cases) active inflammation causing enlargement takes place, it is to be rather encouraged than arrested, and the gland then removed." He says he has frequently pursued this plan with the most satisfactory results; but it is in just these cases that the method of Hoffmann finds the happiest application. Often the inflammatory attacks are not extensive enough to produce an enlargement of sufficient size to be seized by the guillotine; and at all times, preferably when there is no inflammatory engorgement, the little crypts can be entered by these olive-pointed right-angled knives, their mouths enlarged or united, and the cavities shaped so that they cannot retain their easily decomposing secretion. There are often seen cases, where the tonsils are of minimum size, where only two or three crypts are chronically diseased, but where these cause the patient frequent discomfort, annoyance or alarm. It would be tedious indeed to wait until they were large enough to be guillotined.

(To be continued.)

A LAW in Germany requires that all drugs intended for internal use be henceforth put up in round bottles, and those for external use be placed in hexagonal bottles. This enactment is precautionary against poisoning.

REDUCING THE TONSILS.[1]

BY THOMAS AMORY DE BLOIS, M.D.

There are conditions in the throats, of both children and adults, in which it becomes necessary to reduce the size of the tonsils. This does not refer to the enlargement of inflammation, nor to the sometimes sluggish return of tonsils to their normal size after more or less severe attacks of tonsillitis. But whether congenital, the result of disease, or the accompaniment of certain diatheses, the fact still exists that in certain cases the tonsils interfere with the well-being of the individual and relief of some kind is called for.

This interference sometimes manifests itself by lessening normal and quiet respiration, particularly during sleep — less often it is shown in the act of swallowing; besides there is a popular belief, that recurrent attacks of tonsillitis are due to the enlarged condition of the tonsils. But this latter is probably a substitution of cause for effect! Frequent attacks of tonsillitis will in most cases produce enlarged tonsils, rather than be caused by them.

Entire removal of the tonsils, or a complete peeling out of the gland, is an operation which was once practised in Italy, but has now fallen into disuse, and as a substitute for it, a slicing off of a portion was much used. This amputation was done both by the bistoury and scissors and also by the tonsillotome. The latter had various mechanical actions — cutting while sliding back, cutting while being pushed forward, cutting by circular scissors, cutting both tonsils at the same time — to be used according to the fancy of the operator or inventor, and all resulting in the same clipped gland, with a hard, flat, cicatricial surface in the fauces.

The pain of tonsillotomy even under cocaine was considerable; the dread of the operation, where it was understood, was great. Although I have removed tonsils under ether, I think it is generally considered that the operator should have the assistance of the patient in freeing the respiratory tract from blood. Then if you did not use ether, you had the panorama of the screaming child, the hysterical mother, the cracked ice, and the nasty, styptic iron — not dangerous but very unpleasant! The blood frequently oozed; it seldom spurted; and although, as Dr. D. B. Delavan, of New York states, there is not a fatal case of tonsillotomy on record,[2] yet bleeding to syncope has sometimes occurred.

To obtain the same result, perhaps to crawl out of the cutting operation, many substitutes have been devised. Injections of different kinds into the structure of the tonsils were used, applications of nitrate of silver or London paste (caustic potash) being pushed to the bottom of the crypts of the tonsils. Sometimes considerable benefit was derived from the ulcerative action of these escharotics.

I have used electrolysis in chronic hypertrophy of the tonsils, in which cases I sometimes introduced one and sometimes two electrolytic needles. I certainly got absorption and diminution in size by the action of the galvanic current; but the operation was slow, was painful and had to be frequently repeated, and each successive treatment brought only repeated dread to the patient.[3]

Following in the footsteps of Dr. Charles R. Knight, of New York,[4] I have removed tonsils with the cautery loop, either fixed or contractile; but this adds little to the advantages of ordinary tonsillotomy, except the arrest of hæmorrhage and the sealing up of the cut surface.[5] Dr. Knight's experience with the cold-wire snare ecraseur is, to say the least, not encouraging; even under cocaine the pain was described as being so intense as to form a great obstacle in the mind of the patient (an adult) to submitting to the removal of the other tonsil with the galvanic cautery loop. As regards the effect of the mode of removal on the subsequent cicatrization, it does not seem to me to make very much difference. The burned surface seems to repair as quickly as the cut surface; both leave the same hard cicatrix. Of course there is always the liability of burning the pillars of the fauces and causing some inflammation and œdema from that accident.

Another operation, not original perhaps with my colleague Dr. Leland, but at any rate first used here by him, consists in the transfixion, from one crypt to another, of the tonsil, with a stiff, steel probe. (I have for this operation made use of the ancient and discarded steel hand-plugger of the dentist.) Then the intervening tissue is torn through by a more or less vigorous tug or twist. After half-a-dozen or so of these tracts had been thus divided, the gland is left to suppurate and contract during healing. I have made use of this procedure frequently, particularly, as is often the case at the City Hospital, after the patient has been thoroughly cocainized, it is discovered that the electricity has decamped for parts unknown. Then this tearing operation is the best thing to do to conciliate the parents, who expect something to be done and who have been sent there with that expectation, possibly, by their "family doctor."

I confess that sometimes, in Dr. Leland's operation, I have wondered whether the whole tonsil and perhaps the pharynx besides, would not come away when I sometimes tugged to break through a particularly thick bridge of tissue. And besides this, I do not think the after-results are quite as beautiful as they should be. There is a very gnawed or worm-eaten look to the surface — suggestive of the shaggy coat of the chorion under powerful microscopic enlargement. The mucous covering of the tonsil has certainly been saved, but there is an untrimmed look about the whole thing, like an unfinished picture.

Lastly, we come to ignipuncture. Fifteen years ago, before the discovery of the local anæsthesia of cocaine, and when the galvano cautery was not much in use, Dr. F. H. Bosworth, of New York, was in the habit of thrusting a silver wire, previously heated over a spirit lamp, through enlarged follicles of the pharynx to bring about scar contraction. This operation, after the general use of the galvano-cautery point, became quite the routine procedure. Exactly when this ignipuncture was used in the reduction of enlarged tonsils is difficult to state. Dodart[6] reports it as the operation of choice. In a paper by Ouspenski[7] "the method by galvano puncture is highly praised." Valat,[8]

and Wilhelm Roth[9] both speak in praise of the operation, particularly for children. "Roth advises the operation, preceded by an application of a twenty-per-cent. solution of cocaine, to be repeated four or five times at intervals of two or three days. He finds this sufficient to reduce the tonsils to their normal size, with scarcely any pain and without the risk of troublesome hæmorrhage, which contrary to his own experience," he says, "is not uncommon, especially in young children."[10]

Whether the tonsils of the American present are larger and more difficult than those of the German past, I know not; but certainly I have never obtained the brilliant results nor the total absence of pain depicted as above. At the City Hospital during the past winter, I have operated with the galvano cautery in about thirty cases during six months of continuous service. These cases ranged in age as follows: there was one case of two years of age; one of three years; three of five; one of six; seven of seven years; one of eight; one of ten; three of eleven; one each of twelve, thirteen and fifteen years; two of sixteen; one each of seventeen and nineteen; three of twenty years; two of twenty-one, and one of twenty-three years. After that there was one case of thirty-one, and one of forty, illustrating Sir Morell McKenzie's theory that the tonsils undergo spontaneous atrophy after thirty years of age. I endeavored to do what I could for as many patients as I saw. I do not know whether this number out of, we will say, four hundred new patients (such being about the attendance of the winter months) would represent the proportion of enlarged tonsils; but that is all that the record shows. My usual procedure is as follows: Allow that the patient is a child of five or six years of age, I make an application to the tonsils, with a cotton stick wet with a solution of muriate of cocaine, say of a strength of four or five per cent. I try to get as little of this into the pharynx as possible and endeavor to keep the child's mouth open and tongue quiet until some drying or absorption has taken place. Then they are allowed to expectorate, and of course they get rid of all the cocaine on the tonsils. In five or ten minutes I repeat the operation, and watch the pulse and also the child, for toxic symptoms are possible! If the child be strong, I may make a third application. In the case of an adult it is about the same, except that I use a ten or twenty per cent. solution of cocaine. At the expiration of perhaps fifteen minutes from the time of the first application, while holding the tongue down with a depressor, I push the cautery point down into the tonsil about a quarter of an inch. I purposely try not to strike one of the crypts, the mouths of which I do not care to seal up. The pain, I do not think is very severe, even after you have got through the mucous coat which I believe is the limit of cocaine anæsthesia (when it is not injected). Some slight inflammation follows and some little sloughing from the burned parts. I have occasionally seen a diminution in size (which I estimated at about a quarter) follow at the end of ten days after the first burning. The ignipuncture should be repeated perhaps three times, which will probably give as good results as can be obtained in this way. I will not burden you with a history of my thirty cases, and tell you how much relief A. B. got, and how much C. D. did not. In a treatment of this kind it is largely routine, one case closely resembling another. About half the cases will show some improvement after the first burning, and this will be more apparent in children of from five to fifteen years of age than in any other cases, for the younger ones do not tolerate a proper application either of cocaine or fire, and in the older ones the tonsils do not seem to reduce so easily.

There are certainly one-quarter of the cases in which progress is either so slow or so unsatisfactory that further treatment in this way is abandoned. Then the tonsillotome will make its appearance. I have had four such cases. It appeared to be the only thing to do. I do not wish to convey the impression that galvano-caustic puncture is by any means a perfect method of treating the tonsils. But take it all in all, it is the best that we at present have at our command, and it is certainly far better than the wholesale clipping which formerly was the fashion, when we believed that every enlarged tonsil should be cut.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

JOHN C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, May 1, 1893, DR. J. G. MUMFORD in the chair.

DR. DEBLOIS read a paper on

REDUCING THE TONSILS.[1]

DR. G. A. LELAND presented a paper on

RECURRENT TONSILLITIS.[2]

DR. FARLOW: The tonsil is an organ liable to have all sorts of irritants about it and in it, and these irritants should be removed if possible. Troubles with the teeth, tongue, mouth, pharynx, naso-pharynx and stomach can cause the tonsil to enlarge. It should be noted whether the tonsil is adherent to the pillars of the fauces and such adhesions should be freed. All secretion should be removed from the follicles and especially from between the tonsil and the anterior pillar and from the sulcus between the upper and lower lobes of the tonsil, the two latter being favorite places for the retention of large masses of irritating secretion.

Where there are a number of enlarged and diseased follicles I have been in the habit of breaking down the walls between the follicles and opening up several follicles into one common opening, in the way that several fistulous tracts might be better drained by laying them open into a common tract. It is also possible to cut out a piece of tonsil which contains several diseased follicles near together.

Dr. DeBlois speaks of cocaine working on the surface of the tonsil only. According to my experience, the tonsil is not a sensitive organ and cocaine used on the mucous membrane causes sufficient anæsthesia to allow very deep cauterizations and incisions without pain.

In children with soft tonsils internal treatment is often of great service and local astringents are of some, but not much, benefit. I have been able to use the cautery in many instances with very good effect. But

[1] See page 375 of the Journal.
[2] See page 373 of the Journal.

where the tonsils are the seat of true hypertrophy and are very large, it is, by all means, the best plan to remove them. I usually give a little ether, just enough for primary anæsthesia, put the cold wire snare well round the base of the tonsil and with the écraseur movement it is possible to remove the enlarged organ without the loss of any blood. Where the tonsil does not project sufficiently to be caught in the wire I have sometimes cut the capsule and with my finger broken up the friable inside of the tonsil with the result that a considerable diminution in size has followed.

Dr. DeBlois has spoken of the tonsils atrophying as one grows older. I have had a lady in my office to-day, 57 years of age, both of whose tonsils are very large — a simple hypertrophy.

With regard to intratonsillar abscess, as spoken of by Dr. Leland, I should say that such cases were very rare. I have seen a few instances of cysts, resulting from the retention and liquefaction of secretion in several follicles whose walls had broken down forming a cyst near the surface. But true abscess has usually been found around and not in the tonsil.

Two years ago I had a very interesting case of conversion of the entire tonsil into a large cavity filled with cheesy matter. The opening to this cavity was quite small. After thorough evacuation and disinfection a few applications of the cautery caused the entire cavity to close up so that I was no longer able to find the opening.

DR. TEMPLE: I should like to ask the reader whether in these cases of recurrent tonsillitis in children eight to twelve years old he has had any better results following out the lines of treatment early, say at the age of eight or nine, than where the case has been delayed longer, in other words, whether the recurrence of the trouble does not place the tonsils in such a condition that it is hard to treat them effectually by the method he suggests.

DR. DEBLOIS: I think treatment should be carried out as soon as we observe the enlarged condition of the tonsils.

In reply to Dr. Farlow I would say that it seems to me the difficulty that he spoke of in cutting through and then using the cautery-point when cutting away the dividing lines between several crypts is, that the chances are, that you do not seal up from the bottom. If you can be sure of striking the bottom of your cavity it certainly is a very excellent way to use the cautery. I think that after the operation of tearing or burning down the tonsil, then if tonsillotomy is necessary it certainly affects the stump that remains. Since I wrote this paper I saw for the first time one of the cases which I spoke of where I had persistently burned through and endeavored to reduce a tonsil in a young woman of sixteen and finally, as a last resort, cut it out with the guillotine. The stump was scarcely visible. I had never seen a stump disappear as this did. Generally they stand out with a hard flat surface with sharp edges requiring a secondary operation to reduce them.

Dr. Farlow spoke of not having mentioned the matter of peeling out the gland. I think I spoke of it in the first part of the paper as having been practised in Italy. Dr. Daly, of Pittsburgh, had a way of seizing the tonsil with a pair of sharp-pointed forceps and drawing it towards the median line and then almost removing it with a sharp curved bistoury. I think that there has been in use a method with the cold wire snare of removing *parts* of the tonsil, particularly where it is lobulated.

Dr. Leland and I have written on rather different subjects. He took up the conditions connected with inflammatory processes in the tonsils, whereas I took only the chronic hard condition not connected with inflammation, except as a result.

DR. LELAND: I simply advocate this method as one I have used about eight years. I think it would be an easy one for the general practitioner to adopt. It is not adapted to all tonsils. Some of the large rubbery tonsils we cannot take the time to do in this way. If we can get a pair of tonsils out in five minutes, it is folly to take six or eight sittings to do it. Where you have a nervous family, with one or both parents very much opposed to having the guillotine used, and more opposed to having ether used, you can rather surreptitiously introduce this knife and the tonsils shrink away very satisfactorily.

DR. NICHOLS: I have had ever since I can remember one or two attacks of tonsillitis in the winter, and a year ago last December, Dr. Leland united the crypts of one tonsil with the blunt hook; and about ten days later, the other with the knife. Since that time I have never had any trouble in the way of tonsillitis.

Recent Literature.

The Chronic Disorders of the Digestive Tube. By W. W. VAN VALZAH, A.M., M.D. New York: J. H. Vail & Co. 1893.

This is a small octavo of 150 pages, and is a combination and reprint under one cover of various articles previously contributed to several medical journals. A paper on sea-sickness is added. There are five chapters, and two papers are added in an appendix. The author has aimed to make each chapter complete in itself. We notice in the text quite a number of foreign idioms, and there is also a tendency to "fine writing," which had better be spared where so large a subject is condensed into so small a book, and where there is an expressed desire to make each chapter complete in itself. The chapter on sea-sickness will not carry a large measure of comfort either to the perplexed practitioner or the perplexed patient.

The International Medical Annual and Practitioner's Index. A Work of Reference for Medical Practitioners. Eleventh Year, 1893. New York and Chicago: E. B. Treat.

The opening article in this book, "The Present Status of Therapeutics," by Professor Hare, is excellent. This is followed by the brief mention of a number of new remedies; but the main portion of the volume, which is illustrated, is devoted to what is called, "A Dictionary of New Treatment in Medicine and Surgery, 1893." Diseases are here alphabetically arranged, recent methods of treatment outlined, and the names of the physicians who have employed the given treatment, together with references to their articles, are added. "The Medical Annual, 1893," published in England, contains the same text as "The International Medical Annual," except for a few pages at the end of the volume, together with a mess of advertisements, etc., of interest chiefly to British practitioners.

"MEDICAL EDUCATION IN AMERICA."

IN the issue of the London *Lancet* of September 2, 1893, which is devoted to medical education, there is an article on medical education in America. The article, on the whole, is not an injudicious or discreditable one. The author criticises us from a somewhat elevated stand, and points out the mistakes we have made, says we are doing very well, but does not think that on the whole medical education in the leading schools in this country is on a par with medical education in England. He takes Harvard and Yale as the types of the best medical schools in this country. Some of the criticisms which he makes are good, others are not. Some of his statements are correct, others are not — as is too often the case when a Briton writes or talks about persons or things pertaining to other countries than his own islands.

It has not occurred to us for some time past to make any comparison between the leading medical schools in this country and the English schools. So far as we can judge by the fruits, medical education in the best schools in this country is far ahead of that in the English schools. For one well acquainted with medical literature there can be no doubt that the decadence of medical science in England during the last forty years has been most marked. This decadence commenced at the very time when medical science began to bloom in Germany under the influence of the stimulus which great teachers like Virchow, Rokitansky, Skoda, Frerichs and Traube gave to it. The reason is not far to seek. The stimulus which was given medical education in Germany at that time was due to the greater use of the experimental method in medical science leading to a closer investigation of the problems of disease. The falling off in England has been largely due to the small place given in medical education to the laboratory and to research. In medical education in Germany there is the further advantage of a close union between general and medical education. The medical faculty is the faculty of medicine of a great university, and profits by the stimulus which it receives from other branches of learning.

There is no doubt that the antivivisection laws of England have exerted a marked influence in retarding the advance of medical science. The very class in England which regards it as a noble sport to harry foxes to death with hounds and which shoots tame pigeons, is horrified at the idea of performing an experiment on a carefully anæsthetized animal, though such an experiment might greatly increase human knowledge. We, here in America, have also felt the need of laboratory teaching and research, and it is only in comparatively recent years that that part of medical education has begun to have the importance given it which it deserves. To the Johns Hopkins University, as well as to Harvard and one or two other schools, must be accorded the credit of giving to the laboratory the high place which it should properly hold in education.

At the present time in Harvard, as far as the student is concerned, the facilities for teaching in all branches of medicine are fully as great as can be found elsewhere. The clinical material for the purposes of teaching is abundant. The teachers are well-trained men familiar with the best methods of teaching in Germany and France, and they are sufficiently numerous to permit close contact of the student with the teacher. In most of the departments the student has the advantage of learning the views of different men on the same subjects. Abundant opportunity is given him to familiarize himself by practice with the methods of investigating disease. In obstetrics, not only does he have the various stages of labor explained to him at the bedside, but no student leaves the school before he has himself attended a number of cases of parturition.

The numerous hospitals of the city give him abundant opportunity for hospital work as a resident interne. Nor have the scientific branches of medicine, if one may speak of them as separated from the practical, been neglected. The first and second years of his course are largely given up to study in these branches. He receives in these both theoretical and laboratory instruction. The opportunities given him for laboratory work in anatomy, histology, medical chemistry, (including examination of urine), physiology, bacteriology and pathology are unsurpassed in any of the European schools. The theoretical lectures and laboratory instruction are given in a building conveniently located and admirably arranged for the purpose, the cost of which the author of the article in the *Lancet* learned on direct inquiry — with the view possibly of advocating the construction of a building with the same admirable equipment in England. The little slur with which the statement of the cost is accompanied may be regarded as both harmless and gratuitous.

As far as the student is concerned he is well taken care of, but the medical school which would be the

medical faculty of a great university, has another duty to perform. Only a part of its duty is done when it sends out its young men well equipped for the practice of their profession. The university has a much higher duty to perform in advancing human knowledge; and it is this which is its glory, and which gives it its best reputation. When we think of the great universities abroad, we do not think of them so much as educational centres where men are taught, but we think of them as the places where knowledge is increased. We think of the laboratories of Berlin, not as places where the student is instructed, but as the places which gave Virchow and Helmholtz facilities for their work. We do not think of the hospitals there, as the places where preeminently medicine is taught, but as the places which gave the material and the means for the work of Traube, Frerichs and a host of others.

There can be no doubt that we think too much of what is called the practical side of medical education. Medicine is not a fixed science; there are comparatively few laws in it which are certain and of general applicability. Many of the supposed facts which the student learns will be found to be erroneous in the course of a few years; and if he has not learned to investigate for himself, to observe and reason independently, then he has not learned the best. And this best sort of training cannot be given him; it must grow into him and become a part of him. It is only possible for him to acquire it when he is in contact with men who are investigators, and when the spirit of investigation is in the air he breathes. We cannot give a man malaria; we do not know exactly the manner in which it enters into him; but if he go into a country where, as they say in the south, "the air is full of it," he will have his chill in due season.

Certainly the best men we have here and the best men in England also, are men who after their medical education at home (applying the term medical education to the years of study before a degree is given) have studied in the Continental universities, especially in the universities of Germany. What is it that they get there which has such an influence on them? It is not that they have superior opportunities of seeing disease; it is not that the facilities for teaching there are better than ours; but it is their contact with men who are investigators, and the absorption through such contact of some of the spirit of investigation. For such a medical department, especially for the scientific branches, large endowments are necessary. Larger endowments, even, than any of the German universities have, because here the cost of living is enormously in excess of what it is in Germany.

That with the same facilities our Faculties of Medicine would be as productive of good as the German cannot be doubted. Our medical schools have been hampered in the first instance by the absence of a close and integral union with those other branches of learning which compose the faculties of a university, by being more or less technical schools where the art of medicine is taught; secondly, by the absence of endowment, making the remuneration of the teachers dependent on the fees of the students, and the work of research almost impossible.

THE BACTERIOLOGY OF DIPHTHERIA.

It is now generally admitted that the Klebs-Löffler bacillus is the cause of diphtheria, hence the presence of this bacillus in the exudate is necessary for accurate diagnosis. This fact is now recognized and the bacteriological study of this disease is everywhere assuming great importance.

It is known that the presence of a false membrane is not characteristic of diphtheria, for various caustic chemical agents may produce it, and parasites other than the diphtheritic bacillus, such as the staphylococcus aureus and the streptococcus pyogenes.

Veillon has lately published[1] an interesting *résumé* of the mode of action of the Klebs-Löffler bacillus and of other micro-organisms influential in producing or favoring the complications of this disease.

The Klebs-Löffler bacillus having gained access to the excoriated skin or mucous membrane and effected lodgment there, multiplies actively; sometimes, though very rarely, it causes only a little redness (angina without false membranes), but generally, it produces a violent inflammation of the mucosa, and soon a false membrane appears. In fact, the parasite vegetates on the surface of the epithelium, where it readily secretes its toxic products, the mucosa becomes congested, œdematous; the epithelial cells swell and become vesicular; the chorion is infiltrated with leucocytes and a few red corpuscles; the small vessels are often thrombosed; at the same time, the exudated fibrine forms on the surface of the mucosa a thick network whose meshes enclose lymph cells, red corpuscles and necrosed epithelial cells. It is in the interstices of this false membrane that the bacilli pullulate; "*they never penetrate the mucosa, they never invade the glands, the internal organs, the blood.*" This last statement is not in accord with other observations and is probably more positive than our present knowledge would justify.[2]

But the activity of the bacillus is not limited to the production of the false membrane, the angina and the croup; it secretes a toxine which is readily absorbed and poisons the whole organism. This toxine, studied by Roux and Yersin, is fabricated out of the protoplasm of the bacillus, and is found in abundance in the culture bouillon and may be freed, by filtration, from the bacilli. This poison, which bears a striking similarity to a diastase, or to the venom of certain serpents, is soluble in water, and is precipitated by alcohol; it is attenuated and destroyed by a temperature of 60° C to 100° C.

Gamaleia believes this poison, which has not yet been isolated in a state of purity, to be a nucleo-albumin derived from the bodies of the bacilli. It is

[1] Semaine Médicale, September 20th.
[2] Journal, vol. cxxviii, p. 502.

extremely active. A centigramme of the evaporated residue of a bouillon culture is sufficient to kill eight guinea-pigs, each weighing a pound. By the inoculation of this poison in animals, almost all the characteristic lesions of diphtheria may be reproduced. Sometimes a subcutaneous injection causes mortification of the skin and an eschar. It is this toxine which produces the general prostration, the fatty degeneration of the liver and heart, the nephritis and albuminuria, the fibrinous effusions in the pleura, congestions and even hæmorrhages in the internal organs, and lastly, the paralyses so characteristic of diphtheria.

That the disease, though primarily local, very soon becomes general by reason of its toxine, is proved by the fact that these paralyses often follow benign cases, and death has been known to supervene by syncope in full convalescence — evident proof that the myocardium has been touched by the toxine.

But, in a great many cases, the diphtheritic bacillus and the toxine which it secretes are insufficient to explain all the lesions and symptoms of diphtheria; for, in fact, the disease is much more complex than has been generally supposed. Certain accessory germs, mainly cocci, during the course of the disease invade the pseudo-membrane, the inflamed mucosa and sometimes the internal organs, having obtained a nidus favorable for their development in the diseased focus. These accessory germs increase the severity of true diphtheria. It is these, in Veillon's estimation, which form the thick exudates which cover the tongue and the gums, and which cause the fetidity of the breath. These microbes are principally the streptococcus pyogenes, the pneumococcus and the staphylococcus pyogenes.

The streptococcus exists quite often in the mouth of the healthy man and under the influence of a disease like diphtheria, it might be expected to develop abundantly and become pathogenic. Even where it is not a previously harmless parasite of the mouth, it may be introduced, through dust, in the air of respiration. This parasite seems to augment the inflammatory reaction; it tends constantly to infiltrate the mucosa, and it often penetrates the glands by the lymphatics, causing suppuration. It is found in the tracheal or peritracheal abscesses after tracheotomy; and in a certain number of cases, it causes the purulent pleurisies and the broncho-pneumonias which are so formidable when occurring in diphtheritic children. The toxine of diphtheria, by its depressing influence, evidently favors the development of the streptococcus, which often infects the entire organism, causing those septicæmic forms which are so often fatal.

Next in frequency after the streptococcus comes the pneumococcus, which may be found in the false membranes, and like the streptococcus may cause suppurations, otitis, purulent pleurisies and broncho-pneumonias. Sometimes this microbe is associated with the streptococcus.

The staphylococcus pyogenes is much less frequently associated with the Klebs-Löffler bacillus; it may, according to Veillon, cause suppurations of little gravity (small abscesses) and impetigenous eruptions. In rare cases, the bacteria of putrefaction have been found associated with the specific bacilli and the pyogenic cocci, causing secondary gangrene (Netter).

As a result of this knowledge of the pathogeny of diphtheria and of the accidents which attend it, and which may be defined: (1) local accidents due to the Klebs-Löffler bacillus; (2) general accidents due to the toxine; (3) accidents due to the secondary infections, it is evident that the treatment must be sufficiently complex to oppose each of these sets of morbid manifestations.

The parasite being localized in a limited point of the mucosa, it is natural that means should be sought to destroy it *in situ* and prevent its development. The remedies which have been employed with this intent are manifold; the ideal antiseptic must be active enough to kill the bacillus or arrest its multiplication, while so little caustic as to respect the integrity of the mucosa. Löffler favored corrosive sublimate, Roux and Yersin phenic acid. The sulforicinated phenol has high endorsements; the same may be said of camphorated naphthol.

The difficulty is to reach the parasite, which is generally well protected in the meshes of the false membrane. Veillon, in accordance with the principal authorities of the French school, advises ablution of the false membrane by means of cotton wool wrapped around curved forceps. Rather, however, than wound the mucosa and make it bleed, he would let the pseudo-membrane alone, contenting himself with sprays and irrigations to limit the spread of the disease. The lavages should be very frequent, every hour or even every half hour.

To antagonize the toxine, Veillon regards the frequent irrigations also as excellent, for these may be expected to wash away a part of the poison, which is soluble in water. As the toxine has been found to be much less active in an acid medium (as shown in culture bouillon), lactic or tartaric acid may with advantage be used as one of the remedial agents to be frequently employed in the form of spray or irrigation; Veillon prefers a saturated solution of boric acid to which lactic acid is added in the proportion of one per cent.

But as no local applications can affect the toxine which is already absorbed and in the blood, some antidotal agent must be sought for that can meet and neutralize the poison in the organism. It may be that such antitoxine will be long a desideratum, but Veillon expresses much faith in sero-therapy, which he thinks has "a brilliant future" awaiting it. Behring and Kitasato seem by their studies to have arrived at a method of attenuation of the diphtheritic virus by which guinea-pigs may be rendered immune against diphtheria, and an injection of trichloride of iodine is said to have the same effect in animals that have been inoculated with the Löffler bacillus. An animal in which Behring's serum has been injected is found

weeks afterward to be protected against powerful doses of the virulent toxine.

At the present time, these experimental notions seem for many reasons to be with difficulty applicable to man, and often when the physician is called in, the toxine has already made irreparable ravages in the economy. The method of sero-therapy will, however, be perfected and future experimenters will, perhaps, succeed in obtaining a curative serum still more active, or they will isolate the antitoxic principle, which will be easier to manage.

MEDICAL NOTES.

Notification of Tuberculosis. — The Philadelphia County Medical Society has appealed to the Board of Health, of Philadelphia, to place tuberculosis upon the list of contagious diseases to be reported to the Board.

Yellow Fever. — The outbreak of yellow fever at Brunswick, Ga., has increased steadily the last week. On October 1st there were twelve new cases reported and this number has increased daily until there are now about thirty new cases each day. The death-rate so far has been low. The disease, which appeared at Jessup October 1st, has not assumed a serious aspect there as yet.

Cholera. — The number of cases of cholera reported from infected districts in Europe is steadily diminishing; but there is a constant increase in the number of places reported infected. This is especially true in Spain and Holland, where widely separated districts are reporting each a few cases daily. In Italy there is a decided improvement in the epidemic, both in Palmero and Leghorn and Naples where there are but a few new cases. In Russia there is a very large number of cases, with a heavy mortality. Moscow, Keiff, Podolia and Nijui Novgorod are the most severely afflicted, having a total of about seven hundred deaths a week with a constantly increasing number of cases throughout the provinces. So far the quarantine station at El Tor has been remarkably free from the disease and but one case has occurred among the pilgrims.

An Anomalous Biceps Muscle. — Thébault recently showed to the Anthropological Society of Paris a human biceps muscle which had three supernumerary muscular bundles. One rose from the long belly of the biceps and was inserted in the pectoralis major. A second had its origin from the fleshy body of the muscle and joined the brachialis anticus. The third bundle extended from the upper surface of the muscle to the superior margin of the capsule of the shoulder-joint. This anomaly is analogous to the condition found in the gibbon.

Paris Water-Supply. — The doubts at first entertained as to the sufficiency of the new water-supply of Paris, have been completely cleared away. The 110,000 cubic metres delivered by the new pipes from Avres are more than sufficient; and even the long drought failed to overtax the supply, 28,000 cubic metres more than last year having been available. The Seine water will soon be no longer used, as plans have been submitted to bring to Paris water from Breuil. The effect of this new water-supply will be to greatly improve the health of Paris.

Medical Fees in Russia. — An official regulation of medical fees is to be exercised by the Russian Government. There are three classes, divided according to the Russian social scale which is in itself somewhat complicated. The obligatory fee in each class is proportionate to the supposed ability to pay. The first class includes capitalists, landed proprietors, manufacturers, bankers and merchants in large cities who are expected to pay a fee of five roubles. The second class, professional men and employés of the seventh and eighth class, pay three roubles, while all others, villagers, etc., are to be treated for thirty kopeks.

BOSTON AND NEW ENGLAND.

Report on Sanitary Legislation. — At the next meeting of the Section for Clinical Medicine of the Suffolk District Medical Society, October 18th, the committee appointed to secure from the legislature improved sanitary legislation will make its final report.

Public Bathhouses. — The Boston public bathhouse statistics for the past summer show a smaller attendance than that of last year, there being a difference of nearly 120,000 in the total number of bathers. The houses for men that are most largely patronized are those at L Street, South Boston, and at Craigie's Bridge, and those most used by women at the Charles River Bridge and at M Street. There were 159,771 bathers in June, 430,505 in July, 358,905 in August, and 88,297 in September. The total number of men was 825,614, and of women 181,864.

Conference of Charities and Correction. — The first New England Conference of Charities will be held in Channing Church, Newton, on October 24th, 25th and 26th. Besides the general subject of charity organizations, sessions will be devoted to the discussion of "The Feeble-Minded," "Probation, in Relation to Punishment of Crime," and "Destitute, Neglected, and Morally Exposed Children."

Recent Bequests. — The will of the late Dr. Parsons, of Providence, bequeathes his medical library to the Rhode Island Medical Society, and four thousand dollars to the Rhode Island Hospital, to establish a free bed in memory of his father, Usher Parsons. The residue of the estate, after paying all of the bequests, is to go to the Rhode Island Hospital. The estate is reported as very large.

NEW YORK.

Professor von Helmholtz's Visit. — Professor von Helmholtz sailed for Germany on October 7th by the steamer *Saale*. On the evening of the 6th, he delivered an address on the ophthalmoscope at the

College of Physicians and Surgeons; after which a reception was given him at Columbia College by President and Mrs. Low. On the following night a reception was given in his honor at the Century Club. During his stay in New York Dr. Helmholtz was the guest of Dr. Herman Knapp, and an interesting episode of his visit was his meeting with Dr. Alexander Graham Bell, whose invention of the telephone was one of the results of the professor's investigations into the laws of sound.

DEATH OF DR. RICHARDS. — Dr. Thomas L. Richards, one of the young physicians who contracted small-pox from the case at the Vanderbilt Clinic which was mistaken for one of chicken-pox, died on October 1st at the Riverside Hospital on North Brothers' Island. The other physician, Dr. Norris, who had the disease in a very light form, and who, during his convalescence, rendered all the service that he could to his unfortunate comrade, was discharged from the hospital cured on the very day that Dr. Richards died.

Miscellany.

SMALL-POX IN THE "GOOD OLD DAYS."

A CORRESPONDENT sends to the *Lancet* the following curious advertisement of the last century, as a comment on the present continuance of antivaccination sentiment. The prevalence and dread of small-pox in those days is hardly to be imagined now:

"WANTED, a man between twenty and thirty years of age, to be a footman and under butler in a great family; he must be of the Church of England and have had the small-pox in the natural way. Also a woman, middle-aged, to wait upon a young lady of great fashion and fortune; the woman must be of the Church of England, have had the small-pox in the natural way, very sober, steady and well-behaved, and understand dress, getting up lace and fine linen and doing all things necessary for a young lady that goes into all public places and keeps the best company. Enquire of the printer of this paper. – Oct. 1, 1774."

BOSTON DISPENSARY.

THE statistics of this institution for the year ending September 30th are as follows:

The number of new patients treated at the Central Office is 26,405, classified as follows:

Medical Department. — Men, 2,838; women, 5,212; children, 3,647; total, 11,697.

Surgical Department. — Men, 2,311; women, 1,095; children, 824; total, 4,230.

Department for Diseases of the Skin. — Men, 875; women, 595; children, 342; total, 1,812.

Department for Diseases of the Nervous System. — Men, 649; women, 571; children, 79; total, 1,299.

Department for Diseases of the Throat and Nose. — Men, 888, women, 816; children, 540; total, 2,244.

Department for Diseases of Women. — Women, 949.

Department for Diseases of the Eye. — Men, 214; women, 206; children, 194; total, 614.

Department for Diseases of the Ear. — Men, 178; women, 194; children, 207; total, 579.

Department for Diseases of the Genito-Urinary System. — Men, 1,694; women, 45; children, 1; total, 1,740.

Department for Diseases of the Rectum. — Men, 132; women, 65; children, 5; total, 202.

Orthopedic Department. — Men, 39; women, 36; children, 51; total, 126.

Dental Department. — Men, 215; women, 263; children, 435; total, 913.

The number of visits made by patients, old and new, at the Central Office is 63,876, classified as follows: Medical, 22,346; surgical, 41,530; total, 63,876. The number of patients treated in the Districts is 16,326 (including 213 cases of midwifery) classified as follows: Men, 2,848; women, 635; children, 7,127; total, 16,326. The results of treatment in the Districts are as follows:

Discharged, cured or relieved	14,925
Removed to hospitals	1,067
Died	327
Remaining under treatment	82
	16,401
Under treatment at last annual report	75
	16,326
The number of patients treated at the Central Office and in the Districts is	42,731
The number of cases of midwifery attended during the year	213
The number of cases attended since July, 1856	7,052
Whole number of patients since October, 1,796	1.203,978
Whole number of patients since July, 1856	1,085,175
Average daily attendance at the Central Office	210
Largest number present any one day, September 25th	336
Smallest number present any one day, December 26th	42
Number of recipes put up at the Central Office during the year	68,045
Number of house recipes	52,869
Number of district recipes	15,176
Largest number put up in one day, April 10th	378
Smallest number put up in one day, December 26th	49
Number of paid recipes	62,375
Number of free recipes	5,770

The following changes in the staff have been made:

Surgeons. — Dr. Rufus E. Darrah in place of Dr. Arthur K. Stone.

Physicians. — Drs. William H. Prescott, J. J. Thomas, Augustus S. Knight, William E. Chenery, John L. Morse, in place of Drs. Dixwell, Sherman and Washburn.

Department for Diseases of the Nervous System. — Dr. Frederic Coggeshall. Assistant, Dr. William R. Woodbury in place of Drs. Bullard and Burr.

Department for Diseases of the Throat and Nose. — Dr. William S. Boardman in place of Dr. Coolidge, Jr.

Department for Diseases of the Eye. — Drs. Edward L. Parks and Frederic A. Davis in place of Drs. Hall and Jack.

Department for Diseases of the Ear. — Assistant Dr. Joseph Hicks in place of Dr. Bryant.

Department for Diseases of the Genito-Urinary System. — Dr. Charles M. Whitney in place of Dr. Tilden.

Department for Diseases of the Rectum. — Dr. Hodges resigned.

Orthopedic Department. — Dr. Frank S. Whittemore in place of Dr. Darrah.

District Physicians. — Drs. Edward A. Peace, Malcolm Stone, Benjamin Tenney, Edwin W. Dwight, Franklin G. Balch, John B. Blake, Horace D. Arnold, Frederic B. Lund, John Dane in place of Drs. Knight, Craigin, Hicks, Wentworth, Thomas, Chenery, Prescott, Whittemore and Holden.

Apothecary. — Joseph S. Lang. Assistant Apothecaries. — Wallace Maccullum, Arthur D. Macdonald.

OBITUARY. — WALTER GAY STEBBINS, M.D.

DR. WALTER G. STEBBINS died of diphtheria at the Boston City Hospital, October 8th, aged twenty-eight years. He was a son of the late Judge Stebbins and was born in Springfield, Mass. He graduated from Yale College, where he held high rank as a scholar, in 1886. After studying law for a year, he entered the Harvard Medical School in the fall of 1888, and received his degrees of A.M. and M.D. *cum laude* in 1892. He served as surgical house-officer at the Boston City Hospital for eighteen months ending last

January. In his work at the hospital he showed a good surgical judgment and scrupulous attention to the comfort of his patients, many of whom had occasion to be grateful for acts of personal generosity and kindness which he went out of his way to render. Following this service he was house-officer at the Boston Lying-in Hospital from March to September, his work being always faithful and invariably stamped with a deep impress of his individuality. After a brief vacation he returned to the City Hospital for the few weeks prior to his departure for Europe, to act as Executive-Assistant and Admitting-Physician in the absence of one of the regular staff.

He began his duties at the hospital on Tuesday noon, September 26th. On that afternoon he examined, among other cases an applicant for admission to the diphtheria ward, and on the following day, two more. Thursday evening he complained of a slight soreness of his throat. On examination nothing was to be seen but a few follicular patches on one tonsil and a general redness. Friday night a membrane had formed on that tonsil and a few follicular patches were to be seen on the other tonsil. That night a diagnosis of diphtheria was made, which was verified on microscopic examination. Early on Saturday morning September 30th, he was removed to a private room in the diphtheria ward, and vigorous treatment was begun. Sunday morning he developed an intensely septic condition, and from that time the decline was constant and progressive. His courage was unbroken, and he had faith in his recovery to the day of his death.

He was a close observer and a clear, logical thinker, deeply interested in the more serious relations of his profession. Tenacious of purpose and of great though unostentatious industry, he was singularly modest and genuine in his manner. To his friends there was a sense of something rare in his friendship, for his outward reserve and air of self-absorption was not readily broken; but when acquaintance had ripened into friendship, there was shown great depth and warmth of kindliness. A keen sense of humor and an unexpected vein of drollery made him a most charming companion. His sense of honor was fine and instant. He was conscientious, generous and self-reliant, retiring in disposition and exceedingly courteous in manner.

Correspondence.

A STATEMENT OF SOME FACTS IN REGARD TO THE ORIGIN OF THE PRACTICAL APPLICATION OF ANÆSTHESIA IN SURGERY.

BOSTON, October 2, 1893.

MR. EDITOR: — The following, my contribution to a discussion in the Oral Section of the Pan-American Medical Congress last September, I should like to have go on record in the JOURNAL, which already has published so much of value in regard to the introduction of ether as an anæsthetic. That sulphuric ether was repeatedly used as an anæsthetic by Dr. Long of Athens, Ga., in his surgical practice as early as 1840, seems indisputable from the reliable evidence collected and published by the late Dr. Marion Sims of New York, but a few years ago.

The fact that Dr. Long did not publish it to the world does not affect the priority of its use.

Next comes, about four or five years later, the experimental discovery and practical application by Dr. Wells of Hartford, Conn., of the anæsthetic properties of nitrous oxide gas.

Then come facts known to me personally, as I was "behind the scenes." About a year or more later, Dr. Morton, remembering vaguely that Dr. Wells had faith in anæsthesia by the inhalation of something, applied to Dr. Jackson with the inquiry if there was anything that could be so used. Dr. Jackson informed him that in his personal experience, sulphuric ether had relieved his suffering from the accidental breathing of chlorine gas, adding a caution in regard to its use. Dr. Morton, finding Dr. Jackson's information correct in regard to the "letheal" effects of sulphuric ether, by persuasion induced Dr. Jackson to unite with him in procuring a patent to control its use. Dr. Jackson's medical friends reminding him of the breach of ethics in getting such a patent, he withdrew from the patent. It was *then* that Dr. Morton claimed the sole discovery of ether anæsthesia, and wishing to have some other respectable backing, he went to Dr. John C. Warren, then the head of the surgical staff of the Massachusetts General Hospital, and said, in his persuasive way, that he had discovered a "compound," which he called "letheon," that would prevent pain in surgical operations, and would be pleased to show its effects on some hospital patient.

Dr. Warren consented to the trial, which proved successful; but he, with the rest of the staff, declined to adopt or endorse it unless they knew what it actually was. Of course, Dr. Morton had to tell them that it was sulphuric ether. They then began its use; and it was *their endorsement* which gave it the successful start in the surgical world, without which it is very probable it might have fallen into the list of empirical fancies.

The summing up of these facts seems like this: First, Dr. Long's successful private practice, followed after several years by Dr. Wells's success, which his diffident nature hindered him from pushing to notoriety. Then Dr. Jackson's instruction to Dr. Morton, which he followed out and brought to the notice of Dr. Warren and the surgical staff of the Massachusetts General Hospital; which staff, having eliminated its elements of quackery, tried effectually, and with their substantial endorsement gave it to the world. To that *endorsement*, it seems, is due the permanent consideration that anæsthesia has since received.

JACOB L. WILLIAMS, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPTEMBER 30, 1893.

Cities.	Estimated population for 1893.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Consumption.	Diarrhœal Diseases.	Typhoid fever.	Diphtheria and croup.

Deaths reported 2,877: under five years of age 1,292; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhœal diseases, whooping-cough, erysipelas and fevers), 680, diarrhœal diseases 362, consumption 310, acute lung diseases 219, diphtheria and croup 120, typhoid fever 91, whooping-cough 34, scarlet fever 20, cerebro-spinal meningitis 19, measles 11, small-pox 10, malarial fever 7.

From whooping-cough Chicago 9, Philadelphia 8, New York 6, Brooklyn 4, Pittsburg 3, Boston 2, Washington and Cincinnati 1 each. From scarlet fever Philadelphia and Boston 3 each, New York, Chicago, Pittsburg and Milwaukee 2 each, Brooklyn, Washington, Cincinnati, Cleveland, Lowell and Somerville 1 each. From cerebro-spinal meningitis New York and Washington 4 each, Worcester and Lynn 3 each, Chicago 2, Philadelphia, Brooklyn and Gloucester 1 each. From measles New York 8, Milwaukee, Nashville and Springfield 1 each. From small-pox New York 10. From malarial fever New York 4, Brooklyn 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending September 23d, the death-rate was 19.7. Deaths reported 3,897; diarrhœa 394, diphtheria 116, fever 88, whooping-cough 86, scarlet fever 63, measles 21, small-pox (London and Bradford 2 each, West Ham and Birmingham 1 each) 6.

The death-rates ranged from 13.7 in Portsmouth to 30.3 in Preston; Birmingham 19.8, Bradford 18.8, Cardiff 16.5, Halifax 17.6, Leeds 24.0, Leicester 18.4, Liverpool 25.0, London 18.9, Manchester 18.9, Newcastle-on-Tyne 21.2, Sheffield 22.3, Sunderland 26.8, West Ham 18.6.

METEOROLOGICAL RECORD,

For the week ending September 30, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 30, 1893, TO OCTOBER 6, 1893.

By direction of the Secretary of War, leave of absence for three months is granted CAPTAIN WILLIAM D. CROSBY, assistant surgeon.

MAJORS ALFRED A. WOODHULL and ALFRED C. GIRARD, surgeons, are detailed as delegates to represent the Medical Department of the Army at the annual meeting of the American Public Health Association to be held at Chicago, Ill., from the 9th to the 14th of October, 1893.

MEDICAL SCHOOL OF HARVARD UNIVERSITY.

EVENING LECTURES.

The Faculty of the Harvard Medical School invite graduates in medicine to attend on Wednesday evenings, at 8 o'clock, at the Medical School, any or all of the evening lectures on special subjects which have been arranged according to the following schedule:

Prof. C. J. Blake. "Middle-ear Operations." Two lectures. October 18th, 25th.

Prof. Thomas Dwight. "The Topographical Anatomy of the Thorax and Abdomen, illustrated by frozen sections." Two lectures. November 1st, 8th.

Asst. Prof. M. H. Richardson. "The Applied Anatomy and Surgery of the Vermiform Appendix," "The Anatomy and Surgery of the Gall-Bladder," and "Abdominal Emergencies." Three lectures. November 15th, 22d, December 6th.

Prof. H. P. Bowditch. "Anthropometry and the Laws of Growth." Two lectures. December 13th, 20th.

Prof C. S. Minot. "Structure and Functions of the Uterus." Two lectures. December 27th, January 3d.

Asst. Professor Ernst. "Advances in Bacteriology." Two lectures. January 10th, 17th.

Dr. Edward Cowles. "Mental Physiology." Two lectures. January 24th, 31st.

Dr. W. F. Whitney. "The Pathology of the Fallopian Tubes, including Tubal Pregnancy." Two lectures. February 7th, 14th.

Prof. E. S. Wood. "Urinary Diagnosis." Two lectures. February 21st, 28th.

Dr. John Homans. "Ovariotomy." Two lectures. March 7th, 14th.

Dr. J. J. Putnam. "The Present Status of the Therapeutics of Nervous Diseases." Two lectures. March 21st, 28th.

Dr. P. C. Knapp. "Traumatic Nervous Affections." Two lectures. April 4th, 11th.

Dr. Myles Standish. "Functional Nervous Disturbances due to Ocular Errors." One lecture. April 18th.

Asst. Prof. T. M. Rotch. "Infant Feeding." Two lectures. April 25th, May 2d.

Prof. F. W. Draper. "A Special Medico-Legal Subject." One lecture. May 9th.

Dr. Henry Jackson. "Diseases of the Heart." Two lectures. May 16th, 23d.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, October 18th, at 8 o'clock.

Papers: "Malignant Endocarditis," Dr. G. M. Garland.

"A Case of Dysphagia and Dilatation of the Œsophagus with Pneumatosis," Dr. G. Liebmann.

Report of the committee appointed by the Section on Clinical Medicine of the Suffolk District Medical Society: "To Secure from the Legislature Improved Sanitary Legislation," by Dr. David W. Cheever, Chairman.

F. C. SHATTUCK, M.D., *Chairman.*
HENRY JACKSON, M.D., *Secretary.*

APPOINTMENTS.

DRS. FRANKLIN G. BALCH, JOHN B. BLAKE, JOHN DANE, EDWIN W. DWIGHT, FREDERIC B. LUND and EDWARD A. PEASE have been appointed district physicians to the Boston Dispensary.

RECENT DEATHS.

WALTER GAY STEBBINS, A.M., M.D., M.M.S.S., died at the Boston City Hospital, October 8th, aged twenty-eight years.

DR. CESARE OLIVIERI, died in Naples, September 17th, aged seventy-one years. He was one of the most conspicuous figures in the Naples school, being the director of the Pellegrini Hospital and clinical lecturer at the Incurabili. He had for some time been afflicted with a grave tracheal malady and underwent a few days ago the operation of tracheotomy at the hands of his pupil, Dr. Mottola. Everything had gone well and artificial respiration was established and maintained, without inconvenience, but in the early morning of the 17th, Dr. Mottola on approaching the bedside saw that the throat had been wrapped round and round with a towel. He addressed Dr. Olivieri, and, receiving no answer, found that he was dead, having withdrawn the canula from the throat, which he had afterwards enveloped in the manner described. On a table was a letter in which Dr. Olivieri, in despair of ever being cured of his malady and shrinking from the prospect of continued suffering, had expressed his determination to put an end to his days.

BOOKS AND PAMPHLETS RECEIVED.

Chloroma and its Relation to Leukæmia. By George Dock, M.D. Reprint. 1893.

The Bile Salts, Urea, etc., as Therapeutic Agents. By Samuel G. Dixon, M.D. Reprint. 1893.

A New Instrument for Controlling Tonsillar Hæmorrhage. By H. Hoyle Butts, M.D. Reprint. 1893.

Address on Hygiene. Delivered by Prof. Samuel G. Dixon, M.D., at the meeting of the State Medical Society, Williamsport, Pa.

Results in Ninety Cases of Pulmonary Tuberculosis Treated at the Winyah Sanitarium at Asheville, N. C., from May 1, 1891 to May 1, 1892, with a Comparison of Results Obtained With and Without the Use of Tuberculin. By Karl von Ruck, M.D., Asheville, N. C. Reprint. 1893.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S., Lecturer on Anatomy at St. George's Hospital, London. New American, from the thirteenth enlarged and improved English edition. Edited by T. Pickering Pick, F.R.C.S., Examiner in Anatomy, Royal College of Surgeons of England. Philadelphia: Lea Brothers & Co. 1893.

ISOLATING WARDS AND HOSPITALS FOR INFECTIOUS DISEASES.[1]

BY G. H. M. ROWE, M.D.,
Superintendent of the Boston City Hospital.

THE finding of the "Rosetta Stone" unlocked the secret which the ages had thrown over Egyptian hieroglyphics. The discovery of the bacillus was the key to the mystery of the cause, development and spread of infectious diseases. The impossible became possible. The pathological laboratory has demonstrated that infection is a micro-organism whose characteristics are being gradually revealed; and, what is of greater importance, it has taught us the agents for its destruction.

The physical laboratory has not exhausted the limits of the power and usefulness of electricity, nor has the pathological laboratory yet worked out the full scope of infection in its multifarious and far-reaching destructiveness.

These investigations, and the deductions from them, will make the basis of future professional treatment and the management of infectious diseases; but the economic and social bearings of the problem demand study from other points of view. Time forbids an historical or statistical review, and I proceed at once to briefly work out a few hospital equations that are paramount in the management of infectious diseases.

This audience needs not to be told that on the first appearance of an infectious disease, it should be immediately removed to a place of isolation, not only for its proper treatment, but for the protection of others. If the case appears in a home, probably an attempt will be made to isolate there, usually resulting in a separation that does not isolate. Epidemics are created by such futile attempts. Sanitary practice does not keep pace with sanitary knowledge. Not removing a person with an infectious disease to a hospital or some place securing absolute isolation, should be held as a punishable offence against society. Public health will never be assured till an enlightened popular sentiment co-operates to this end.

Every general or cottage hospital should have a suitable place to promptly isolate all cases of infection that may arise within its own walls. Infection, in this connection, includes not only eruptive fevers, but also all diseases liable to convey surgical infection. In recent years, whenever a general or well-appointed cottage hospital is built, a separate building is found among its resources for this purpose. But there are many pretentious hospitals having more than one hundred beds for general medical and surgical diseases, founded twenty years or even less, without such provision. The same is true, not only in America, but in England, even in London, owing to the original defective plan, or for want of the money necessary for the construction of such a building. There are scores of pretentious hospitals in the United States where provisions for infectious cases cannot be found outside the buildings where such cases may arise. When an infected case appears, the usual policy is to temporize by placing it in some part of the building supposed to be less exposed than the ward where the case previously was assigned. This makeshift is never satisfactory; and if other persons escape, it is usually by a happy chance. No hospital of modern construction should for a moment hazard any compromise in providing proper isolation in a building for exclusive use of infectious cases. With such a building properly equipped, and with a suitable ratio of intelligent nurses, whose hospital life is regulated by discreet and rational rules, the management of infection becomes somewhat easier. In wards having a score or less of patients suffering with a variety of infectious diseases, the regulations demand great exactness. The problem becomes yet more difficult when the wards number from forty to fifty such cases. In municipal hospitals having several hundred beds, many infectious cases, eliminated from the regular medical and surgical wards, must be provided for. This aggregates quite an array of infectious cases, in one ward for men, another for women. Besides the complication of infection, requiring the greatest skill, these wards are generally attended by the Visiting and House Staff, who are likely to have duties in other parts of the hospital. The relations of these wards to other parts of the house, in the matter of domestic service, supplies, clothing, laundry work, and the infinite number of minute adjustments, all combine to exact the most judicious and vigilant *régime*. Many cities or large towns of from 8,000 to 15,000 inhabitants have cottage hospitals, which are forced to meet the requirements of their communities. They cannot select their cases where public opinion is not yet rightly educated on such matters, and the hospital is apt to condone harmful admissions, under the delusion of keeping peace. Medical science demonstrates that public welfare makes imperative special isolating wards, not only in municipal but in cottage hospitals. This is more easily accomplished in hospitals that are private corporations, but is difficult in hospitals dependent on municipal appropriations.

There is a variety of practice about admitting to the wards connected with general hospitals such infectious diseases as scarlet fever, diphtheria, measles and the ordinary infectious diseases occasionally epidemic. But no hospital, either large or small, municipal, corporate or cottage in its organization, should receive infectious fevers into its general wards. Is it absurd to state a rule so self-evident? I have frequently seen, in this country, a case of scarlet fever or diphtheria simply removed from the other children by putting it in a room by itself — a mere pretence of isolation. I have also seen in a prominent London hospital, with a medical school attached, cases of scarlet fever and diphtheria in beds contiguous to those of patients with ordinary medical diseases. Exclude infectious diseases from all general hospitals, unless provided with separate special buildings for each disease. These wards should be absolutely isolated by distance, with separate service, both nursing and domestic; and the physicians and surgeons in charge, as well as the house staff, should have no active connection with the general wards. Every precaution should be taken to render the care and treatment, if not absolutely, yet practically, independent, so as to reduce the possibility of carrying infection to other parts of the hospital. With obvious advantages, it is far from the ideal plan. The difficulties and dilemmas of infectious-disease wards attached to a large hospital, are so numerous that the wisest policy seems to forbid it, except as a relief for

[1] Read before World's Auxiliary Congress, Chicago, (Convention of Charities and Philanthrophy, Section on Hospitals and Training Schools for Nurses,) June 13, 1893.

cases developing within its own walls. In large communities, the only system that is beyond criticism is to make for infectious diseases a separate establishment, independent and isolated. Bear in mind in this discussion that cholera, typhus fever and small-pox are excluded. Obviously, from their deadly nature, these must each be treated in a hospital specially devoted to its care, isolated in location as well as classification, although not necessarily under different boards of government. It is comparatively easy to lay down dictums indicating the best method, but pernicious conditions exist in many American cities which complicate the problem. It is a lamentable fact that the cities in this country possessing accommodations for infectious diseases among the poorer classes, to say nothing of the "well-to-do," can be counted on the fingers of one hand. To the best of my knowledge, Boston is the only large city where a hotel guest or a citizen in good circumstances can obtain suitable accommodations in a hospital if he is ill with diphtheria, scarlet fever or small-pox. In most cities the better class of corporate general hospitals absolutely refuse him admission. He is referred to the health authorities. What then? Generally the resources at their disposal are merely barracks or old buildings, diverted to hospital purposes after being abandoned as unsuitable for uses less humane. I do not forget the numerous cottage hospitals, with special isolating wards, which have sprung up within the past fifteen years in our more thrifty and enterprising towns. This indicates a growing intelligence in medical matters and the possible advance to separate buildings.

But it is in the larger municipalities where the proper accommodations are most deplorably lacking. This situation is the more humiliating, considering how many American cities and towns erect new and pretentious hospitals, at almost needless expense, on the best modern lines, while little or no progress is made towards establishing isolation hospitals for the poor, to say nothing of buildings to which the better class would resort. We recognize the superior systems employed in European capitals, especially in Germany, and also in the health districts of Great Britain, notably the urban sanitary districts.

Political methods, so rampant in municipalities, greatly affect sanitation and public health, and too often prove a stumbling-block to progress. The present rapid strides in scientific, educational and industrial affairs, and in public works, absorb so much energy and capital, that public sanitation will wait indefinitely, unless the medical profession employs Wendell Phillips' favorite weapon, "Agitate, agitate!" Optimists would fain believe that the trend of education, the truths of the laboratory, the altruistic spirit of the times, will eventually make clear to average intelligence the importance of having the proper means for stamping out the deadliest foe to public health. It is the duty of hospital workers and sanitarians not to cease forcing upon public authorities the necessity of intelligent action, until every municipality, through its public treasury, shall provide special hospitals always available for infectious diseases. Is it not the wisest policy to put such hospitals under the immediate control of the local board of health? They have so close a connection with other vital matters properly belonging to health boards, that it conduces to unity of action to have the suppression of infection under one authority — a practice that obtains in Great Britain.

But what general plan shall be pursued for special infectious disease hospitals, say, in a city of about 500,000 inhabitants, with a total requirement of perhaps 250 beds?

The first step is a site sufficiently large for liberal distribution of buildings, reasonably easy of access, and yet well isolated from sections thickly populated. In the present state of public opinion, if it is *not* easy of access, it defeats its own ends. Small-pox, like cholera and typhus, should be provided for in a hospital by itself; and the opinion of so eminent an authority as Dr. Thorne Thorne, that a small-pox hospital should not be within a mile of an inhabited house, is a wise and safe guide. As in Glasgow, small-pox might be cared for within the boundaries of an infectious disease group of buildings, but administered by itself, and having no physical contact with the rest of the establishment. Other divisions should provide for the ordinary infectious diseases, each disease having its own buildings with divisions for each sex. Each building may be absolutely separate, and yet a component part of the whole. The group should have an administration building, a domestic building, a service house containing the heating installation, laundry, mortuary, and a special home for nurses and the domestic service. Nurses should always, especially in infectious disease hospitals, be given quarters of their own in a building not occupied by patients, and of a quality to attract the class of women most desirable for hospital work.

The wards should be of moderate size, not to exceed thirty beds. The number of buildings for each disease should be sufficient to allow one building to, so to speak, "lay fallow" for renovation and disinfection. This reserve is a large factor in reducing the mortality in an infectious-disease hospital. This generous installation of site, buildings and appointments, is not always practicable, either from the topography of a city, an available site, or the financial condition of a municipality. Such establishments, we are happy to say, do exist. The Belvedere Hospital for Infectious Diseases in Glasgow, Scotland, is a most notable example. It covers thirty-one acres of land, and has thirty-five buildings with accommodations for infection usually prevalent in a large city. No better argument for insolation hospitals can be adduced than a rehearsal of the experience of the health authorities of Glasgow in changing the most unhealthy city in Great Britain, with the largest mortality, into a clean, healthful city, with a low death-rate.

A more feasible but less perfect arrangement is a site in or near the thickly-settled portions. Insure the best possible isolation by high walls and perfect administration. Provide separate administration and service buildings, give each disease and sex its own wards, and keep the ratio of beds to patients as liberal as possible. Such provisions, intelligently planned and wisely administered, will afford a powerful weapon to crush out infection. Liverpool, a city especially exposed to infection, has an admirable instance of a hospital of this class; and so eminent an authority as Mr. Henry C. Burdett, assures us, that, "on the whole, this hospital may fairly be regarded as one of the best arranged infectious hospitals yet erected. Considering the restricted site, the arrangements are most satisfactory."

The opinion is gaining ground among hospital superintendents and sanitarians that large numbers of infectious cases cannot be treated to the best advantage

under one roof without increasing the mortality-rate. This has been demonstrated in hospitals and institutions devoted to the care of sick children. The ideal way to treat a case of acute disease highly infectious, would be to have two rooms which the patient should occupy alternately for twelve hours, with proper safeguards in all the conditions of transfer. The same law of rotation, with a larger proportion of time, would be admirable for the occupancy of infectious disease wards. Many small, isolated buildings on one site yield better results than a few buildings of a larger size on a restricted site. Increased cost is an objection to this. Unfortunately, public opinion, squeamish and short-sighted in public sanitation, backed by legislators ambitious for low tax-rates, and cajoled by the always sensitive tax-payer, is an active and potent obstruction to the more intelligent methods.

Fire departments recognize that it is the first five minutes that counts; so the first case of infection is the most important one to fight. Dr. Thorne Thorne has made the most exhaustive study ever attempted on infectious disease hospitals, and he instances scores of examples to show that epidemics have been crushed by having the means to isolate the first case. He insists that such buildings should be constructed in non-epidemic times, rather than under conditions of panic, and that immediate and permanent usefulness of hospitals is impaired by hurried erection.

In conclusion, I am asked how the City of Boston ranks in the means for the suppression of infectious diseases.

Boston has possessed, since 1877, a small-pox hospital with accommodations for fifty ward patients, and six rooms for private paying patients. By the irony of fate the last private patient was a well-known Boston poet. The hospital is half a mile from the nearest habitation, located on an excellent site, well-appointed as most cottage hospitals, which it resembles in external appearance. It is to-day, and has been every day during the last sixteen years, occupied by a man and his wife, both nurses experienced in the disease, and ready at all times to receive a patient. It has its special ambulance which can always be summoned by telephone, and a reserve of portable huts and protected nurses when many cases occur. Dr. McCollom, the City Physician, confidently asserts that 150 small-pox patients can be properly provided for at forty-eight hours' notice. This, again, is a good illustration of Dr. Thorne's proposition; and the suppression of small-pox in Boston, and its very low mortality through a long series of years, is an object-lesson worth heeding.

The Boston City Hospital has 484 beds, distributed among eighteen wards, including a men's ward of ten rooms, each accommodating four cases, either of erysipelas, cellulitis, pus in any form, or any uncleanly case arising within our own walls or from outside. There is also a ward containing twelve rooms, accommodating forty-eight women, which receives similar cases, including pelvic or puerperal septic cases.

The hospital also has two other wards, one for scarlet fever and one for diphtheria, each having thirty-two beds for both free and pay patients. These are separate buildings, built in 1886, of high cost construction, and in air-supply, heating and ventilation, service rooms and special appointments, equal to the best of modern hospital wards; indeed, they are the most admirable of the hospital. In all respects they supply the same amount and quality of professional care, nursing and comforts afforded by any ward in the hospital, whether free or paying. The nursing is done by the nurses in the Training School, and the seniors of the House Staff are in turn isolated for attendance in the wards.

These wards are administered by the strictest regulations and are practically isolated; but their proximity to the general wards imperils others, and proves the correctness of my proposition that no wards designed for infectious fevers from without should be an integral part of a large general hospital. In spite of every safeguard, and after allowing for sources of infection from ward visitors and the dangers imminent to a hospital of 750 people, cases now and then do crop out that may fairly be attributed to the infectious fever wards. The labor involved in a large general hospital is always great and exacting. Ought it to be augmented by the strain of preventing the transmission of infection from special wards to the non-infectious wards?

During the last seven years, 752 cases of scarlet fever and 2,227 cases of diphtheria have been treated in these wards. It has given a wide experience of the dangers of isolation disease wards on the grounds of a large general hospital, and teaches "how not to do it."

This unhappy condition, I am glad to say, will soon be remedied. After a repeated and persistent course of education imposed by the hospital management upon the city authorities, Boston is constructing a special hospital for infectious diseases which I feel sure will be unrivalled in this country. The trustees already have $237,000 solely for this purpose. This, however, will not complete it, and $140,000 additional has been promised in the next loan bill, making $377,000 for this special purpose. Contracts have been made for $203,000, and the buildings are well under way. Time forbids a description of these buildings, but they are in the best lines of modern hospital construction, and intended for 250 patients, at a cost of about $1,500 per bed. The plans and details are the result of much study of eminent authorities, and will give Boston a strong weapon for fighting infectious diseases. For the present, it will be under the management of the Boston City Hospital, and will be administered in a manner equal, and we hope superior, to the general wards. The plans of these wards may be seen in the Boston City Hospital exhibit in the Anthropological Building.

In the May number of the *Forum*, the learned President of this Section, in an article on municipal sanitation, asks this question, "Where is the place to which a lady living in a boarding-house, or temporarily stopping at a hotel, could take her child afflicted with scarlet fever?"

In Massachusetts, the cities of Boston, Cambridge, and Newton, all possess such accommodations. Three other hospitals in New England have isolation disease wards, either under construction or projected. The isolating wards of the Boston City Hospital have private rooms for eighteen paying patients at $15.00, $20.00 and $25.00 per week. Their accommodations, treatment, nursing and general care, including diet, compare well with that usually given medical and surgical paying patients in first-class general hospitals.

Boston goes a step further. The hypothetical case of scarlet fever — and also any citizen, rich or poor — can have his clothing and all fabrics exposed to infection, taken for purification to the new and well-equipped sterilization house of the Board of Health and returned, without charge.

Hospitals are only one part of the splendid engineery

demanded for working out the extermination of infectious diseases. I cannot forbear calling attention to the collateral means. There must be efficient local boards of health, co-operating with State boards, all of which are controlled by a central national organization under the United States government. The highest intelligence of expert sanitarians would thus penetrate all communities and concentrate action on a common foe.

TRACHEOTOMY AND INTUBATION AT THE BOSTON CITY HOSPITAL.[1]

BY GEORGE W. GAY, M.D.,
Visiting Surgeon.

PREVIOUS to July 1, 1892, tracheotomy for croup had been done 514 times at the Boston City Hospital. One hundred and sixteen patients recovered (22 per cent.). Intubation has been done 502 times between December 31, 1886, and the above date. There were 91 recoveries (19 per cent.). In 58 instances both operations were performed, and only 7 recovered (12 per cent.).

A clearer statement of the facts would be as follows: primary tracheotomies 456, recoveries 110 (24 per cent.); intubations without tracheotomy 442, successful 90 (20 per cent.). This shows a difference of four per cent. in favor of the older operation.

Before the introduction of intubation 327 tracheotomies had been done and 95 recovered (29 per cent.). Since the new method came into vogue in this hospital in December, 1886, 129 primary tracheotomies have been done, with 15 recoveries (11 per cent.). During the latter period the ratio of recoveries under the various modes of treatment is as follows: intubations 20 per cent., primary tracheotomies 11 per cent., secondary tracheotomies 12 per cent.[2]

In estimating the relative value of tracheotomy and intubation it is well to have a clear understanding as to the purposes for which these operations are done; as to the definite results to be reasonably expected from them. In the great majority of cases of croup the result largely depends upon three conditions, to wit: laryngeal obstruction, bronchial croup and septicæmia. Now it is more than doubtful if either of these operations has any direct influence whatever upon the extension of the membrane, or upon the septic infection. They are done to overcome any obstruction to free and easy respiration located in the larynx, and no other direct result can reasonably be expected of either procedure. The type of the disease, more than all things else, determines the result of the treatment.

The great importance of giving relief to the laryngeal difficulty is indicated by the nature of the affection itself and also by the fact, that life is prolonged, and more time is thereby obtained in which to combat the various complications. In very many instances the operations are succesful and satisfactory, although the result of the disease is fatal. The patient succumbs to sepsis in some of its various forms or to some other complication, but has no more trouble from the dyspnœa. The operative or surgical part of the treatment was successful, in that it accomplished all that could have been expected of it, by overcoming the difficulty in breathing through the larynx.

Hence, I submit, that a more rational criterion by which to estimate the comparative merits of tracheotomy and intubation would be the amount of relief to the laryngeal dyspnœa resulting from each operation. Judged by this standard, rather than by the result of the disease, which operation gives the most satisfactory relief to the difficult and labored respiration of acute laryngeal stenosis in children?

Every one who has had much to do with tracheotomy, is familiar with the favorable change, which follows the introduction of the tube into the trachea, providing the obstruction is not too low in the air-passage. Unfortunately the respite after both operations is all too brief, but for some hours it is so striking that one needs to be on his guard as to the ultimate prognosis.

In 110 cases of the later intubations at the Boston City Hospital, a record of the immediate effect of the operation upon the dyspnœa was made, with the following results: In 75 instances the relief was immediate and complete: 22 patients were so much benefited that no further operative treatment was required. In 13 cases no relief was obtained by the laryngeal tube. In one instance membrane was pushed down in placing the tube. Immediate tracheotomy was done and the child recovered. In another favorable case it is doubtful if the tube entered the larynx at all. In several of the cases little or no relief was obtained by opening the trachea after intubation, which is not an uncommon result, except in those instances of displaced membrane.

Any method of overcoming the dyspnœa of croup, which gives sufficient relief for all practical purposes in nine cases out of ten, as indicated above, is worthy of our respect and consideration.

Does tracheal section relieve dyspnœa in those cases in which intubation fails? That is the key to our subject and a correct answer will decide the question at issue. Should membrane be pushed down by the laryngeal tube and the patient be unable to expel it, then tracheotomy may be depended upon for relief. These cases, however, are not very common and there are not many exceptions to the rule, that if intubation does not relieve the dyspnœa, little benefit need be expected from tracheotomy. It is obvious that neither operation will do much good, if the obstruction is situated below the point reached by the tracheotomy tube which does not extend enough lower than the laryngeal tube to make any difference in the result. Cases of rapid or difficult respiration due to extension of the morbid processes or to sepsis, are not benefited by any method of treatment with which I am familiar.

Secondary tracheotomy has been performed 58 times in this hospital previous to July of this year. Seven recovered (12 per cent.). It will be noticed that the results of primary and secondary tracheotomies in late years are about the same, and are due to the fact, that only the worst cases are subjected to this mode of treatment. Intubation, even if not successful, does not seem to lessen the patient's chances for relief, except in the gravest cases, when any disturbance may result in collapse. Except in those cases in which the laryngeal tube becomes occluded in its introduction, very little benefit resulted in many instances from opening the trachea, after a fair trial of intubation. It is best just to say, that the lack of skill and experience must be held responsible for some of the failures of the new

[1] Read before the Surgical Section of the New York Academy of Medicine, October 20, 1892.

[2] For the later statistics in this paper I am indebted to Dr. W. H. Prescott, formerly house-surgeon.

method in the above cases, rather than the character of the operation itself. The failures of intubation were generally due to pushing down membrane, faulty introduction of tube, or to the obstruction being situated so low that no operation could give relief. In the great majority of cases the right tube, properly placed in the larynx, will afford adequate relief to the acute symptoms of laryngeal obstruction.

The fact that 502 intubations have been done at the Boston City Hospital during the past five and a half years, and only 129 primary tracheotomies, shows pretty conclusively, that the new operation has supplanted the old one to a very considerable extent in that institution. Intubation, as a rule, is the primary operation, and only in case of failure, is the trachea opened. Considering the large number of surgeons who have charge of our diphtheria wards at different times, it is remarkable to what an extent this operation is performed. There is necessarily a personal equation in these matters, and unless a particular mode of treatment has much in its favor, it is hardly to be expected that a dozen different surgeons would resort to it year after year in preference to its old and well-established rival. Such are the facts, and the lesson is unmistakable.

Intubation is by no means a perfect method of relieving laryngeal obstruction. That is yet to be invented. But it has sufficient advantages to give it a permanent place in the treatment of this affection. It will never entirely supplant tracheotomy, as the latter possesses some desirable features which cannot be claimed for the former. The most important of these is the facility of swallowing. The dysphagia is the most serious objection to intubation. In a small number of cases it is difficult to get the patient to take sufficient food and stimulants by reason of the choking at every attempt to swallow. A good nurse possessing tact and perseverance can overcome this difficulty to a great degree, but unfortunately such a person is not always attainable. In a hospital this objection does not have that importance which appears in private practice. In a large proportion of cases, however, the difficulty is not great enough to lead one to abandon the plan of treatment.

Among other objections to the laryngeal method are the facts, that occasionally the tube is coughed up repeatedly; that it becomes occluded; that there is no expectoration; that for some reason, not always apparent, it does not relieve the dyspnœa; and, finally, that the tube can not always be introduced into the larynx. While it is true that all of these complications are met with, yet they are not sufficiently common, nor so difficult to overcome, as to lead any one, who has had a fair amount of experience, to give up the method. Tracheotomy is by no means free from complications, such as hæmorrhage, sudden blocking up of tube, shock, etc.

That any one with reasonable dexterity, who has done both operations a good many times, should consider the new one the more difficult to perform, is beyond my comprehension. One requires from five to ten minutes including the time necessary for preparation; the other from half an hour to an hour. In the new operation no anæsthetic is required; the light is of secondary importance; there is no hæmorrhage, and except in the worst cases little danger is to be apprehended from shock.

Unless one's early experience with intubation has been peculiarly favorable, he is prone to condemn the method upon insufficient evidence. Croup is not an easy disease to manage by any method known to the profession, and the new one is no exception to the rule. A fair amount of skill, perseverance and experience are requisite for a satisfactory management of these cases. From thirty to fifty examples of each operation are necessary to enable one to form an intelligent opinion of the advantages and disadvantages, the accidents and complications incident to each. Personal peculiarities will always be a factor in choosing the method of treatment. But the strongest advocates of intubation will be found among those who have had the largest experience, which is the best and safest of all teachers.

In conclusion, allow me to say, that in a majority of cases I think intubation is preferable to tracheotomy for the relief of acute laryngeal obstruction in children under seven years of age for the following reasons: It relieves dyspnœa; it is more quickly and easily done; consent of parents or guardians is more readily obtained; it will be resorted to earlier in the disease; it requires no more skill and care in the after-treatment than does tracheotomy; the tube takes care of itself; it is less likely to "gum," or to become obstructed; no anæsthetic is required; as there is no cutting, there is no hæmorrhage; it is not regarded as a surgical operation by the parents and friends; and finally, the records of the Boston City Hospital indicate, that the results are nearly as favorable, as after the other method of treatment.

Such are the reasons for the opinion expressed in this paper, and they are based upon the experience of my colleagues, and of myself, in upwards of a thousand operations. The type of the disease will vary at different times, thereby affecting the results. Accidents and complications will occur not infrequently in both plans of treatment. But after making due allowance for these facts, as well as for individual preferences and peculiarities, I venture the statement, that Dr. O'Dwyer's operation will remain in the opinion of a large number of surgeons for a long time to come, what it is at present, a reasonably safe, efficient and satisfactory method of relieving acute laryngeal stenosis in children.

It is stated in a German paper that more than twice as many people died in London last winter from influenza as died in the same city, during the year 1843, from cholera.

RECURRENT TONSILLITIS.[1]

BY G. A. LELAND, M.D.

(Concluded from No. 15, page 374.)

THE following illustrative cases may bring out some points that have not been touched upon in the foregoing, and emphasize others:

CASE I. Miss M. G., a lady of thirty summers or thereabouts, was sent to me on the 24th of August, 1889, for an earache which had been coming on for a day or two. Examination of the ear showed no congestion or bulging, denoting inflammation or effusion into the tympanum; and I told her, therefore, that probably the pain in the ear was reflex from some other cause, very likely from the throat. On inquiry, she said that she had a little sore throat at the present time, that she had been subject to recurrent attacks of tonsillitis for four or more winters, that during every winter a slight cold would start up an attack of tonsillitis, which would last from four to six weeks, including recovery. As she was much in society, these attacks of tonsillitis interfered very much with her winter's pleasure since a slight cold taken while out of an evening meant being housed for a month or more. During these winters constant treatment with gargles, sprays and applications gave no lasting benefit. These attacks occurred also in the summer, but with less frequency; the ears were apt to feel full and to itch a good deal. Examination of the throat showed both tonsils very much enlarged, surfaces pitted with holes, through which projected the tops of the inspissated secretion filling them. The left tonsil at this visit was red and swollen, as if taking on a slight degree of inflammation. I introduced the blunt hook and tore away the partitions between several of the crypts, expelling much of their contents, and causing a little depletion by hæmorrhage, and then washed them out with Dobell's solution by means of the long-nozzled syringe. She expressed herself as immediately relieved of the earache, and continued her journey to a summer resort. As she was in transit, I was unable to do very much of an operation and was content to simply relieve the discomfort in the ear. She experienced this relief for some time, but soon after had a large swelling come on the left side of the neck, which was very painful and was accompanied with considerable fever and malaise. The resident physician at the resort could see no reason for it on examination of the throat, and had to await developments. Finally, an abscess burst, probably in the under part of the tonsil, out of sight, and the physician could not find the opening, but much blood and pus were discharged for three or four days. This produced a great deal of physical depression, and the patient was quite a long time in recuperating. On October 16th, I again examined the throat and was able to find no lesion to account for the abscess or its place of exit. Having determined to have her tonsils reduced by the method in question, I united several of the crypts at this sitting, and painted with equal parts of tincture of iodine and glycerine. She remarked that her ears felt very well until the day before, but she then began to feel the old irritation return. This operation was repeated on October 26th and November 14th, when some of the little light-colored, fibrous-feeling tips were cut off with the bistoury. By this time with these four operations, the tonsils, which at first projected perhaps half-way to the uvula, had shrunk down to the level of the pillars of the fauces. February 20 and 24, 1890, I again saw her with a very severe cold, but no trouble at all with the tonsils. On May 19th, she had a very mild attack of inflammation of the fauces and naso-pharynx from a cold which occluded the left nostril, and the tonsils were somewhat involved in the inflammation. The few crypts remaining were brought into notice by the inflammation. They were torn and cut again and a few projections removed. This was repeated on May 29th and June 3d, which last operation was for trimming up, and a few little holes were enlarged and again painted. At the end of the summer I saw her again for a slight cold which she had in the head, but she had had no symptoms of tonsillitis throughout the summer. In January of 1891, tonsillitis was very common, almost epidemic, and her right tonsil was seared a little on the 14th of the month with the galvano-cautery point in order to treat a very small point of local redness. Since that time she has had no trouble at all with her throat. I saw her about a year ago, the tonsils had disappeared behind the pillars of the fauces, and in looking at her throat one would never suspect that they had ever been enlarged. This then is the fourth winter since her tonsils were operated upon, and from being formerly laid up several times in the winter with this recurrent disease, she has had absolute immunity from it, and I have no reason to doubt that it will be permanent.

CASE II. Mr. P. J., seventeen years of age, was sent to me October 31, 1889, by the foregoing case who was a relative. On the sixth and seventh year before, he had been much troubled with attacks of tonsillitis, but they were not very severe. The tonsils were very large, especially the left one, projecting even to the uvula, the surfaces studded with the mouths of crypts, and bands of fibrous tissue reticulated over their surfaces. They interfered very much with speech, especially with singing and together with a few adenoid vegetations in the naso-pharynx, interfered also very much with breathing. Five years before he had had an acute inflammation of the left ear with rupture of the membranum tympanum and hearing was variable, sometimes much impaired, with colds. He submitted very gracefully to the operation in question, and by the last of December, after seven sittings, the tonsils had disappeared behind the pillars of the fauces, the pillars themselves had come together so as to be in their usual position, and his voice, color, flesh and general health were very much improved. In this case the parents were averse to the amputation of the tonsils with the guillotine, and were pleased to think that they could be reduced in another way which did not seem so barbarous. A letter from his mother, received last week, says: "He has gained much in flesh and color; his general health has improved; and he has had no further trouble with the throat, which formerly caused him to lose much time from his studies."

The following case is interesting because an intra-tonsillar abscess:

CASE III. Miss C., a lady in good circumstances, and of about thirty-two summers, had from a child been troubled with very severe ulcerated throats which continued till she was about twenty-seven, when they took on the added evil of abscess formation. The first attack was double, one on each side, eleven years ago. She never had more than one attack per year except

[1] Read before the Boston Society for Medical Observation, May 1, 1893.

once when the second attack occurred in January, but was much lighter than the May attack. The regular attacks occurred in May and in *every* May. Three weeks were usually required before the abscess broke, and two more before she was able to sit up a moment; and usually four months before she recovered her usual tone; and then it was time to look forward to another attack. Each attack was followed by one of acute rheumatism. I saw her about three years ago, with Dr. Bush, at the height of the attack. I was unable to reach pus with the curved bistoury; and I think I have never, before nor since, seen so much suffering in such an attack.

In the fall, after recuperation, the method of treatment under discussion was employed by me and she was seen about the usual number of times, and the tonsils shrank away very satisfactorily. The next May was to test the result. On the 31st day at noon, she appeared at my office, just twenty-three months ago, saying that the old trouble was again upon her. One small red nodule appeared in the centre of the right tonsil. It was incised, and a small amount of greenish pus exuded. She went home relieved, only to call me again at about nine o'clock for increasing pain and fever, chilliness, headache, and in general, the old symptoms. A small amount of pus showed at the site of the puncture, and the hole was enlarged. With her reluctant permission, I introduced the tip of my right digit into the mouth, and finding the incision, pushed it into the tonsil where was found a cavity whose wall felt like the inside of a rubber ball. The opening was torn very wide on withdrawing the finger. The pain was very severe, and bravely borne. She was sure she would be ill as usual the next morning, but at my call, was up and about, dusting the parlor, after a quiet, painless, restful night.

Since then she has had no tonsillar trouble, and only one slight sore throat. Her general health is much improved; she has much less rheumatism; and has noticed the better sound and flexibility of the voice, and absence of fatigue in its use. From being constantly debilitated, she is now in robust health.[2]

Case IV. Mrs. A. P., (twenty-seven, married, with several children) has had tonsillitis and an irritable sore throat (but never quinsy, so-called, or tonsillar abscess) for eleven years; never was free from a sore throat summer nor winter, always worse in winter; her voice was much affected, both for talking and singing, and singing was entirely given up on account of it; general health was much impaired and weight was only from ninety to one hundred and nine pounds, although according to her stature she ought to have weighed over one hundred and twenty; complained very much of trouble with breathing while asleep and frequently had to moisten mouth with some gargle or drink which was constantly kept by the bedside; had constant dropping down the throat and malodorous breath, but had no trouble with ears and no dyspepsia, rheumatism, nor gout; had diphtheria nine years ago and thinks throat has been aggravated very much since.

On examination, the tonsils were found to be moderately enlarged, surface perforated by crypts containing more or less cheesy, decomposing secretion; nasopharynx reddened and somewhat thick, markedly so at the lymphatic patches behind the posterior pillars. There were a few small adenoids in the vault. She submitted at the first visit, October 31, 1890, to the operation in question upon the left tonsil, and a number of pieces were removed with the forceps and bistoury. A weak solution of borax, as hot as could be borne, was ordered for gargle. She was also operated upon on the 7th, 14th and 21st of November, and a few adenoids were at the same time removed with the forceps. She did not suffer much between the visits, and having a good deal of "sand" was obliged to submit to but four operations in all. The tonsils shrank away entirely between the pillars of the fauces, and she was dismissed with the recommendation to come again should a single follicle start up to be inflamed, and give her any idea that the old symptoms were returning. I have not seen her since; but a letter dated April 26th of the current year says that she has had no symptoms of a sore throat since the treatment was finished, nor of catarrh; that she has had no odor of the breath and not a sick day since; that she can talk and sing as well as ever; and that her general health has improved, and her weight is now between one hundred and twenty-five and one hundred and thirty pounds. It is not to be expected that she will ever be troubled again.

Case V. A little girl, G. H., seven years of age, has had trouble with adenoids and tonsils since birth. At two years of age she had scarlet fever and the throat has been very sensitive and tonsils very troublesome ever since. At the first visit, December 7, 1892, she was just recovering from the fourth attack of tonsillitis during that year. There were two attacks the previous winter, one in the summer and one the first week in September, and the day before the visit she was out for the first time since another attack. This last time the tonsils were enlarged for two weeks, and painting with iron, etc., was not of much avail until eight days ago the attack culminated in an acute tonsillitis. Under the care of another practitioner she had been kept along, and the naso-pharyngeal hyperplasia had satisfactorily diminished as she advanced in age, but she has had on the average about four attacks of acute tonsillitis every year. Being so young it was thought advisable to do but little at each operation, but in this case the parents were glad to find a method which would not require tonsillectomy. She submitted to seven operations only, which were considered sufficient, for the tonsils had shrunk well away, although the surfaces were slightly nodular. She went away with the ordinary injunction as to the return of the inflammation in even a single follicle; and on February 10th (the last operation occurring on the 26th of January), on a very rainy and stormy day, I was sent for in a hurry because it was thought the tonsils had again lighted up; but at my visit I found the child playing about apparently perfectly well, with no sore throat. The parents had been frightened because she had awakened that morning a little languid, as usual in such attacks, and they had seen some redness about the fauces, and thought that my prognosis was refuted. I was very happy to assure them that, although the fauces were slightly reddened, the tonsils were not affected at all, and that there was no cause for alarm.

She has gone through this very trying spring, when sore throats have been more than usually prevalent, without another attack.

Of course, I do not consider this case as one which

[2] Since the foregoing was prepared for publication, the patient came in June 3d to say that the second May had already passed, and that she had escaped all symptoms of throat trouble, and, therefore, was entirely satisfied that the treatment had been a success.

is of as much importance as the others which have been longer finished; but I report it as one which, under the old methods of treatment, for five years at least has still had four attacks of "quinsy sore throat" every year, and which in a most trying season since operation has thus far escaped; and I am almost willing to wager she will have continued immunity from her old enemy.

It would be useless to continue to enumerate cases which have been benefited, since their relation would be believed by some and disbelieved by others, as is often the case; but these few are cited as examples of the beneficial effect of a treatment which I am persuaded is not in common use among physicians, both general and special. This method is not brought forward as the best in all cases, but in those cases where the tonsils are too small to reach with the guillotine; in those where there are but a few diseased crypts; in tonsils which perhaps are not enlarged at all, it is of the greatest value, at least in my hands. It is advocated as a very good method where, as is so often the case, the patients or their parents are much averse to the amputation of the organs; and certainly, in my experience at least, when this method is carried out to a satisfactory termination, the stump left is much better than by any other method. I do not claim any originality in bringing it forward except that perhaps these knives, which I have not seen described nor recommended before, I think are an improvement over the blunt hook of Hoffmann, which certainly gives a great deal of pain where the tonsils are toughened by fibrous hyperplasia.

Clinical Department.

CHOLECYSTOTOMY FOLLOWED BY CHOLECYSTENTEROSTOMY: A FINAL REPORT.

BY E. P. HURD, M.D., NEWBURYPORT, MASS.

In the Journal of March 28, 1893, is a preliminary report by Dr. G. W. Jones, of a case of cholecystenterostomy performed by him in Newburyport early last January. It becomes my duty as attending physician of the patient to make a final report. The poor woman unfortunately died early in April of marasmus resulting from the operation.

The first operation, cholecystotomy, performed about a year ago in the Anna Jaques Hospital, was called for by the wretched condition of the patient, who had for several years been suffering from repeated attacks of gall-stone colic, unfitting her for her work. My diagnosis of biliary lithiasis was confirmed by that first operation, eight gall-stones of variable size (and facetted) having been removed. No calculi were discovered in the common bile-duct or in the cystic duct. It was not at the time determined whether there was present any stenosis of the choledochus. The patient made a good recovery, but a biliary fistula remained, which refused to heal, though repeated attempts to close it were made by Dr. Jones and by myself. The fact that this fistula would not close, and that there was an almost daily escape of bile, and in quantities which often weakened the patient, led us to think that there must be partial stenosis of the choledochus, not *total* stenosis, for there was evidence (coloring of stools, absence of jaundice) that some bile constantly found its way into the intestine.

Miss C., in October, went to Cambridge for further medical advice, and came home early in the winter resolved on having another operation performed, which might cause the bile, then running off by the fistula, to be utilized, and might restore her to health again.

This operation is well described by Dr. Jones in the Journal article above mentioned. After the intestine (believed to be a loop of the ileum) was attached to the gall-bladder in the manner described by Dr. Jones, it was perforated, a drain made of silk-worm gut was inserted into it, and the deep wall of the gall-bladder with the intestines dropped back into place. The opening into the gall-bladder was packed lightly with gauze, and the central abdominal incision was closed and sealed with collodion.

The immediate result of the operation was favorable. For a fortnight there was no untoward symptom. Dr. Jones's report was made from data communicated by me and Miss Bement, the nurse, down to about January 25th. Then constant fæcal and biliary discharges manifested themselves. These discharges were biliary and mucous only till about the time when I took out the silk-worm gut drain, ten days after the operation, when fæcal matters and chyle began to be mingled with the discharges from the fistula; I say, *chyle*, for there was often material that seemed to be imperfectly digested food, and I was on several occasions assured that broth, milk, etc., had been voided by the fistula in almost the same condition as when swallowed. Miss Bement had seen milk appear at the fistula five minutes after being swallowed.

It was supposed at the time of the last operation that there would be no doubt about the rapid healing and firm cicatrization of the old fistula; there would now be no longer any reason why biliary, much less fæcal matter, should be discharged externally. The event was different from what we fondly expected. We had now, not only our old biliary fistula, but a fæcal fistula along with it — a fæcal fistula communicating with some part of the small intestine rather high up. An attempt was made by Dr. Jones and myself about the middle of February to close up this fistula. We cut around it till we had dissected up a funnel-shaped tube leading down to the gall-bladder; around this a stout catgut ligature was thrown, and the portion above was enclosed in a buried catgut suture bringing the freshened tegument well together. It was all of no avail; in three days the discharge had burst through the artificial coverings interposed to compel it to seek the natural channels.

From that time Miss C. went rapidly down. Appetite became *nil;* there was constant vomiting of food and drink: and it soon became necessary to stop all nourishment by mouth and to feed the patient by rectal enemata. It is seldom that a physician is compelled to witness a more painful and hopeless illness; the only relief that could be given for the distress was the subcutaneous morphine injection.

A swelling (which eventually nearly or quite subsided) formed over the right lobe of the liver which led me to fear the formation of hepatic abscess. The continued outflow by the fistula excoriated the external parts and made them very painful; this distress was only partially mitigated by absorbent powders. The obstinate vomiting of alimentary matters, of glairy mucus, the burning pain experienced along the gullet and in the stomach might have suggested acute gastritis; but we often witness the same symptoms in

ileus and volvulus. There was a dry and parched tongue and incessant thirst. The urine was scanty and high-colored and the bowels constipated, though copious stools could be elicited by glycerine injections. For a time there was a decided icteroid hue of the teguments and conjunctivæ.

There is no particular reason for dwelling further on a case which was as distressing as it was disappointing to all concerned. Miss C. lingered on, and died of inanition and starvation about the middle of March. The quantity of nourishment taken by mouth for more than six weeks was very small; and the amount actually appropriated much smaller, for very little was really retained. The poor woman was, as might be supposed, exceedingly emaciated.

In the absence of a post-mortem examination (which was denied) no entirely satisfactory analysis of the symptoms and explanation of the cause of death is possible. What I have to suggest is largely of the nature of conjecture, and will be comprised under two heads:

(1) A fæcal fistula was established between a portion of the small intestines and the abdominal wall, giving an escape externally to much excrementitious matter with more or less chyle. Unless such fistulous orifice can be closed, serious results are certain to happen, as our best surgical authorities testify. I might quote in point from Cooper, Chelius, Gross, Erichson, Druitt and others. Sir Astley Cooper, for instance, mentions the case of a man with a strangulated umbilical hernia which sloughed and occasioned an artificial anus. As he was recovering from the effects of the strangulation and sloughing, and was allowed to take food in any considerable quantity, it was observed that part of what solids he ate passed out at the artificial anus within half an hour after he had swallowed them, and that fluids passed out in ten minutes after they had been taken into the stomach. Although he took sufficient food to support a healthy person, he wasted rapidly, and died in three weeks. On examining his body after death, and tracing the jejunum, the lower part of that intestine was found entering the hernial sac, and in it the opening was situated.[1]

(2) The intestine in this operation was brought into direct communication with the gall-bladder so that the latter was in all probability constantly contaminated by fæces and microbes from the small intestine. In fact, the gall-bladder, by virtue of the operation, was converted into a diverticulum of the intestine. Hence the possibility — I may say the probability if not certainty — of infection of the liver by way of the intestine. The bile, as is known, does not flow continuously but intermittently; though undoubtedly antiseptic, it can not act when it is not present. It has seemed to me, the more I have thought of it, that by making the gall-bladder a *quasi* diverticulum of the intestine, we furnish just the best possible conditions for microbic infection of the liver. In the physiological state, the intestine, if not shut off from the mouth of the choledochus by a membranous valve, is virtually excluded from the duct by the fact that the latter opens obliquely into the digestive tube, passing through the muscular coat of the duodenum whose contractions act the part of a valve; moreover, the choledochus becomes narrowed at its mouth to such an extent that in a state of rest its lumen is virtually effaced.[2] It will be seen that the conditions are altogether different when, instead of having the intestine with its microbes and fæcal contents nearly shut off from the liver (which even then in certain morbid states cannot altogether protect itself from infection), we have the intestine in direct communication with the gall-bladder by a fistulous orifice.

I am aware that the ready reply to this argumentation will be that every operation of the kind — every cholecystenterostomy — presupposes just such direct communication between the intestine and the gall-bladder, that there are now on record some ten successful cases, and that in one successful case, that of Mayo Robson, it was the colon that was made to communicate with the gall-bladder.

No one can reply to this objection till he has ascertained the subsequent history of all the cases on record. How many of these reported cases have been complete and permanent cures?

But granting the entire success of a part if not all of the cases, from that of Winiwarter in 1881 to Mayo Robson's last operation, we can only suppose a satisfactory result possible by a process of cicatrization and healing which shall closely imitate the natural physiological condition, that is, a minute orifice of communication, and a membranous barrier or valve to oppose the passage of fæces into the gall-bladder, while permitting the flow of bile from the gall-bladder into the intestine. Possibly this result might have been attained in our case, provided we had not put in that drain of silk-worm gut, *or provided I had removed it earlier.*

But it is useless to speculate further as to the causes of failure in this unfortunate case. The operation as performed was unquestionably a brilliant one; and the untoward result, in connection with such theoretical considerations as I have indicated above, has convinced me that cholecystenterostomy must always be an eminently hazardous operation.

HISTORICAL RETROSPECT.

The first to advise the operation of cholecystenterostomy was Nussbaum in 1880, for cases of irremediable occlusion of the common bile-duct. The first to perform it on the human subject was Winiwarter, in 1881. The second operation was performed by Kappeler, six years afterwards. The operation was done at one sitting. July 6, 1887, he incised the gall-bladder and duodenum and approximated them with a suture of serous and mucous coats. There was complete recovery. Montastyrsky operated about the same time, and lost his patient. Socin, November 19, 1887, performed cholecystenterostomy in a manner similar to Kappeler, with recovery of the patient. The fifth case was that of Fritzsche, April 24, 1888. The case was one of impaction of gall-stone in the choledochus. He made an opening into the intestine and gall-bladder and united incision with catgut sutures of mucous coat and silk sutures of serous coat. Patient died on May 4th.

The sixth case was that of Mayo Robson, March 2, 1889. He joined the gall-bladder with the colon, uniting mucous and serous coats with chromicized catgut sutures. He reports a good recovery. The seventh case is that of Terrier, August 13, 1889. After incision of gall-bladder and duodenum, he approximated with two rows of sutures, put in drainage-tube, and sutured the gall-bladder to the abdominal wound. He reports a good recovery. This case strikingly resembles the Jones and Tuttle case whose unfortunate

[1] Lectures on Surgery, vol. iii.
[2] Les Infections biliaires (Dupré) Paris, 1891.

termination I have here reported. The eighth case is that of Courvoisier, March 28, 1890, who attached the gall-bladder by serous sutures to the colon, after having opened the choledochus and curetted several gall-stones out of the hepatic duct.

There are a few more cases to add — some successful, some unsuccessful. Bardenheur's two cases both terminated fatally. He united the gall-bladder to the duodenum with an elastic suture in the centre and a single row of silk sutures around it, expecting that the elastic suture would produce a pressure atrophy, and that a fistula would remain. The autopsy of both these patients showed that the result expected was not obtained. Czerny in the *Annals of Surgery*, October, 1892, reports two more cases; one died of hæmorrhage, and the other survived the operation.

July 30, 1892, Lambothe, of Belgium, operated on a patient who had an external biliary fistula following cholecystotomy. "He drew out a piece of the colon through an incision in the abdomen close to the fistula, and then applied Dupuytren's enterotrite in the manner that that author used it for the repair of an artificial anus, finally performing a plastic operation to close the external opening." The report says that "the patient survived the very tedious operative procedures." Korte, in 1891, reported to the Berlin Medical Society a case in which the suture was used for approximation; the patient recovered.

Dr. J. B. Murphy, of Chicago, whose able and exhaustive article in the *Medical Record* for December 10, 1892, will long be quoted in connection with the subject of cholecysto-intestinal operations, reports two cases of his own, performed in 1892, in which the results were favorable. He was the first to propose, in order to overcome the tremendous difficulties of the *technique* of the operation, the use of an apparatus which he calls the "anastomosis button." These buttons consist of two hemispheres which are inserted in slips or ends of the viscera to be operated on. These hemispherical bodies are held together by an invaginating cylinder. A running thread is placed around the slit in the viscus, so that when it is tied, it will draw the cut edges within the clasp of the bowel. A similar running thread is applied to the slit in the viscus into which the other half of the button is inserted, and the viscera are then brought together. Pressure atrophy at the edge of the bowel is produced by a brass ring supported by a wire spring. The opening left after the button has liberated itself is the size of the button.

This device "retains its position automatically"; the union "is effected without sutures"; it produces a pressure atrophy and adhesion of surfaces at the line of atrophy; "it insures a perfect apposition of surfaces without the danger of displacement."

The operation, as Dr. Murphy describes it, must be one of great ease and safety.

There are two points brought out in Dr. Murphy's paper which are of interest in connection with the case of my patient. The one is in relation to the effect of a permanent fistula of the gall-bladder and constant escape of bile secreted, such as frequently follows cholecystotomy. When the fistula of the gall-bladder only allows a portion of the bile to escape, the patient and animal, as in Dastre's experiments on artificial biliary fistula, can live without suffering greatly from the loss; that is, they are capable of digesting with a much smaller quantity of bile than they naturally secrete. But if we let the entire quantity of bile escape through the fistula, the patient soon succumbs.

In the case of my patient, there was a permanent biliary fistula remaining after the operation in the spring of 1892, and at times an excessive escape of bile, yet not all the bile that the liver secreted was lost (as was determined by the character of the stools) and there were, in fact, days, when there was no discharge from the fistula. I think that I am right in affirming that during all these months, this young lady, though weak and unable to work, had yet a fair digestion and did not emaciate.

The second point is this: In all the successful operations on animals that have been recorded, the establishment of a cholecystenteric fistula has been followed by more or less contraction of the orifice of communication between the gall-bladder and intestine, and the formation of a valve on the intestinal side of the opening by one or two folds of mucous membrane closing over it, permitting the bile to flow out, but preventing the entrance of any thing from the intestine. The gall-bladder also undergoes marked contraction. Murphy calls particular attention to this point. In one of his cases (a dog which had been made the subject of experimentation) the necropsy showed the gall-bladder contracted to a tube not much larger than the ductus choledochus, and a valve formed by a fold of intestinal mucous membrane. Water would flow freely from the side of the gall-bladder into the bowel, but would not flow from the bowel into the gall-bladder on account of this valve. It is not only probable, but may be regarded as certain that in all the really successful operations in the human subject a similar protective valve has been formed, and a similar contraction of the gall-bladder has taken place.

It is evident that where the gall-bladder is attached to the abdominal wall — as in my patient — the difficulties in the way of such a salutary result would be greater. Reasoning from the unsuccessful issue of this case and all the facts as stated above, I am inclined to advise surgeons after they have once done a cholecystotomy and failed, never to attempt a cholecystenterostomy. Had the primary operation in the case of Miss C. been a *cholecystenterostomy* performed according to those modern methods of technique which have given the best success, and with which my friends Jones and Tuttle are so familiar, it is quite probable that it would have been a success. But in saying this, I do not desire to be understood as attaching any blame. A cholecystomy is always the easier and safer operation, and unless the surgeon is perfectly sure that he has stenosis and occlusion of the ductus choledochus, he will naturally and rightly choose this operation in preference to a cholecystenterostomy.

I have dwelt somewhat at length on this subject for this operation has but lately acquired a right of domain in surgery; it is a formidable operation and surgeons want all the light which they can get before attempting it; and the case I have reported has its lessons.

AN advertisement recently appeared in a New York daily, offering $5,000 to any man who would submit to an experimental surgical operation involving some risk. One hundred and forty-two answers were received. Two physicians in Ecuador are the advertisers, who wish to establish a gastric fistula, and repeat the observations made by Beaumont on St. Martin.

A CASE OF CHRONIC TETANUS FOLLOWED BY SCARLET FEVER.

BY J. HOWARD CLOUD, M.D., SANDY RUN, PA.

On the afternoon of June 2, 1892, John G., age 18, presented himself in my office, complaining of stiffness of his jaw, pain in the masseter muscles, and a feeling of general muscular soreness. On examining him I found that he was unable to open his mouth farther than to admit the end of his thumb. His tongue, he stated, felt somewhat swollen. Temperature 99° F. He had vomited on the previous day, being compelled to stop work, which was in a swamp in severely hot weather. I noticed that upon the palmar aspect of the right hand near the base of the index finger, a recent scar about one inch long, and on inquiry found that three weeks before he had been cut with coal in the mines, producing a wound which had healed slowly. At present there was no pain nor discharge. Being able to swallow, I gave him a prescription containing fifteen grains of bromide of potassium and ten grains of chloral hydrate every three hours.

June 7th, I saw the case in consultation with Dr. Neale of Upper Lehigh. Patient had a temperature of 100°; pulse 90; had bitten the tongue; and from the description of the mother, he evidently had had an attack of opisthotonos during the night. He complained of severe pain in the epigastric region (the abdominal muscles being in a state of tonic spasm), increased muscular soreness and slight constipation. Urine negative. The bromide of potassium was increased to thirty grains and the chloral to twenty grains every three hours.

June 8th. Temperature 99.4°, pulse 88. Had slept well during the night, and also during the day. When awakened, felt quite refreshed, but would soon become drowsy. Had had no convulsions, but still complained of epigastric pain. Ordered one-tenth of a grain of calomel every hour, as a laxative.

June 9th. Opisthotonos twice during the night, and had bitten tongue.

June 11th. No opisthotonos, nor so much rigidity of masseter muscles. He could open his mouth far enough to admit the last phalanx of his thumb. Reduced the dose of the bromide and chloral one-half. From this time on the patient had no return of the convulsions, and the rigidity and pain in the masseter and abdominal muscles became less. Temperature ranged from 100.4° to 98.6°, and the pulse from 99 to 72.

June 26th. Walked a little with a cane.

June 29th. Felt well, with the exception of headache, but with a temperature of 103.2°, and pulse 110. Had had no evacuation from the bowels for three days, he having run out of the calomel, which had acted throughout the disease very successfully as a laxative. Gave an enema of hot soap suds.

June 30th. Temperature 102°, pulse 80.

July 1st. Temperature and pulse normal. Stopped the bromide and chloral.

July 5th. Patient progressed nicely until this date, when he developed a temperature of 105°, and a marked and typical rash of scarlet fever. There was a distinct history of contagion seven days before. The fever pursued a regular course, free from complications. Desquamation began July 11th; first in fine scales; then they increased in size, were thicker and more or less immovable, accompanied by some fissuring of the skin. Removal of the flakes disclosed a raw weeping surface beneath, soon to be covered by another set of brownish-gray fish-like scales.

Thus did the process keep on for the remainder of July and during August, September and a portion of October. Improvement first took place upon the face, which had not been so severely affected as were the trunk and extremities. Healthy skin then showed itself in the upper extremities; next upon the trunk and lower limbs; and lastly the feet became free from the scaling process.

Aside from the fact that all cases of tetanus are interesting, this one is rendered more so by its being followed so closely by scarlet fever, having such a pronounced and prolonged stage of severe desquamation, which would lead one to the conclusion that, owing to the nature of the preceding disease, with its large expenditure of nerve force to the peripheral motor nerves, the healthy action of the trophic nerves of the skin, had in some way been compromised, and the nervous system so exhausted, as to permit the scarlatinal malady to produce such excessive dermal inflammation.

Medical Progress.

REPORT ON THERAPEUTICS.

BY F. H. WILLIAMS, M.D.

THREE CASES OF ATROPINE-POISONING, ONE TREATED WITH TANNIN AND TWO WITH MORPHINE.

C. Binz [1] reports two cases of atropine poisoning and quotes others which illustrates the use of morphine as an antidote to atropine.

In the first case, which was treated with tannin, a boy, seven years old, took nearly the whole of a bottle of solution of atropine, intended for the eyes, which according to the recipe, contained .05 atropine sulphate in 10 c. c. of water. A few minutes later he lay raging on the floor, alternately screaming and laughing, in constant motion and with a flaming face. About half an hour after the atropine was taken, his physician gave him one gramme of tannin, but in spite of this the raging condition lasted for two days in undiminished violence and then it gradually decreased until on the fourth day he fell into a deep sleep and recovered.

In the second case, a boy three years old, took, between 8 and 9 A. M., a solution of atropine intended for the eyes; the exact amount taken could not be determined. About 12 o'clock he was brought into the clinic and his stomach was washed out; the patient was restless, threw himself about, uttered fearful sounds and did not recognize his father and mother. At 12.15 P. M., .003 of hydrochlorate of morphine was subcutaneously administered, but it did not bring rest. At 12.30 another injection of .005 was given and a few minutes later all appearance of disquiet had ceased and about 1 o'clock the boy was in a sound sleep. At 4 P. M. he waked up and was again excited. At 5 P. M. he took some milk with relish, but there was manifestly still much physical disturbance and .003 morphine was again injected. Quiet followed, but no sleep. At 11 P. M. he fell asleep and gradually recovered without further use of morphine.

[1] Centralblatt für klinische Medecin, No. 2, 1893.

The third case was that of a workman, fifty years old, who had suffered since 1885 with sciatica. In one of these attacks his physician, by mistake, injected subcutaneously atropine sulphate instead of morphine. A few seconds after this the patient was in a raging condition, tried to climb up the walls and thought he was pursued by animals and fearful forms. Twenty drops of .01 of morphine in 25 c. c. of water was administered every hour. In the afternoon the patient gradually became quiet and sleep followed. Except for great exhaustion during the days that followed, the patient was well and since then has had no sciatica.

Binz concludes by saying that morphine would not be suitable for every case, nor in every stage of atropine poisoning, but only in the excited stage. Choral hydrate may be used instead of morphine, but it has a more weakening effect on the heart than the latter and must be used with great care.

THE TREATMENT OF MALIGNANT TUMOR BY REPEATED INOCULATIONS OF ERYSIPELAS; WITH A REPORT OF TEN ORIGINAL CASES.

Dr. William B. Coley [2] gives in more or less detail an account of six cases of sarcoma and four of carcinoma in which he has used erysipelas inoculations. In addition to these 10 cases of his own he refers to 28 other cases of sarcoma and carcinoma in which erysipelas, either spontaneous or artificial, intervened. Of these 38 cases, erysipelas occurred accidentally in 23 and was the result of inoculation in 15 cases. Seventeen of these cases were carcinoma and there resulted three cures and one death; 17 were sarcoma and there resulted seven cures and one death; four were sarcoma or carcinoma and there were two cures.

Dr. Coley groups by themselves the 15 cases (seven carcinoma, eight sarcoma) in which erysipelas was artificially produced and states that among these there were three cures; carcinoma, 1; sarcoma, 2. He then goes on to say, "when we reflect that in nearly all these cases the tumor was not a primary growth, amenable to operative treatment, but either a recurrence after operation had been tried and failed, or from its nature inoperable, then and then only are we in a position to fully estimate the importance and value of erysipelas as a *curative* agent." The writer next considers the cause of cancer, its treatment by repeated injections of fluid cultures and the dangers associated with erysipelas, and draws the following conclusions:

(1) The curative effect of erysipelas upon malignant tumors is an established fact.

(2) The action upon sarcoma is more powerful than upon carcinoma in about the ratio of three to one.

(3) The treatment of inoperable malignant tumors by repeated inoculations of erysipelas is both practicable and not attended with great risk.

(4) The curative action is systemic and probably due chiefly to the toxic products of the streptococcus, which products may be isolated and used without producing erysipelas.

(5) This method should *not be employed indiscriminately* until further experiments have proved its limitations.

A note at the end of this article contains the following:

"*Toxic Products.* — During the past month I have been using a preparation of the toxic principles of erysipelas in four cases of inoperable sarcoma. The injections have been made into the tumor itself, and repeated every forty-eight hours. The reaction has been almost identical in character with that produced by true erysipelas, though milder in degree, and it has always passed away within twenty-four to forty-eight hours.

"The temperature has never risen above 103.5°, and has usually dropped to normal the following day. I have frequently made use of the toxic products of the *bacillus prodigiosus* in combination with the products of the erysipelas coccus, to intensify the action of the latter and always with the desired effect. (This peculiar action of the one germ upon the other, I may add, was noted by Roger in his recent experiments on rabbits.)

"Every one of my four cases of sarcoma has shown a marked and progressive decrease in the size of the tumor, and in one case (*vide* paper, Case VI) a sarcoma of the back and groin, the tumor has entirely disappeared and the injections have been stopped. The patient has regained his normal weight (one hundred and sixty-five pounds) and has returned to work.

"These results have been so encouraging that, for the present at least, I have decided to use the toxic products of erysipelas in preference to inoculating the germ itself. The advantages of doing so are very great. The necessity for isolation is avoided and the action of the products can be so carefully regulated that the danger element can be entirely eliminated."

[The erysipelas inoculations are obviously attended with danger to the patient; the toxic products should rather be chosen and the results of their further use will be awaited with great interest. F. H. W.]

OBSERVATIONS ON THE NATURE AND TREATMENT OF ANGINA PECTORIS.

Dr. J. Burney Yeo [3] after discussing the known modes of causation of attacks of angina pectoris, summarizes the indications for treatment as follows:

(1) To maintain or improve, when defective, the general nutrition; to avoid all strain, physical and emotional; and so to relieve cardiac feebleness and excessive effort.

(2) To relieve dyspeptic conditions and flatulent or fæcal distension of the stomach and intestines.

(3) To forbid the habitual consumption of agents which may exercise a toxic action on the heart, such as tea, coffee, tobacco, alcohol, etc., or that may introduce or develop toxines in the alimentary canal.

(4) To avoid and remove all gouty and other blood contaminations.

(5) To give such tonic remedies as may improve the cardiac tone and lessen existing tendency to cardio-vascular degeneration.

(6) To relieve the paroxysmal attacks by sedatives and stimulants.

(1) Under the first indication Dr. Yeo speaks of the necessity of careful attention to hygienic measures; the life of the patient must be one of complete repose of mind and body — a repose alternated with gentle exercise. Life in the open air and in a mild climate is also beneficial. The diet must be carefully looked after and sometimes be almost exclusively of milk. If the digestive powers are greatly weakened it may be necessary to have recourse to pre-digested foods or to give with the food some artificial digestive agent. The writer mentions a number of dishes that may be

[2] American Journal of Medical Sciences, May, 1893.

[3] The Practitioner, May, 1893.

easily assimilated and then goes on to say the physician should see that a sufficient quantity of water is taken, both for eliminative and assimilative purposes, a point often overlooked.

(2) The co-existence of dyspeptic states must be treated in accordance with general principles — an alkaline bitter stomachic, composed of sodium bicarbonate, nux vomica and calumba, an hour before the two principal meals, will be found valuable. Regular evacuation of the bowels of fæcal accumulations is most essential — checking as it does the formation of injurious toxines in the intestines, eliminating waste substances and relieving abdominal disturbance. Dr. Yeo here suggests various remedies as aperients.

(3) This indication is also an important one, for certain of the slighter forms of angina are no doubt dependent on, and the more serious forms may be provoked by, the habitual use of certain substances which come, in course of time, to exercise a toxic action on the heart. The action of these toxic agents is all the more subtle because they may be taken for many years without apparently producing any injurious effect. This is particularly the case with *tobacco*, the toxic effects of which on the heart are often delayed until, or even after middle age, when they will perhaps somewhat suddenly make themselves felt. The toxic and degenerating influence of alcohol falls upon different organs in different individuals; but whenever anginal symptoms arise complete abstinence from alcohol should be insisted on or its very sparing use in a very dilute form. Tea and coffee are often provocative of the slighter manifestations of cardiac pain and discomfort and they are prone to be aggravated by any emotional disturbance. All these toxic agents must be forbidden so long as any tendency to anginal attacks exists.

(4) The next indication is to remove and avoid all gouty and other blood contamination. The importance of *elimination* in the treatment of angina pectoris is universally admitted. When renal elimination is defective from the co-existence of renal degeneration, the bowels and the skin must be acted on. When the kidneys are sound, the free use of pure water, or some suitable mineral water having some slight stimulating action on the kidneys, may avoid the necessity of free purgation; but in all cases a thorough daily evacuation of the bowels should be procured and free action of the skin should be maintained by warm baths and frictions. In gouty cases, and in all cases of defective elimination, the diet should be sufficient, but careful and spare, avoiding all excess. Animal food should be taken only in great moderation and fresh vegetables and fruit carefully prepared and cooked so as to be made easy of digestion should take its place. All alcoholic stimulant should be avoided and if acceptable to the patient a few weeks of exclusive milk diet may be advantageous.

(5) Dr. Yeo considers next the medicinal treatment of these cases, and first, the appropriate treatment in the intervals — that is, of the constitutional condition underlying the paroxysmal attacks. He points out in certain cases the value of the milder preparations of iron, combined with small doses of digitalis, in other cases of the greater value of arsenic; the usefulness of strychine as a cardiac tonic, of potassium iodide when angina pectoris is associated with obvious signs of cardiac vascular degeneration and of the gouty state, etc.

(6) Those who see in the causation of the anginal paroxysm the predominating influence of vaso-motor spasm consider that the main indication for the relief of the paroxysm is to administer medicinal agents which are known to have the power of relaxing the arterioles; they therefore advocate the use of the nitrites, such as the nitrite of amyl, nitro-glycerine, and sodium nitrite. That these agents do relieve the paroxysm in many cases of angina is certain; that they do so wholly by their action as vaso-dilators is extremely doubtful. In the first place they are capable of relieving the anginal attack when there is no certain evidence of the existence of vaso-motor spasm. Dr. Douglas Powell says he has found them "far more reliable in the graver cardiac cases than in the purer vaso-motory," but it is in the latter that they should prove most efficacious if the prevailing theory of their action were true. Balfour and Grainger Stewart both believe that they act as direct analgesic agents, and that they have the power of relieving pain in other as well as in cardiac neuralgias, independently of their relaxing action on the blood-vessels; and this view Dr. Yeo adopts as the most consistent with the clinical history of the disease.

The effect of sodium nitrite is said to be more lasting than that of nitrite of amyl or nitro-glycerine. It is given in tablets of 2½ grains; one to four of these may be given for a dose. At the onset of an attack, in addition to the inhalation of the nitrite of amyl which, owing to the rapidity of its action, is the most suitable remedy to start with, some warm diffuseble stimulant may be given, such as thirty minims of sulphuric ether or a drachm of nitrous ether, with a drachm of sal-volatile or a little brandy in an ounce or two of peppermint water. Feet and hands if cold may be placed in hot water. Balfour has been disappointed in action of nitro-glycerine and prefers inhalations of nitrite of amyl; and when these fail — as they often will — he resorts unhesitatingly to chloroform inhalations; sulphuric ether may be used, but it is not rapid enough. Chloroform may be poured on a sponge in a smelling-bottle and the patient is told to breathe it through his nose as deeply as possible. "In this way relief is obtained in a few seconds, and so soon as the narcotic influence is produced the smelling-bottle drops, and with it rolls away all risk of any overdose." In severe and protracted attacks it may be necessary to have recourse to hypodermic injections of morphine.

THE RELATIVE VALUE OF THE SEVERAL SUBSTANCES RECOMMENDED AS ANTIDOTES TO PHOSPHORUS.

Dr. E. Q. Thornton in this article[4] comes to the following conclusions which are based on chemical tests together with a number of experiments on animals. Permanganate of potassium is the best antidote for phosphorus-poisoning; it must be well diluted one-half to one per cent. or vomiting will result before the chemical reaction has taken place in the stomach; it must be used before the poison has been absorbed, and given in excess, as a considerable portion of the permanganate is reduced by the organic substances of the stomach.

Sulphate of copper, whether given in excess or in the same chemical proportions required to make the change, produces violent gastro-intestinal inflammation. In the experiments of phosphorus-poisoning

[4] Therapeutic Gazette, No. 1, 1893.

made on dogs, the animals died in those cases in which sulphate of copper was used as an antidote. Dr. Thornton is of the opinion that this drug should not be used.

The animals to which hydrogen peroxide was administered after phosphorus-poisoning recovered, but suffered from exhaustion and severe gastro-enteritis. The hydrogen peroxide is too slow in oxidizing the phosphorus.

Old French oil of turpentine, which is acid in reaction, is said to form with phosphorus a cystalline sperm-aceti-like mass; the ordinary oil of turpentine does not bring about this change, and as the former cannot be obtained in the market it should cease to be considered as a practical antidote.

THYROID FEEDING IN MYXŒDEMA, CRETINISM AND PSORIASIS.

At the meeting of the British Medical Association,[5] at Newcastle, Dr. George Murray showed some cases of myxœdema, and as these were some of the earliest where thyroid feeding was used, they give an opportunity to note the effect of time in the result. Two years ago, his first case, a woman, was almost unable to walk, had lost nearly all her hair, was very deaf, her speech was nearly unintelligible, and she had very markedly the cutaneous affection characteristic of myxœdema. A glycerine extract of the gland was first injected, and the patient improved almost immediately. Later feeding with the raw gland or with a few drops of glycerine extract was substituted for the injection and improvement went on uninterruptedly. The patient can now attend to her household duties, her hair has grown again, and her speech and hearing are normal. She is extremely sensitive to the least overdose, and can only bear about five minims daily of Brady & Martin's extract; if the remedy is withdrawn she begins to get puffy and stupid again. In all Dr. Murray's cases there was not the least tendency to the establishment of a tolerance; the same dose continuing to have the same effect after a long course of treatment, and the effect of an overdose was just as apparent at whatever stage it was given.

Dr. Murray found in his experiments on monkeys, that by the removal of the thyroid gland he could produce the characteristic myxœdematous condition, and then restore them to a normal condition by supplying them with the thyroid juice of the sheep, being able to repeat the experiment at will with constant results in the same animal.

Dr. Bramwell and Dr. Thompson obtained remarkable results by the use of the thyroid gland in sporadic cretinism. One of Dr. Thompson's cases was a boy, who had a normal sister, many inches taller than himself, although several years younger. Under thyroid feeding the brother began almost immediately to grow and was still rapidly reducing the distance between his sister and himself. Dr. Murray also spoke of a cretin under his care, who grew nearly an inch in a few weeks as a result of thyroid feeding.

In the first case of myxœdema which Dr. Bramwell treated there was in the course of treatment profuse desquamation of the skin of the palms of the hands and soles of the feet. And he noticed that the same phenomena occurred in the subsequent cases submitted to the same treatment, which comprised eleven of myxœdema and three of sporadic cretinism. This effect on the skin led Dr. Bramwell to try the internal administration of the thyroid extract in psoriasis. The first case of psoriasis was of nine months' duration, and was general over the whole body. On February 4th half a thyroid gland was given, and the dose was continued daily; by the 10th there was decided improvement; on the 14th the crusts on the back were shed in large scales leaving smooth skin; by March 3d, the cure was nearly complete. On April 1st, as there was apparent arrest in improvement, the thyroid treatment was abandoned and arsenic was given, but with disastrous results. On April 11th, the thyroid treatment was resumed, fifteen minims of Brady & Martin's extract being given daily. On June 6th the patient was discharged cured.

The second case was of seven months' duration. On May 10th, five minims of thyroid extract were given. On the 15th, the dose was doubled, and on July 14th the patient was discharged cured.

The third case was of six and one-half years' duration, and notwithstanding the previous failure of all other treatment the patient was practically cured after six weeks of thyroid treatment. Dr. Bramwell has tried this treatment in several other less severe cases, with complete success except in two instances. In one of these failures the patient was an epileptic who was taking large doses of bromide during the thyroid treatment, and that may have been the cause of the failure. Dr. Bramwell has tried this treatment in a case of lupus, and considerable improvement resulted. He hopes for equally good results in cases of acute eczema.

Dr. Simons stated that he had seen a case of obstinate psoriasis improve remarkably from the administration of Pöhl's spermine. He suggested that the action of all animal extracts might be, as Pöhl thought, due to an oxidizing influence on the tissues.

ON THE USE OF SOYA BEANS IN DIABETES MELLITUS.

Dr. W. Hale White[6] describes in this article three cases of diabetes mellitus, selected at random from several in which he has used soya-bean biscuits with good effect. The first of these cases was that of a man who had been admitted to Guy's Hospital twice before for the same disorder. On the second occasion he was, on admission, passing 5,040 grains of sugar a day. After a stay of seven weeks, during which he was dieted with gluten bread and the ordinary diabetic diet, he left, passing 640 grains a day. On this occasion, his third admission, he passed during the first seventeen days of his stay at the hospital an average of 3,850 grains of sugar a day — the first two days over 11,000 a day — and the daily average quantity of urine passed was 127 fluid ounces. The patient during this time was on ordinary gluten-bread diabetic diet; four soya-bean biscuits were then added daily for six days, and the average quantity of sugar passed was 2,431 grains a day, and the daily average quantity of urine 89 fluid ounces. Then twenty soya-bean biscuits were substituted for the gluten bread, and during the following forty-three days the average quantity of sugar passed was 636 grains a day, and the daily average quantity of urine 69 fluid ounces. As the quantity of sugar passed decreased, the specific gravity of the urine fell. The patient gained two stone in weight while he was taking soya biscuit. When he was dis-

[5] Therapeutic Gazette, September 15, 1893.

[6] The Practitioner, May, 1893.

charged on this occasion, he was passing about 300 grains of sugar a day. The biscuits produced no diarrhœa nor other ill effect.

Two preparations of the soya bean are sold in England — soya bread and soya biscuits. The oil is removed from the flour from which they are made, and the writer says this may account for the fact that, so far as his experience goes, they do not produce diarrhœa, and that this is the experience of many others who have tried them. The biscuits, which are thoroughly baked and dried, are very palatable and will remain good an indefinite time; but the bread, however carefully made, will not in summer, at any rate, keep more than two or three days. Dr. White states that many patients prefer the taste of soya-bean preparations to gluten bread; they form a good substitute therefor, and it is a great advantage to be able to vary the monotonous food of patients suffering from diabetes mellitus. He also states that according to Dujardin-Beaumetz soya-bean bread contains less than three per cent. of starch or sugar, while the latter finds that the best varieties of gluten bread contain at least sixteen per cent. of starch and saccharine substances. Twenty-three soya-bean biscuits weigh six ounces, the amount of gluten bread given in the usual diabetic diet at Guy's Hospital.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Long Branch, N. J., July 25, 26 and 27, 1893.

FIRST DAY. — TUESDAY.

THE PRESIDENT'S ADDRESS

was delivered by Dr. Henry M. Lyman, of Chicago.

After some reminiscent remarks relating to the study of nervous diseases, he called attention to their predisposing causes, and said that we must not be content with the simple recognition of disease, but must be able to classify it etiologically as well. Such is the fact with regard to rheumatism affecting the nervous system. The marked forms chiefly affecting sensation are not so commonly recognized, and are frequently ascribed to other causes. They are usually observed in elderly people of a nervous temperament and an arthritic diathesis, and differ from many other similar disorders of sensation in being transient, vagrant and of brief duration. Among these ailments is a universal prickling over the surface of the skin; sometimes it is limited to certain points where the patient experiences a sudden sharp prick, like a flea bite. This may interfere with or delay sleep. Another disorder of cutaneous sensation often affects the scalp, and is occasioned by irritation of the superficial nerves of that region. The duration of the attack rarely exceeds a single day. Closely associated with these disorders are the various transient perversions of sensation that may be felt in the Eustachian tubes, the pharynx and about the fauces. Another of the symptoms of marked rheumatism is a peculiar and disagreeable feeling in the tongue. This sometimes assumes the severity of a genuine neuralgia, and manifests a greater degree of persistence when associated with obesity, diabetes or gout than when connected with rheumatism alone. The œsophagus and fauces, and sometimes the muscles of the eye-balls, are similarly affected. These patients are also attacked by a paroxysmal cough associated with headache. The most distressing of all these forms of pain is gastralgia. The previous history and the concurrence of other rheumatic symptoms of a more stable character will, of course, add greatly to the certainty of the diagnosis.

HETEROGENEOUS PERSONALITY.

Dr. Smith Baker, of Utica, read a paper with this title. He defined heterogeneous personality as that condition in which the characteristics of ancestry are not blended into a permanent whole, and reported the case of a little girl who presented frequently recurrent attacks of functional perversions and distress which could not be satisfactorily explained except upon the inference that the dissimilar traits noticeable in her grandparents had not been blended in the personality of her mother, and so had proved to be the ground-field of the grandchild's affection. But the question arises, Is such a view of the case professional or scientific good sense?

We can never answer intelligently until the commoner facts of family life shall have been more minutely studied. Thus, such trite matters as dreams, somnambulism, the solving of problems unconsciously or subconsciously, the up-rush of facts and arguments in the act of composition and the play of genius should be investigated.

Inquiries in states of acute illness, and the study of moods and transformations of character, etc., all should receive more attention by physicians, in order that causation in cases of functional derangement may be the more accurately conceived. In doing this, assistance may be found in many instances of so-called reflex disease. Heterogeneous personality should always be looked for in the neuropathic constitution. But more particularly is this of use in considering the problems presented by neurasthenia and the sexual perversions. Not so frequently, perhaps, is the trouble owing to the commonly assumed overwork, etc., as to the unceasing warfare within between the "lower" impulse, and the "higher" determination. Students, professional men and many others whose physical abnormities or mental peculiarities, reveal the sensitive, easily impressed nature, are especially apt to be victims of the uncoalesced personality. Its bearing upon questions of marriage and parentage renders it worthy the attention of all.

Dr. Lyons, of New York, referred to the opposite sides of character as seen among the insane. An educated woman may be agreeable and lovable in her normal condition, but vicious when in the abnormal state. He knew of such a patient who would frequently apologize and do her utmost to resist the impulses to do wrong. He thought that such behavior might be due to abnormity in the development of the cerebral hemispheres or to some interference with the circulation.

Dr. Parsons, of Sing Sing, expressed the view that in persons with a tendency to evil thinking and acting, such might be overcome by suitable environment. After a time the absence of restraint permits of a continuance or permanency of the abnormal condition. This would probably account for many of these cases.

Dr. Hinsdale, of Philadelphia, spoke of two au-

thenticated cases of double consciousness. He thought that the medico-legal features of such cases, as well as those of changes in personality, were of especial interest, and should be reported and carefully analyzed.

DR. SEGUIN, of New York, believed that atavism was the more rational explanation. Blending of the characteristics of ancestors occurs normally. It was not right to confuse double consciousness of an epileptic nature with conflicts of character and personality.

DR. J. J. PUTNAM, of Boston, said that the treatment rested upon the systematic development of character. Hypnotism has taught us much in regard to this condition, and brings out in a striking manner certain phases of character. He recommended the development of the inhibitory powers.

DR. F. X. DERCUM, of Philadelphia, thought the case reported by Dr. Baker recalled the fact that there was lowered vitality at certain epochs, in women. Relationship between states of health might account for the peculiar mental variations.

DR. BAKER, in closing the discussion, referred to the various definitions of personality as being not sufficiently inclusive of the facts to be of accurate use. He urged the importance of the study of the subject, especially in its bearing not only upon the causation of actual disease, but in its relation to all our educational ideas and practices as found to-day in our school system. In this way we find means of obviating detrimental traits, and also of making dominant those more desirable and healthful.

DETENTION HOSPITALS FOR THE INSANE.

DR. MATTHEW D. FIELD, of New York, read this paper. After speaking of the wrongs inflicted upon the insane by committing them to county jails and prisons, there to mingle with tramps while awaiting the appointing of physicians to pronounce upon their mental condition, he gave a description of the reception pavilion for the insane at Bellevue Hospital, and the methods of examination and commitment by the city examiners. He declared the pavilion to be in every respect a hospital, with resident physicians and competent trained attendants. Though a plain and inexpensive building, it served its purpose very well. He advocated the establishment in all large cities of similar hospitals for the reception of those suspected of lunacy. He said that an ideal institution for this purpose would be a hospital constructed on the pavilion plan for the reception of the insane, inebriate and neurotic, with a small amphitheatre and sufficient wards for proper classification and detention for a reasonable time. A competent visiting, resident and examining staff of medical officers should be chosen, and clinical instruction regularly given. Such a hospital would secure prompt, humane and scientific treatment. The opportunity for longer observation, securing histories and examinations, would result in more complete and accurate certification. There being no need for hasty transfer to other institutions, the feeble, sick and certain selected cases, could be detained for treatment, and clinical instruction would be easily accessible to the entire medical profession.

DR. KNAPP, of Boston, said that there are no detention hospitals in Boston, and they have felt no urgent need for them under existing Massachusetts laws. A few emergency cases requiring immediate restraint are admitted to the general hospitals. Otherwise, they can be taken at once to the nearest asylum on emergency certificates. These consist of two separate certificates. A bond must be given by the superintendent or one of the physicians, to the effect that the patient is to be formally committed or released within five days. This system has proved eminently satisfactory, and has rarely been abused.

DR. MILLS, of Philadelphia, stated that the method described by Dr. Field was in vogue at the Philadelphia Hospital. There was a detention ward for isolating cases of insanity. Two physicians are assigned to examine these patients before commitment. This ward has also been used for several years for clinical instruction.

DR. PRESTON, of Baltimore, remarked that their lunacy laws were inadequate. They were endeavoring to establish a detention ward. At present insane patients are kept at police stations, as no general hospital is prepared to receive them. Their method of dealing with such cases was entirely unsatisfactory.

DR. PARSONS agreed with Dr. Field, and believed that such a ward would serve to diminish the number of improper cases sent to asylums.

DR. BAKER thought that a detention ward would prove extremely valuable for suspected cases of insanity, as found in private practice.

THE PRESIDENT said that in Chicago they have such a ward in the City Hospital, where these cases are detained until transferred. Their commitment laws are now quite satisfactory.

THE TEMPERATURE IN GENERAL PARALYSIS OF THE INSANE.

DR. FREDERICK PETERSON, of New York, read a paper with this title. He first reviewed the literature of the subject, calling attention to the statements of various authorities, that there are in general paresis extraordinary daily variations of temperature, that the average bodily temperatures are subnormal or hyperpyrexic, and that axillary asymmetry of temperature is particularly frequent. With the assistance of Dr. Langdon, the temperature of twenty-five cases from the wards of the Hudson River State Hospital for the Insane was carefully studied. Observations were made every two hours for one week in each case, and in ten cases temperatures were taken in the two axillæ simultaneously every two to four hours for a week.

He had reached the following conclusions:

(1) As regards the average bodily temperature, it corresponded with physiological norms. The statements in literature as to hyperpyrexic or subnormal averages could not be sustained.

(2) The diurnal oscillations of temperature in paretics also corresponded to physiological norms. Observations found in literature as to frequent extraordinary daily variations in such cases seemed to be absolutely erroneous.

(3) Asymmetrical axillary differences were so small that they could not be considered as abnormal, and certainly not of any diagnostic significance.

(4) When unusual variations of temperature occur in general paretics, their cause must be sought for in conditions not related to the pathological phenomena of paralytic dementia, but depending upon other thermogenic features unrecognized by the physician, or "masked" by the mental state of the patient. Thus, in Case II of his series, an increasing hyperpyrexia was noted during the second week's observations; but the pneumonia causing it was "masked" until the

fifth or sixth day, the patient dying on the sixth day. Again, in Case X, where the highest single daily oscillations was 3.4°, and the average daily oscillations for the week 2.2° F., the patient had bed-sores on the sacrum and heels, and was undoubtedly somewhat septicæmic. That the temperature might vary in the paralytic seizures of these cases, was not gainsaid, no observations having been taken in such conditions.

Dr. Gray, of New York, said that a large number of different pathological conditions are often included under the name of general paresis. He thought a number represent the terminal stages of intracranial syphilis.

Dr. Isaac Ott, of Easton, Pa., did not believe that the heat centres could be located from the symptoms of general paresis.

Dr. J. J. Putnam mentioned that he had occasionally noted oscillations of temperature in paretics.

Dr. B. Sachs, of New York, agreed with Dr. Gray as to the question of diagnosis. The results of his observations coincided with those of Dr. Peterson. He had recorded the rectal temperature. Elevations were often due to complications from gastric disturbances. The temperature was usually a little higher than in those who had no organic disease. He inquired if clinical studies of the heat centres had ever been made.

Dr. Ott, in reply, said that he knew of only two cases of pistol-shot injury to the brain associated with immediate rise of temperature.

Dr. Parsons remarked that in one of his cases the temperature was always normal.

Dr. Chas. K. Mills, of Philadelphia, regarded the manifestations of general paresis as so diverse in character that we could thus account for the different experience of various observers.

(To be continued.)

Recent Literature.

Various Forms of Hysterical or Functional Paralysis. By H. Charlton Bastian, M.A., M.D., F.R.S., F.R.C.P., etc. 8vo, pp. xi, 199, with two diagrams. Philadelphia: J. B. Lippincott Company. 1893.

One of the most difficult problems of clinical neurology is to decide whether the symptoms of some obscure affection are due merely to so-called functional conditions or are the beginnings of some insidious degeneration in the nervous centres. More than one case of disseminated sclerosis or diffuse myelitis has been regarded as "hysterical" for months, until the development of grave symptoms settled the diagnosis. These lectures, which have been reprinted from the *Lancet*, do not render a solution of such problems a simple matter, — which no one would expect — but they do throw some light upon them, and, by a more scientific and careful classification of the facts now in our possession, they put our knowlege upon a better basis, give us better methods of investigation, and thus represent a distinct advance. As the author says, "A fuller and more accurate knowledge can only be brought about by a continuous methodical investigation and record of all the minute details." The diagnosis of "hysterical" or "functional" paralysis is but a half diagnosis, and many confuse matters still more by using the two terms almost synonymously. The problems of a "regional" and "pathological" diagnosis are still untouched. In regard to pathogenesis the author confesses our limitations. A part of the cases may be attributed to vaso-motor changes, yet such a theory has as yet no distinct evidence in its favor. In other cases the vaso-motor theory seems improbable, yet the difficulties of assuming a primary limited failure of nutrition are even greater. In regard to regional diagnosis, although our knowledge is still very limited, nevertheless by a close analysis of the symptoms, and a detailed examination much may be done. The author shows that some cases are of cerebral and others of spinal origin, and he gives the characteristics of paralyses due to functional changes in the different portions of the cerebral nervous system. Where the kinæsthetic centres in the Rolandic and marginal areas are alone affected, there is a loss of muscular sense with flaccid or spastic motor paralysis. If the sensory region of the internal capsule be also involved there is hemianæsthesia; and if the capsule alone be affected there is no paralysis, but a loss of muscular sense. If the efferent fibres from the kinæsthetic centres be affected there is paralysis without loss of muscular sense. In the spinal cases, if the pyramids be affected there is spastic paralysis without distinct loss of muscular sense, and no cerebral symptoms. If the anterior cornua be affected there is a flaccid paralysis. He therefore thinks that functional paralyses differ in degree and not in kind from those due to organic change, and he holds that the symptoms once thought distinguishing, such as muscular atrophy, bed-sores, incontinence, nystagmus, etc., are not infallible guides. Unfortunately he apparently does not follow his reasoning to its logical conclusion and accept fully the teachings of recent investigations. His study, however, paves the way to the thesis that must finally be accepted, that there is no "functional" disease, but that every morbid condition is due to some change in the structure of cell or fibre.

To the lectures is added the essay on the muscular sense, published in *Brain* some years ago, in which the author's well-known views as to the kinæsthetic nature of the Rolandic region are maintained, an essay on attention and volition, and a note on the sensory centres for touch and common sensibility.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-Book specially adapted for Students of Medicine and Pharmacy. By W. Simon, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons; Professor of Chemistry and Analytical Chemistry in the Maryland College of Pharmacy, Baltimore, Md. Fourth edition, thoroughly revised. Philadelphia: Lea Brothers & Co. 1893.

The present edition of this manual has been thoroughly revised, and contains some additions. The sections on qualitative analysis and physiological chemistry are still incomplete, though they will doubtless be of service to the student if supplemented by lectures and demonstrations. These branches of chemistry should not, in our opinion, be given a place in a book which is substantially a text-book of descriptive chemistry. As a whole, however, the book before us is one of the best of the numerous works on chemistry which have been prepared specially for the use of the medical student.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 19, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

"GREATER LOVE HATH NO MAN THAN THIS."

THE Greeks made their gods simply themselves with all their potentialities glorified into certitudes, as if to demonstrate what a Greek could be at his finest and best. The hero was merged into the god. The world has ever been quick to recognize valor, delights in brave exploits, exults in signal instances of moral courage, and makes haste to raise monuments to its heroes. Humanity loves to see itself at its best. Our rich inheritance from the ages in stories of daring on the battle-field, or heroism on the quarter-deck, has, perhaps, blinded our eyes to the silent, single-handed combats where there is no enthusiasm of numbers, no excitement of banners and drums, no shout of victory. And perhaps among the glorious company of heroes unchronicled and martyrs unsung, no profession holds so large a place as that of medicine.

The physician knows that a foe as deadly as a bullet and far more insidious lurks in the micro-organism. But undaunted, high-hearted, strong in his professional loyalty, he takes the risk which personal contact involves, with no thought but wresting his patient from the grasp of death. But the world too often fails to see that thus the doctor merges into the hero.

Every physician knows many instances where his professional comrades have fallen by his side, struck down by infectious fevers or septic absorption received at the bedside of a patient. Notable instances have recently brought this peril afresh to our minds. A contemporary journal, in the last issue, records the death of a practising physician who caught the infection of yellow fever from a patient whom he was attending, and also the death of a promising young doctor to whom the infection of typhoid fever was communicated from a child patient at the New York Hospital. Last week it was our melancholy duty to report the death of a brilliant young physician of unusual qualities of mind and heart, who caught diphtheria from a patient at the Boston City Hospital.

On another page of this week's issue will be found the resolutions passed by the Visiting Staff of the hospital upon his death. In another editorial column of this week's issue also are references to several deaths from disease contracted in the discharge of duty among medical officers in the Marine-Hospital Service.

It will be observed that the personal risk is greatest to the hospital physician, not only on account of the large number of patients and variety of diseases which come under his care, but because the most malignant and extreme cases are naturally aggregated within hospital walls. It must be remembered that the physician and surgeon runs his greatest risk in that part of his calling where his skill and services are bestowed gratuitously.

Every call for medical aid in great epidemics has always brought a swift response of willing hearts and ready hands. Physicians have set aside all personal comfort and gone to the unpleasant surroundings of loathsome disease, doing not only the work of nurse but even of household drudge, because all others had fled in terror from the dead and dying. Self-sacrifice is, after all, the real essence of heroism. The great scourges, formerly regarded as dispensations of Divine wrath, but now known to be results of sanitary pollution, are yet full of imminent peril to the practitioner. The very scientific knowledge which helps him more intelligently to combat disease has also revealed the extreme subtlety of his invisible foe, and made clearer his hazardous calling. But increase of knowledge brings no shrinking to the physician. He puts fear under his feet and walks serenely on in the path of his self-appointed duty. Carlyle says of the hero, "Now and always, the completeness of his victory over fear will determine how much of a man he is."

To the unthinking, the surgeon at the operating table or the physician in the wards for infectious diseases is only a man pursuing his profession. But under the impassive exterior will be found "the stuff of which martyrs are made." He holds his life none to precious to be sacrificed, if need be, in relieving humanity's physical suffering, and surely "greater love hath no man than this, that a man lay down his life for his friend."

ANNUAL REPORT OF THE MARINE-HOSPITAL SERVICE.

THE annual report of the Supervising Surgeon-General of the Marine-Hospital Service of the United States for the fiscal year ending June 30, 1892, is the nineteenth annual report, though it covers the ninety-third year of the service. It also contains mention of many matters outside of the statistical reports of the hospital service which have occurred up to November 30, 1892.

Certain facts in regard to the composition of the service which occupy the first pages of the report are not only very interesting but also of great value as indicative of the character of the men upon whom the grave responsibilities of the service are placed.

During the year two boards convened for the examination of applicants for admission to the medical corps. Fifty-seven applied for permission to appear before the boards; twenty-seven actually presented themselves; and seven only were successful in passing the examinations.

The death of one of the most respected officers of the corps gives occasion for an appreciative notice of the man and also for a general notice of the liability to casualties in the service. Two of the medical officers are suffering from tuberculosis contracted, in one case, "undoubtedly in the performance of his hospital work," and, in the other, "hastened in its progress doubtless by the exposure and severe duty imposed upon him as officer in command of the Delaware Breakwater Quarantine." At least two officers have contracted small-pox, and quite a number have suffered in other ways.

Four different officers have died of yellow fever since 1878. A most pathetic letter from the wife of one of these officers draws attention to the fact that absolutely no provision is made for the families of those who fall in this service. The surgeon-general believes that upon fair representation at least some such provision might be made as has already been made for the benefit of officers and men of the Life-Saving Service, where a man's family, in the event of his death at his post, receives an amount equal to a full salary for two years.

Naturally, cholera occupies a very large share of the report; and the subject is treated in an interesting manner, giving a short history of the present epidemic and the documentary history of the efforts of the general government to control the importation of the disease; yellow fever and small-pox have also demanded attention, and are the subjects of some interesting documents.

It has been the custom for many years to append to the reports of the service, reports on interesting cases and operations, and also reports of fatal cases with the necropsies. These reports are growing in interest and value from year to year; and it is to be hoped that their possible value will be so fully recognized that greater care may be bestowed upon them.

As to the operations of the service in connection with the treatment of sailors of the merchant marine, the report shows that the total number of men treated was 53,610. The total number treated in hospital was 16,022. There were 479 deaths, and the amount expended was $512,657.18.

ACTION OF IODOFORM ON PUS MICROBES AND ON THE LEUCOCYTES.

Maurel, who is well known by his researches on the leucocytes, has undertaken to solve the problem, why iodoform, which is so efficacious in preventing or suppressing suppuration, should apparently have so little action on the pyogenic staphylococci.[1]

[1] Bulletin Général de Thérapeutique.

He first experimented with a virulent culture (on gélose) of staphylococci in the presence of leucocytes. The latter speedily absorbed the staphylococci, but succumbed in less than two hours. In the control field, however, they accomplish their evolution and live from twelve to twenty-four hours. Maurel finds that the death of the leucocytes under the influence of the pus micro-organisms is due to a toxine contained in the bodies of these microbes, not to the mechanical action of the staphylococcus or to the products which the latter yields up to its environment. Under the influence of these same staphylococci, the red corpuscles become diffluent in fifteen hours, then disappear.

Another series of experiments were made by subjecting the figured elements of the blood to the action of iodoform in the dosage of 0.10 to 2.50 per kilogramme of blood. Neither the smaller nor the larger doses were found to be toxic to the leucocytes; the vital activity of these latter was, on the contrary, augmented, and the action on the red globules was *nil*.

A third series of experiments showed iodoform to be without marked action on cultures of the staphylococcus aureus and albus.

In a fourth series of researches, Maurel subjected both the leucocytes of human blood and cultures of the staphylococcus to the action of iodoform in varying proportions and under varying conditions. His conclusions are as follows:

(1) Iodoform attenuates the virulence of the staphylococcus. While in the virulent state, this micrococcus kills our leucocytes in less than two hours — when it is subjected along with the leucocytes to the influence of iodoform, the latter preserve their movements for eight hours, at least, and even complete their evolution.

(2) The staphylococci which have thus lost a great part of their virulence (and to such a degree that they are seemingly devoured by the leucocytes with impunity), keep all their reproductive energy unimpaired, so that virulence and the power of reproduction are independent properties.

A final conclusion is deduced that it is in both these ways — by augmenting the energy of the leucocytes and attenuating the virulence of the pus microbes — that iodoform opposes suppuration, which is, in the language of bacteriology, a massive slaughtering of the leucocytes. These teachings are in harmony with clinical experience as to the benefits of iodoform in preventing or arresting suppuration.

MEDICAL NOTES.

Mütter Lectures. — The Mütter Lectures this year will be given by De Forest Willard, M.D., at the Hall of the College of Physicians in Philadelphia on Tuesday evenings from October 17th to December 19th. The subject is "The Surgical Pathology and Surgery of the Spinal Cord, the Vertebræ and Peripheral Nerves."

YELLOW FEVER. — The conditions at Brunswick and Jessup remain about the same, there being from twenty to thirty new cases of yellow fever each day with one to three deaths daily.

A WEEK ON CATARACT. — The Philadelphia Polyclinic offers physicians a course on cataract for the week commencing October 30th.

A CONTRIBUTION TO THE HISTORY OF ANÆSTHESIA. — In the *Virginia Medical Monthly* for October, Dr. Luther B. Grandby of Atlanta, Ga., has an interesting article on the history of the discovery of modern surgical anæsthesia, which contains some new data relative to the work of Dr. Crawford W. Long.

CHOLERA RIOTS IN HAMBURG. — Several fatal riots have occurred in Hamburg this month growing out of attempts by the authorities to enforce sanitary regulations. They occurred in the suburbs among the poorest and dirtiest classes whose natural abhorrence of cleanliness allowed no extra sanitary measures to be enforced. The health officers, who were accompanied by the police, were surrounded by the crowd who attacked them with clubs and stones. In the last riot two officers were killed and their bodies trampled almost beyond recognition. A company of troops with fixed bayonets finally dispersed the mob. This opposition to the improved sanitation and the flaw in the filtering beds by which the Elbe water was mingled with that already filtered have accounted for the slight increase in the number of cases.

A LARGE OVARIAN CYST. — A case is reported by Dayot, in the *Archives Provinciales de Chirurgie*, of a young girl operated for an ovarian cyst of which she had been aware for three years. Fifteen litres of ascetic fluid were removed and the tumor which contained sixty-five litres weighed all told ninety kilogrammes while the patient weighed but thirty. There were numerous parietal adhesions, but fortunately none to the viscera.

BOSTON AND NEW ENGLAND.

WARNING AGAINST SWINDLERS. — For a few days past, two young men who claim to be connected with the staffs of two Boston newspapers, have been soliciting aid from the business men of the city for a free bed for newspaper men at the Massachusetts General Hospital. No one has been authorized to solicit such a subscription, and the men are unknown to Boston newspaper workers.

BEQUESTS. — The will of the late Mrs. Anne Sweetser, of Boston, bequeaths a thousand dollars each to the Free Hospital for Women and the Massachusetts Eye and Ear Infirmary, and names the Massachusetts General Hospital as one of five residuary legatees.

THE MASSACHUSETTS SCHOOL FOR FEEBLE-MINDED YOUTH. — At the annual meeting of the corporation of the Massachusetts School for Feeble-Minded Youth, last week, the following officers were elected for the ensuing year: President, Dr. Samuel Eliot, Boston. Vice-President, John Cummings, Woburn. Secretary, Col. W. W. Swan, Brookline. Treasurer, Richard C. Humphrey, Boston. Trustees: John F. Andrew, of Boston; Samuel Hoar, Concord; E. C. Clark, Boston; Dr. George G. Tarbell, Boston; John Cummings, Woburn; Samuel Eliot, Boston. The annual report shows an increase in the number of inmates during the year, the present number being 420.

NEW YORK.

CHOLERA AT NEW YORK. — The outbreak of cholera on board the steamer *Russia* which arrived in New York October 9th from Hamburg with two cases of cholera on board, there having been five deaths on the voyage, happily proved of short duration, and while one passenger died after her arrival at quarantine, no new cases developed.

A DIPLOMA DEALER SENTENCED. — Dr. Walter May Rew of New York, whose bogus medical college was exposed last July, was sentenced October 10th to three months' imprisonment in the penitentiary.

Miscellany.

WALTER GAY STEBBINS, M.D.

THE Members of the Medical and Surgical Staff of the Boston City Hospital desire to place upon record and also to extend to the relatives and friends their high appreciation of the character and attainments of the late Dr. Walter Gay Stebbins.

As a student he was zealous, thorough and painstaking; as an officer in the hospital he was faithful, efficient and trustworthy; and as a man he was respected and esteemed by all for his many estimable qualities.

The death of Dr. Stebbins at the beginning of his career so bright in the prospects for the future, seems peculiarly sad, from the fact that the fatal illness was probably contracted while doing temporary duty in that department in which he had, at a previous period, served the hospital faithfully for several weeks without falling a victim to the dread disease.

The members of the Staff hereby express their deep sense of the great loss sustained by this hospital, by the profession and by the community, in the untimely death of their late associate, and they beg to extend their warmest sympathy to the family and friends of the deceased.

GEORGE W. GAY,
JOHN G. BLAKE,
A. L. MASON, } *Committee.*

At a meeting of the Staff of the hospital the above resolutions were adopted; and it was voted to send a copy to the mother of Dr. Stebbins and to the *Medical Journal*, and that they be spread upon the records.

EDWARD J. FORSTER,
Secretary of the Visiting Staff.

BOSTON, October 13, 1893.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING.

A STATED meeting was held at the Medical Library, Boston, on Wednesday, October 4, 1893. The meeting was called to order at 11 A. M., the President, Dr. James C. White, in the chair. Ninety councillors were present.

The following were appointed delegates to other State Medical Societies:

Vermont. — Drs. W. S. Birge, of Provincetown; O. J. Brown, of North Adams.

New York. — Drs. W. H. Pierce, of Greenfield; C. F. Withington, of Roxbury.

New York State Medical Association. — Drs. J. M. Harlow, of Woburn; Geo. B. Shattuck, of Boston.

Seventy-fifth Anniversary of Medical Society of the District of Columbia. — Dr. H. P. Walcott, of Cambridge.

The Committee on Publications, to whom was referred at the last meeting the question of the advisableness of the continuance of the purchase and distribution of "Braithwaite's Retrospect" to the Fellows of the Society, reported that the majority of replies received to a circular asking whether the Fellows would prefer to receive "Braithwaite" as at present, or to give it up and have the annual assessment reduced to $4.00, indicated that they would prefer the latter arrangement. The committee recommended the passage of the following resolutions:

(1) That the subscription to, and distribution of, "Braithwaite's Retrospect" be discontinued as soon as practicable, and that the librarian take the necessary steps to carry out this vote.

(2) That action on the question of the annual assessment be postponed to the next meeting of the council.

After prolonged discussion the resolutions offered by the committee were adopted.

ATROPHY OF THE OPTIC NERVE FOLLOWING IODOFORM POISONING.

Valude[1] has reported to the Ophthalmological Society the case of a boy who had suffered extensive burns which were being dressed with iodoform. Symptoms of poisoning occurred, with vomiting, all of which ceased upon omitting the iodoform from the dressings. Simultaneously with the vomiting, complete amaurosis occurred, which had persisted for a year, and was accompanied by complete atrophy of both optic nerves. The question whether the amaurosis resulted from the burns or the iodoform was decided by the observer in favor of the iodoform, on the basis of its close association with the other symptoms of poisoning and the well-known cerebral disturbances caused by iodoform.

THE PROGRESS OF PSYCHOLOGY.

Professor Cattell, of Columbia College, in reviewing the progress of psychological knowledge, in an article in the *Popular Science Monthly*, speaks most encouragingly of the future possibilities of the laboratory study of this science. The old-time methods of speculative psychology are past. Psychologies are now written which do not range at large through metaphysics, logic, ethics and æsthetics. Gradually the true differentiation of this science and its proper correlation to other studies is being appreciated. It is recognized to be a kindred and equal division of philosophy with physics, physiology or chemistry, and not a subordinate addendum to any one; and this recognition has resulted in the attempt to apply the methods and measurement of exact science to the study of the mind.

The backwardness of psychology is not surprising. Certain material needs must be satisfied before there is time for self-observation; and the elements of physical science are not only more necessary to life than knowledge of the mind, they are also more easily obtained. It is natural, therefore, that as biology is more backward than physics, so psychology is more backward than biology. It is this very backwardness of psychology which accounts for its close connection until very recently with philosophy, which, as knowledge increased and a division of scientific labor became necessary, has been obliged gradually to yield one science after another a separate field. "Philosophy is not the arithmetical sum of the special sciences, but has a peculiar task — to investigate the conditions of knowledge and to form a theory of the ultimate nature and meaning of things. Psychology is no more concerned with these matters than is physics; its subject-matter corresponds exactly to that of any other natural science; and as a natural science, it need not, and should not concern itself with the origin, destiny and meaning of mind, but wholly with the phenomena of mental activity."

For this reason it is important to realize what should not be done in laboratories of psychology. They are not intended for the study of physiology. The functions of the nervous system may throw light on the workings of the mind, but the debt is reciprocal. The commonly used term physiological psychology is awkward. There is a science of physiology and a science of psychology, and there are relations between body and mind. But these relations are wider than this — they are between matter and mind. The world is one world, and all science is interdependent; but the development of psychology has drawn a sharper line between mental and physical processes than was ever recognized before, and psychology can never be made a branch of physiology.

As to the practical application and value of psychological knowledge to daily life, there is in the proper conduct of a laboratory much to be hoped for. As the result of such useful application, he hopes to see more rational progress made in methods of education, that the poor children may no longer "contribute to the progress of educational methods somewhat as the frog contributes to the progress of physiology. In our laboratories of psychology we can test the senses and faculties of children. We can determine whether the course of study is developing or stunting fundamental characteristics, such as accuracy of perception, quickness of thought, memory, reasoning, etc. We can learn what methods best strengthen each of these faculties without injuring the others. The overtasked teacher finds a child slow, and places it with more backward children, which increases its slowness. A more exact test of the child's mind may show that it is indeed slow, but that the slowness is more than counterbalanced by intensity and range. Methods must be applied which will shorten the time of thought, and will not interfere with its force and extent. We can determine what size and composition of class, what length of lesson, session and term are most favorable. We can learn whether it is better for the student to do a thing, to see it, to hear it, or to read about it. We can never build a road to learning which need not be travelled by the student, but we can build a royal road in the sense that it is the shortest and best of roads.

[1] Le Bulletin Médical, 1883, 31.

Above all, our tests and measurements will demonstrate the value of learning itself, and tell us whether under given circumstances it is secured by the development or sacrifice of more essential qualities, such as health of body, serenity of mind, common-sense, honesty and kindliness."

Similarly we may make direct application of psychological tests in medicine or in the solution of many of the subtle sociological questions of the day. "Indeed, the measurements and statistics of psychology, which at first sight may seem remote from common interests, may in the end become the most important factor in the progress of society."

THE MEDICAL ASPECT OF DISEASED TEETH.

ONE of the distinguishing marks of advancing social position is the amount of care bestowed upon the teeth. The attention paid to personal cleanliness marks a general class only, the finer degrees of which are often determined by the especial care of the oral cavity. Aside from the æsthetic reasons for dental cleanliness, and the avoidance of unnecessary pain, which also is a mark of advancing civilization, our present knowledge of bacteriology offers the most cogent arguments for greater care of the teeth. Local caries of the jaw or empyema of the antrum of Highmore are, perhaps, the most serious result which most physicians have in mind in their daily routine. The more accurate searching for ultimate causes of disease has shown the wide-spread and often subtle influence which a neglected mouth may exert. Hipple calls attention to these various results in a recent number of the New York *Medical Journal*. He has found no less than forty fatal cases of pyæmia, acute and chronic, which were directly traceable to a carious tooth.

The anatomical paths of entrance for pathogenic organisms from the teeth are numerous and direct both to the general economy and locally to the brain. An interesting and unusual case was one of fatal actinomycosis in which the autopsy revealed an actinomycotic cavern in the anterior portion of the superior lobe of the left lung, in which was an irregular calcareous body about the size of a No. 6 shot. On microscopic examination this proved to be a small fragment of dentine surrounded by phosphate and carbonate of lime, incorporated with which were numerous threads of the ray fungus. There seemed to be no doubt that the fragment was the carrier of the infection.

He calls especial attention to the importance of buccal cleanliness in cases of gastric disturbance, and speaks of the almost entire futility of sterilizing articles of diet for patients in whose mouth chronic abscesses exist, or whose teeth are covered with tartar mixed with mucus and food in a state of decomposition.

The numerous nervous reflexes — ocular, aural and neuralgic — are easily explained but also easily not associated with their true cause. It is, however, the importance of bacterial infection which should be emphasized. As far back as 1802 Dr. Rush wrote: "I cannot help thinking that our success in the treatment of all chronic diseases would be much promoted by directing our inquiries into the state of the teeth of sick people, and by advising their extraction in every case in which they are diseased. It is not necessary that they should be attended with pain to produce disease, for splinters, tumors, and other irritants often bring on disease and death when they give no pain and are unsuspected as the cause of them."

A PROTEST AGAINST THE OPIUM COMMISSION.

THE British Indian Medical Association has presented a petition protesting against the opium commission appointed with a view to prevent the production of opium in India. They say that the ryots cultivating poppies are more contented and better off than those who cultivate food grains; that many provinces are dependent for their support upon this industry, as the land otherwise cultivated could not be made to yield sufficient returns; that the opium is not used in India to cause intoxication, the greater part being exported; that the natives who do use the drug habitually are dependent upon some form of mild stimulant, owing to the swampy nature of much of the land they work in; that even used to excess the results are less harmful than those of alcohol, which would be the natural substitute for it, and the increased consumption of which would in all reason result in a greater proportion of crime; that the moral effect upon China would not be forthcoming, as the production of opium in China is already conducted on such a scale that to prohibit the export of opium to China would have but two results as regards China — the first, to give to the Chinese opium-growers the most complete protection against foreign competition, and the second, to force those opium-eaters who can afford to pay the higher price which Indian opium commands to consume the inferior product of native manufacturers; that the misery, distress and discontent, that would be caused all over the country by the prohibition of opium, would be rendered intolerable by the increased taxation, which would be necessary to enable the government of the country to be carried on after surrendering the opium revenue.

THE INCREASING PREVALENCE OF THE ITCH.

ABOUT five years ago Dr. J. C. White[1] called attention to the increasing frequency of scabies in this city, both in hospital and private practice. Its increase among the fairly well-to-do classes, as well as among the foreign population, seemed to some extent out of ratio with the increase in immigration to Boston during the years under discussion, namely, 1869 to 1888.

A similar and still progressing frequency has been noted elsewhere; and Stelwagon publishes the results of his observations in Philadelphia during the last twelve years. He finds that in the various skin clinics with which he has been connected the itch now constitutes from ten to fifteen per cent. of all cases. His figures are taken from the Skin Services of the Philadelphia Dispensary, the Northern Dispensary and the University, Philadelphia, Howard and Jefferson Hospitals. In 1880 the number of patients seen was 657, with 11 cases of scabies. In 1891 there were 1,794 patients and 260 cases of scabies, an increase of from 1.67 per cent. to 14.49 per cent. In 1892 there were but 1,339 patients under his observation, 13.52 per cent. of them having scabies.

[1] Boston Medical and Surgical Journal, February 14, 1889.

He did not find the disease at all limited to the poor or foreign population though it was more common among them, nor does he consider his figures complete as the patient treated is often but one of a whole family affected. The increase thus noted in Boston and Philadelphia is not limited to these seaport cities, as is shown by the figures of the American Dermatological Association. In tabulating the cases of skin disease under observation in Boston, New York, Baltimore, Chicago and St. Louis, a steadily increasing percentage of scabies is seen. The figures may be condensed to these footings:

	Patients.	Cases.	Per cent.
1880	11,047	100	0.9
1881	11,076	134	1.21
1882	11,402	202	1.77
1883	15,490	334	2.15
1884	8,934	300	3.36
1885	14,007	442	3.15
1886	14,666	632	4.31
1887	10,366	643	6.2
1888	14,253	965	6.76
1889	17,544	960	5.53
1890	6,481	426	6.57
1891	12,574	678	5.39

In private practice the percentage rose from 0.52 in 1880, to 2.17 in 1887. Since that date private cases have increased almost as rapidly, proportionately, as have the dispensary cases.

The most important cause of this increase is in the steadily decreasing standard of cleanliness of the present immigrants, especially among the Russians, Poles and Italians. "Judged by dispensary observation, it would seem that the itch is the normal state in the steerage of to-day. These cases arriving in our midst are so many additional foci for its spread."

Other important factors are the day-nursery and children's home, "it being not uncommon to find that the invasion of a whole family may be traced to the return home of a child temporarily placed in such institutions."

"Another element in its increase, and especially among the better classes, is to be found in our growing tendency to travel, and the rapid multiplication of travelling salesmen and drummers. With ordinary and proper precautions on the part of hotels, this factor should sink into insignificance, but it is extremely doubtful if the linen in the average hotel bed is always changed, or changed in its entirety, after a single night's occupation; nor are the cheaper hotels alone culpable."

THERAPEUTIC NOTES.

COMPARATIVE INFLUENCE OF LARGE AND SMALL DOSES OF IRON. — The comparative effects of large and small doses of iron and the indications for the one or the other are discussed in the *Therapeutic Gazette*. The experience of the writer in treating twelve cases of anæmia which were as far as possible alike confirmed his belief in the value of small doses. Six of these people received two or three grains of reduced iron three times a day, and the remaining six received one-third of a grain three times daily. The six that received the small doses had far less disorder of digestion than those who received the large doses. They recovered as promptly as those receiving the large doses, if not more so. It is true that in some conditions in which there is gastro-intestinal disorder associated with the formation of gas arising from fermentation or decomposition, and in which the anæmia is largely due to destruction of the constituents of the blood by the absorption of poisonous materials from the intestine, large doses of iron are absolutely necessary, because in these instances only a small quantity of iron is absorbed, and the greater amount of it forms a sulphide of iron, or other compound, with the contents of the intestine. Where we have, therefore, a destruction of the iron in large amount it may be necessary to give it in full dose; but, unless this is the case one-eighth of a grain of reduced iron will in most cases give better results than three grains. Under these circumstances constipation more rarely occurs, and we also avoid in this way the so-called iron headache.

MORPHINE IN PUERPERAL ECLAMPSIA. — In a recent dissertation published by Kranz, under the direction of Veit, he gives the results of seventeen cases of eclampsia during pregnancy and parturition. All were treated in a similar manner by morphine. There were two fatal cases — one due to rupture of the uterus, and one to mitral stenosis with contracted kidneys. Four of the children were dead, in two of whom any deleterious action of the morphine was clearly ruled out. The effect which followed the initial dose, always 0.03 gm., was immediate and often lasting. If necessary the injection was increased gradually to 0.09 gm. in the course of nine hours. The largest amount given in any case was 0.095 gm., in two hours and a half.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCTOBER 7, 1893.

Cities.	Estimated population for 1893.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from Infectious diseases.	Consumption.	Diarrhœal Diseases.	Typhoid fever.	Diphtheria and croup.

Amesbury	10,920	1	0	—	—	—	—	—

Deaths reported 2,356: under five years of age 1,015; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhœal diseases, whooping-cough, erysipelas and fevers), 436, consumption 279, diarrhœal diseases 217, acute lung diseases 205, diphtheria and croup 110, typhoid fever 49, scarlet fever 21, whooping-cough 20, cerebro-spinal meningitis 19, measles 2.

From small-pox New York 3. From scarlet fever Pittsburg 8, Boston 7, Philadelphia 2, Brooklyn, Cleveland, Milwaukee and Chelsea 1 each. From whooping-cough New York and Philadelphia 5 each, Brooklyn 4, Boston 3, Cincinnati, Cleveland and Pittsburg 1 each. From cerebro-spinal meningitis New York 5, Brooklyn and Boston 3 each, Cleveland and Lynn 2 each, Worcester, Somerville, New Bedford and Everett 1 each. From malarial fever Brooklyn 2, New York, Philadelphia and Nashville 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending September 30th, the death-rate was 20.2. Deaths reported 4,001; acute diseases of the respiratory organs (London) 231, diarrhœa 339, diphtheria 124, fever 98, whooping-cough 90, scarlet fever 76, measles 28, small-pox (Bradford 5, London 2, Birmingham and Oldham 1 each) 9.

The death-rates ranged from 12.3 in Huddersfield to 31.0 in Sunderland; Birmingham 16.5, Bradford 21.2, Cardiff 18.7, Halifax 14.7, Leeds 23.2, Leicester 20.6, Liverpool 25.9, London 21.1, Manchester 22.5, Newcastle-on-Tyne 15.6, Nottingham 13.7, Sheffield 20.9.

METEOROLOGICAL RECORD,

For the week ending October 7, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 7, 1893, TO OCTOBER 13, 1893.

Leave of absence for one month, to take effect on or about October 15, 1893, is granted CAPTAIN GEORGE MCCREERY, assistant surgeon, U. S. A., Fort Sidney, Nebraska.

FIRST-LIEUT. ALLEN M. SMITH, assistant surgeon, will proceed without delay to Fort Missoula, Montana, and report to the commanding officer of that post for temporary duty, to enable CAPTAIN WILLIAM D. CROSBY, assistant surgeon, to take advantage of the leave of absence granted him.

FIRST-LIEUT GEORGE D. DESHON, assistant surgeon, is relieved from further duty pertaining to the medical section of the War Department Exhibit, World's Columbian Exposition, Chicago, Ill., and will return to his proper station, Fort D. A. Russell, Wyoming.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 14, 1893.

GEO. H. COOKE, medical inspector, from Navy Yard, League Island, Pa., and to special duty in Philadelphia, Pa.

E. Z. DERR, surgeon, ordered to Navy Yard, League Island, Pa.

B. S. MACKIE, surgeon, detached from duty in Philadelphia, Pa., and wait orders.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, October 23, 1893, at 8 o'clock, P. M.

Dr. F. I. Knight: "On Sending Patients Away from Home." Discussion opened by Dr. E. H. Whittier.

Dr. Edwin E. Jack: "A Case of Recurrent Paralysis of the Oculo-motor Nerve." Discussion opened by Drs. O. F. Wadsworth and G. L. Walton.

JOHN T. BOWEN, M.D., *Secretary.*

RECENT DEATHS.

JOHN S. H. FOGG, M.D., died in South Boston, October 16th. He was a graduate of Bowdoin College in the class of 1846 and of the Harvard Medical School in 1850. He served in the Legislature and was for many years a member of the Boston School Committee. He was an interested student of early colonial and natural history and had wide reputation as an autographist of unusual accuracy of judgment. He was a sufferer for the last twenty years from paraplegic paralysis, but maintained an unfailing cheerfulness and patience in continuing such work as his affliction permitted.

HJALMAR A. ABELIN, M.D., formerly professor of children's diseases in the Carolina Institute, Stockholm, died September 13th, aged seventy-six years.

EPAMINONDA ABATE, M.D., died in Naples, September 26th, aged seventy years. He was much interested in the favorite Italian study of methods for petrification of human corpses and rediscovered the method of Dr. Segato, which had been kept a secret and which was thought to be lost on the death of the inventor. Following up his researches as to the best means of arresting putrefaction, he gave to the results a practical turn for the conservation and transport of alimentary substances. He devised and carried out a special means of importing the flesh of animals slaughtered in South America into Italy — a means till then unknown to his compatriots.

BOOKS AND PAMPHLETS RECEIVED.

Diocese of Massachusetts. Tenth Annual Report. 1893.

Hysterical Aphonia. By W. Scheppegrell, A.M., M.D., Reprint. 1893.

The Duty of the State to the Insane. By Dr. Andrew MacFarlane. Reprint. 1893.

Perityphlitis; Report of Three Cases of Perforating "Cæcitis" and "Pericæcitis." By F. C. Schæffer, M.D. Reprint. 1893.

Tetra-Ethyl-Ammonium; a New Solvent for Uric Acid Discovered at the Edison Laboratory. By Frederick Peterson, M.D. Reprint. 1893.

Quarantine *vs.* Sanitation. Modern Scientific Views of the Cause and Prevention of Asiatic Cholera. By William T. Sedgwick, Ph.D., Boston. Reprints. 1892-93.

Annual Report of the Supervising Surgeon-General of the Marine-Hospital Service of the United States for the Fiscal Year 1892. Washington: Treasury Department. 1893.

Heath's Practical Anatomy, a Manual of Dissections. Eighth edition. Edited by William Anderson, F.R.C.S. With 329 engravings on wood. Philadelphia: P. Blakiston, Son & Co. 1893.

Sarcoma of the Pons and Glio-Sarcoma of the Cerebellum. Acute Ulcerative Endocarditis; a Brief *Résumé* of the Pathology of Eight Cases. Vitelline-Duct Remains at the Navel. By Ludwig Hektoen, M.D., Chicago. Reprints. 1893.

The Medical Press. The Spelling of Some Medical Words. A Temporary Change in the Axis of Astigmatism. The Duty of the Community to Medical Science. The Pernicious Influence of Albinism upon the Eye. By George M. Gould, A.M., M.D., Philadelphia. Reprints. 1893.

Essentials of Bacteriology: being a Concise and Systematic Introduction to the Study of Micro-organisms for the use of Students and Practitioners. By M. V. Ball, M.D., physician to the Eastern State Penitentiary at Philadelphia. Second edition with eighty-one illustrations, some in colors, and five plates. Saunder's Question Compends. Philadelphia: W. B. Saunders. 1893.

Hernia; its Palliative and Radical Treatment in Adults, Children and Infants. By Thomas H. Manley, A.M., M.D., visiting surgeon to Harlem Hospital; consulting surgeon to Fordham Hospital; member of New York Academy of Medicine, American Medical Association, New York State and County Medical Association, National Association of Railway Surgeons, etc. Philadelphia: The Medical Press Co. 1893.

Essentials of Minor Surgery, Bandaging and Venereal Diseases. Arranged in the form of questions and answers. Prepared especially for students of medicine. By Edward Martin, A.M., M.D., clinical professor of genito-urinary diseases; instructor in operative surgery and lecturer on minor surgery, University of Pennsylvania; surgeon to the Howard Hospital; assistant surgeon to the University Hospital. Second edition, revised and enlarged. Seventy-eight illustrations. Philadelphia: W. B. Saunders. 1893.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XVIII.

WOUNDS OF THE FACE.

Wounds of the face open up the whole subject of plastic surgery. The essential point is, that in every operation, the skin that has been cut and torn away should be replaced, and preserved, if possible; for a very slight scar and loss of substance may make quite a difference in the facial expression. Thorough cleanliness, careful matching, sewing up with fine thread and fine needles. I think you have noticed when an amputation stump, or breast, which has been excised, has been shown as a fine result of first intention, a fine even scar which finally sank away into a white line, but on either side of it a long row of very conspicuous stitch-holes; and they are slower to fade away, dimple the skin, and draw it in, making more marked scars. This, however, in the breast makes little difference; but on the face it makes a great difference; so that the finest sewing must be done, or the buried suture used, so as to avoid so many conspicuous punctures.

A large class of operations used to be done to repair the nose, when it was lost. I think surgeons are becoming rather more discouraged about these operations, the restoration of the nose. It can be restored by flaps taken in various directions; but to restore its shape and its color is almost impossible. You generally have a flat, deformed, soft nose, with a very pale color; and it is scarcely less conspicuous than the hole it was meant to cover; consequently, unless you have to operate on the nose for the extermination of active disease going on, it is a question whether it is not better to advise the patient to wear a mask over the nose, than to do a plastic operation on a large scale. The *papier-maché* noses which are made are extremely good, and can be replaced when they wear out, without much expense.

On the eyelids and lips plastic operations are of great importance, especially to avoid extreme drawing down of the lower lid leading to constant flow of tears over the cheek, to gradual change of the inner surface of the lower eyelid from its long exposure, and to danger of ulceration of the cornea from long exposure to the air; so that every resource of grafting or turning over flaps should be practised about the lids; also about the lips, where much can be done.

It is quite a common thing for foreign bodies to be put in the nose and ears by children. One should suspect in the case of a child who is supposed to have a polypus in the nose that he has instead a foreign body. It will prove to be a foreign body in a large percentage of cases. The child has inserted it unseen; is too young or afraid to tell of it. It remains caught on the turbinate bone, produces ozæna, filthy discharge, and is supposed to be a polypus. I say this to impress on you the importance of very thorough examination before any operation is undertaken in the child's nose. The foreign body once found, can be easily extracted in a variety of ways — with the hook or snare; or, if necessary, by cutting up the ala of the nose by a simple incision; turning it one side; taking out the foreign substance; the subsequent scar is almost nothing.

In the ear, the foreign bodies are not so often put in, as they exist in the form of some living creature; either a little bug or a fly, an insect of some sort. There is a very simple expedient to relieve the distress which these insects occasion immediately, which is harmless; and that is to pour in, or inject either oil, or melted mutton-tallow, and allow the latter to set in the ear. It does so in a very few minutes. The insect is imprisoned and killed, and can be syringed out and extracted at leisure. I speak of this as preferable to water because it is more effectual. You will hardly realize the intense agony and almost mania inflicted on a person by the presence of an insect in the ear which is free to buzz on the drum. The torture is terrible; and speedy inflammation is set up, unless the insect is removed. It is easier to destroy the insect in this simple way than to search for it while the patient is in distress.

SUICIDAL OR HOMICIDAL ATTEMPTS TO CUT THE THROAT.

The person who attempts to cut his throat, in the majority of cases, cuts too high to destroy life. A large proportion of the cuts are directly beneath the chin; and, if they go deep enough, open the floor of the mouth. The cut is directly between the hyoid bone and the chin usually; next between the hyoid bone and the top of the larynx; and next opening the trachea. Homicides occasionally seize the victim and cut the throat so thoroughly that a simple transverse cut divides also the vessels; but a suicide rarely divides the vessels; they lie so deep, descend backward so rapidly as they go down the neck behind the sternum, that they are rarely reached by the ordinary transverse cut.

The danger of the ordinary cut throat consists in the effect it is going to have upon the breathing, and upon the chink of the glottis, either by hæmorrhage, or by suffocative œdema. All cuts above or through the larynx, above the level of the chink of the glottis, are dangerous in the consequences they may bring to the glottis itself. The vessels cut are usually small. The nerves which are reached by a transverse incision are few in number, and only terminal branches; and were it not for the chance of trouble taking place in the breathing apparatus subsequently, the injuries would be very rarely fatal.

However, the person sometimes cuts lower down, and cuts below the vocal cords; then he is no more in danger of suffocation than in the operation of tracheotomy; and the cut low down is harmless as regards the dangers of dying of dyspnœa.

The important point in regard to cuts high up is that they should not be closely sewed up without allowing some chance for drainage, and preventing the chance of infiltration into the larynx and the glottis: hence to sew any wound in the throat, which has penetrated deep enough to open the air-passages, is not good surgery. The parts should be approximated without stitching, and secured by a bandage. The parts will heal by second intention, and do very well. Meanwhile, we have entire security; for if the wound is not sewed, we have control of the breathing apparatus.

[1] These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

There are other cases where the passages have been opened above the vocal cords; where the cuts are very deep; and where it is wiser in the beginning to do tracheotomy, and let the patient wear a tracheatube, rather than to risk anything that is going to take place from injury inflicted on the larynx and vocal cords. After tracheotomy, it is perfectly proper to draw together the wounded parts; wire together the larynx, and try to make the wound heal by first intention; but you must be sure, as regards the chance of suffocation, before you adopt any of these measures, Either leave the wound open, or do tracheotomy as a preventive measure. A few of these patients die of shock; but very few. Almost all the suicides, after the commission of the act, come to themselves and wish to recover; and the majority of them do recover, unless the wound has gone so deep as to involve the pneumogastric, or the large vessels; or to lead to some subsequent abscess, or burrowing cellulitis of the neck. The cut of the pneumogastric is usually fatal by producing a slow form of pneumonic consolidation in the lung supplied by the wounded nerve; and the patient usually dies of this complication. Wound of the carotid artery is immediately fatal unless it can be secured at the moment. Wound of the jugular vein is not infrequently recovered from. I mean, of course, the internal jugular vein; for the external vein is a vessel not very dangerous to wound. It was the one formerly selected for venesection in children, when venesection was practised. It is easily secured and not very large.

INJURIES OF THE ABDOMEN.

Cuts and stabs and perforations of the abdominal walls are liable to be dangerous irrespective of wounding the viscera. The dangers are two. One is immediate; and the other is subsequent. Both these dangers can be classed under the name hernia. The immediate danger of hernia is that the wound gaps a little, a little bit of omentum gets forced through the wound and slowly emerges from the abdominal cavity under the peristaltic movements. You will be surprised to see through how small a puncture a large piece of omentum will be extruded on to the wall of the abdomen; and this may become strangulated and make trouble if it remains. The proper treatment is to cleanse the part thoroughly, carefully enlarge the wound, and sponge out the cavity, and restore the omentum into the abdominal cavity, and to stitch it up. Now comes the subsequent danger, which is of hernia after the wound has healed. You can hardly cut through the strong fascia of the abdominal muscles in any direction without the risk of subsequent ventral hernia in the scar. The wound heals by cicatricial tissue. Unfortunately it does not seem to possess, in this region, that great power of contraction, that it has in the burn, or that cicatricial tissue has in the perineum after an injury to the urethra. It is here a soft tissue constantly moved and stretched by the use of the abdominal muscles, and is very apt to yield and gap open after a few months, and give rise to a hernia. In this case we have but one resource. We may try, if we wish, to reduce the hernia; cut down and make a fresh incision, and see if we can get a stronger union than was there before. This is of questionable success. If we do not attempt that, the only other resource is to apply the ventral truss for a hernia, which will keep the bowel in. I allude to this, particularly, because I do not think it is strongly enough insisted on that whenever the abdominal muscles are cut through, the chances of subsequent hernia are very great indeed.

Since the introduction of antiseptic surgery the peritoneal cavity has been opened with impunity, compared with past times; and a new name has been sought from the Greek to describe the operation; the name of laparotomy; and this operation is done for a great variety of purposes. There are two or three of the more prominent reasons why it is done that I shall speak of now. One is for what is called stoppage of the bowels. Of this there are two principal forms. One is twist or volvulus, and the other the folding in of the gut into itself, sometimes called intussusception.

Now it may make but little difference in the prognosis which of these two forms of trouble exists, and either of them may call for operation. The diagnosis between the two may be important and useful as guiding to the proper treatment by operation. We may say in general terms that intussusception is much more common in the child than in the adult. The peristaltic motion is more powerful in the child; the mesentery is more free. The folding in of one portion into another is much more apt to occur in the young child than in the adult. Hence the age of the patient influences us in making the diagnosis. The subsequent symptoms produced by the stoppage also guide us a good deal to the diagnosis. In either of these events, whether intussusception or volvulus, immediate stoppage of peristaltic action occurs above the seat of obstruction; the bowels cease to move, and accumulation of gas takes place; but in the twist or volvulus this is absolute and complete from the beginning; the patient has generally no desire to have any discharge from the bowels, either of wind or other substances, and makes no effort. Everything seems to be dead and still. On the other hand, the child that has an intussusception has, for a day or two after the accident, a constant desire to move the bowels, and is constantly making straining efforts at stool. Moreover, these efforts do produce something. They produce serum and stringy mucus, and occasionally a little blood; and the child is making incessant attempts for the first day or two after the onset; and this guides somewhat to the diagnosis between twist and intussusception. I should say that the diagnosis between the two is important in this way, that the intussusception is not so hopeless as the twist. Nature sometimes, though rarely, cures the intussusception, either by retracting the bowel back into its normal place; or, as is more frequent, by causing it rapidly to adhere, causing the inner piece to slough, making union of the two ends of the intestine, and discharging the sloughing piece through the natural tract and through the anus, by the efforts of the child itself. This sometimes occurs in the course of the second week after the intussusception; though rarely. So in the treatment of these two affections our first efforts in regard to intussusception should be to restore the bowel to its normal condition; and if we had made the diagnosis of volvulus or twist we should know that the treatment we are going to use to push back an invagination, would be worse than useless in volvulus. We use large enemata of fluid or air, and invert the patient, and try to promote retro-peristalsis, to push the bowel back into its normal place. This would be worse than useless in twist. In twist or volvulus the seizure is immediate; pain intense and

localized; efforts at stool are none whatever. Peristaltic motion soon ceases absolutely. The abdomen is like the abdomen of a dead person, except that it rapidly becomes distended with gas above the point of stricture. The high temperature produced by this state of things goes on from three to five days. Generally by the fourth or fifth day the symptoms undergo an apparent amelioration; although this is entirely deceptive, and does not mean that the patient is going to get well. In other words, the temperature falls; pain ceases; no passage takes place from the bowels; no wind is passed; the size of the bowels may not recede; but the temperature falls, and his pain ceases. Meanwhile the pulse flickers and grows more rapid; the capillary circulation is a little obstructed and dark, and he dies usually without suffering; and the signal of the loss of pain and dropping of temperature on the fourth or fifth day means that sloughing of the part or mortification in the abdomen has taken place, to be followed by death.

In these cases we have some hope, that if nothing else has succeeded in relieving the patient, opening the abdominal cavity and seeking for the cause of the obstruction may do so; that an invagination, if not too old, may be reduced; or if irreducible, the two ends of the intestine may be cut off and sewed together, thus imitating the process of nature, which is trying to slough off and unite the pieces: that a twist may be relieved by dividing adhesions.

If then we are thoroughly convinced that other measures are failing; that the diagnosis is reasonably clear; when the second or third day has arrived, it is good practice to open the abdominal cavity and see if we can give relief. Meanwhile, if the diagnosis is uncertain; if the time has not arrived when you think it is safe to open the abdominal cavity; a good deal can be done in the way of relief by medicine; and certain things are very comforting to the patient, and usually check the progress of inflammation. These are, in such violent cases, the free use of opium; and the application of cold, or warmth, to the abdominal wall. Usually warmth is most grateful to the patient; but if cold is grateful, and can be kept up by means of the cold water coil or ice bags, it no doubt is good treatment in checking congestion and effusions. It would be obviously improper, perhaps useless, in these cases where we are pretty clear that a twist or invagination has taken place, to give cathartics. If grave doubts exist as to the cause of the obstruction; if we feel that it may be a temporary stoppage of peristaltic action from spasm; or cessation of flow in the gall-ducts; or from impaction of fæces; then cathartics are proper remedies to use. The question then arises what cathartic? The most useful in allaying the irritability of the intestine are two in number. They act very differently. One, the well-diluted saline solutions of any kind; epsom salts; sulphate of soda, etc., which can be given in small and repeated doses, and produce a large flow of serum from the mucous membrane of the alimentary canal. The other agent is also extremely valuable, because it acts quietly and smoothly; and in the end, if the obstruction is removable, it is irresistable; and that is castor oil; not given in the ordinary way; but in minute doses at short intervals; a drachm every four to six hours, thereby the patient getting from one-half to one ounce every twenty-four hours; and this persisted in, two or three days, will certainly, in the case of ordinary obstruction, if the oil is retained well on the stomach, produce, sooner or later, thorough fæcal evacuations, and without disturbance.

Then we have that large class of cases where the trouble begins by inflammation in or about the appendix, and head of the cæcum; sometimes behind the peritoneum; sometimes within the peritoneum; sometimes beginning by perforation of the appendix; and sometimes, apparently, by cellulitis in and around the appendix, not followed by perforation. It is well-known that perforation of the appendix, with a throwing out of some hard mass into the peritoneum, is not necessarily followed by fatal peritonitis; because a localized peritonitis is immediately set up in a large number of cases. The foreign substance becomes speedily encysted; walled off from the general peritoneal cavity; and finally terminates in the formation of an abscess, which may, or may not, have a fatal result, if left alone. If the adhesions are strong enough, it may seek an opening through the abdominal walls, or lumbar region; or again, as is more frequent, it not seldom finds its way down into the pelvis, and forms a pelvic abscess, and finds an exit, in safety in some cases, in the rectum or vagina; so that perforation through a small opening, letting out a small quantity of fluid matter, is speedily followed by walling in of the offending portion by rapid adhesions. You, perhaps, in seeing some of the results of operations on the appendix, may have seen how rapidly adhesions take place between the coils of intestine, when there is an opportunity to do so.

The question in these cases is very doubtful whether immediate laparotomy should be done, or whether we should wait. Very many patients recover without operation. It is true that they are left afterwards with the chance of another attack of the disease; but it is also true that an operation, which is done, leaves them necessarily with adhesions; with subsequent impairment of the mobility of the parts; chances of subsequent inflammation, as the old adhesions of the original perforation do; so that, although we may save life by operating, we cannot say yet, that we can cure the place we seek to cure. We remove it; but leave the adhesions of surgery in the place of the adhesions of disease.

The diagnosis is made much easier in these cases if any tumor can be felt. By that we mean anything different in sensation to the touch, or percussion, from the rest of the abdomen; any thickening, or hardening, or obscure feel; above all any œdema of the parts, when the disease has gone so far, may make us feel quite positive, if it is on the right side, that we have to do with an inflammation about the cæcum, or appendix. Sometimes, however, the appendix perforates; abscess forms back in the pelvis under the edge of the ilium; nothing can be felt outside; and the little tumor is there, but so deep and overlaid with a mass of intestines filled with air, that it is impossible to appreciate it by the touch. It is in these cases that a careful examination by the rectum may give invaluable information. The finger should be inserted as far as possible into the rectum; you make the patient strain down, and you gain a little; in a certain percentage of cases, where no tumor can be felt outside, it can be detected through the rectum, pressing down in the pelvis in the right iliac fossa; and once detected there, of course it confirms the suspected diagnosis of an abscess about the appendix, which we could not feel from the front. I think this precaution never should be neg-

lected in examining any case of this supposed disease. Even if we feel a tumor outside, I should be disposed to make a thorough examination by the rectum; because we may find, to our surprise, that it has already gone so far that it begins to point, so to speak, in the rectum; and a dimple, with fluctuation, is not infrequently felt high up in the indurated mass in the rectal wall; and tapping may be done there, and the necessity for laparotomy avoided.

I would not have anything I say discourage in the slightest degree the importance and benefit to be derived from opening the abdomen to seek for the products of inflammation in and about the appendix; only, in feeble and tubercular subjects, you will have recurrent attacks about the region of the appendix, which in many cases will get well for the time being, without the use of the knife, by gentle measures; as fomentations and rest, and the free use of opium; and the patient go about, for a long while, without another attack.

COLOTOMY.

Colotomy is opening the colon to make an artificial anus; it is done for obstructive disease of the rectum. That obstructive disease is generally cancer. The rectum, as a rule, is not obstructed by cancer near the anus; it is obstructed higher up. The reason is this: if cancer, or any obstructive tumor forms in the rectum, as high as you can feel with the finger, you find that the bowel is invaginated; conveying to the tactile sense very much the same impression that you feel when you examine the female and insert the finger at the orifice of the os uteri; around this is spread the hardened mass of cancer; that is, the bowel is pocketed through the stricture. You find nothing of this kind in the forms of obstruction which exist within an inch, or inch and half, of the anus. There it is simply infiltration of the rectal wall; a mass of rough and ragged disease, through which you pass the finger into the cavity of the bowel above. Cancer in that region rarely becomes the cause of positive obstruction; whereas higher up, the bowel is being forced down into the obstruction, where it is free to move about; and obstruction takes place by a species of chronic invagination. In these cases it is a fair question whether they will prefer to be relieved by the formation of an artificial anus; if so, the place should be as near the natural outlet as you can get, to save the action of the alimentary canal, for the purposes of complete digestion. It has been found, that when the intestine was tapped very high up, it interfered with the nutrition of the patient. A wound going through the first portion of the large intestine is disastrous to complete nutrition. The nearer to the outlet the better the chance of perfect fæcal evacuations and good digestion.

You have two places, either in the loin and left side, or in the groin and left side. The advantage of the lumbar region is that you avoid the peritoneum. The advantage of the groin is, that, although you go through the peritoneum, you can get at the bowel more readily, and perhaps may make it more easy to wear a truss.

The operation in the groin is the easier; the operation in the lumbar region is the harder. In either case, if you want to be perfectly safe in doing the operation, there is a little manœuvre which may be practised. Suppose it is done in the groin; you cut down and find the sigmoid flexure; pass long, curved needles in several directions and sew the bowel up thoroughly to the abdominal walls; leave it forty-eight hours; take off the dressings, and you find the wound still open; the intestine changed in appearance. This thin glistening bowel is converted into granulations. You can slit it completely open without the possibility of extravasation. On the other hand, if you feel it is safe to do so, you may do the stitching up and securing, and make the incision at the moment of the operation; and this is done in many cases. It is said, that by the contraction of the wound, afterwards, the patient gets control over the solid evacuations. That, aided by a truss, may make the patient comfortable and prolong life. It is not a very dangerous operation.

ONYCHIA.

Onychia is a form of disease about the nails. In its simple form it is called run round, or superficial whitlow; it occurs as a slight suppuration about the root of the nail, followed by the raising up of the epidermis; a yellow deposit of pus and abscess, which runs down along the side of the nail.

The remedy is free incision; washing out; and it gets well.

MALIGNANT ONYCHIA.

There is a form called malignant onychia, which is probably neglected simple onychia in the large majority of cases. We seldom see it in people well nourished. You find examples of it in poor, half-starved children, brought to the dispensaries and out-patient departments. These onychiæ refuse to heal. The nail is extracted; and the part treated as a fungus sore, and it may still refuse to heal, and may end in amputation.

CHANCRES ABOUT THE NAIL.

There is a class of ulcers about the nail which are syphilitic, and unfortunately they are most apt to assail members of our own profession. The number of doctors who get poisoned by a slight agnail, and chancre at the root of the nail, is large. Unfortunately, unless the physician is on his guard, he neglects it and thinks it is a simple whitlow; wonders that it does not heal. He poultices it. It is purely a specimen of hard chancre.

It refuses to heal under any treatment. Soon after that a gland is felt at the elbow and up the arm; and later syphilitic roseola appears on the body and the diagnosis is clear. I mention this, because I have seen quite a number, and heard of a great many more such cases, of a suspicious sore about the nail, in practising physicians. If it were my own case I should promptly take mercury, after such a sore appeared upon me. That speedily settles the diagnosis. The moment the patient is slightly mercurialized, the sore softens and begins to heal.

DEEP FELON OR WHITLOW.

A deep felon or whitlow is a suppuration down under the theca and the periosteum, and usually coming on the last phalanx. It is intensely painful; does not swell much; but makes the pulp of the finger hard, and different in feeling from the tip of the other fingers. The pain is intolerable and persistent; destruction of the parts goes on with great rapidity, unless relieved. Unless it is relieved the pus burrows up under the theca of the tendons and affects other joints of the finger; finally gets to the palm and forms palmar abscess; extends without difficulty under the annular

ligament, runs up under the superficial fascia of the forearm, and finally ends the process of suppuration at the elbow-joint. We see such cases where the arm and hand are subsequently crippled by the adhesions that have taken place.

The only treatment is early and thorough and deep incision; and it is a mistake to wait for it to ripen; the ripening is its destructive process. It never should be allowed to ripen; and a deep incision, made at once, will frequently abort the suppurative process, and lead to healing with granulation, in a very few days.

As a rule, pus is always to be sought for on the palmar side. On the dorsal side it is generally only a secondary consequence. On the palmar surface the pus is to be found. A good deal is said of the propriety of opening on the side of the finger. The danger on the side is damage to the nerve and vessels. The danger of damage to the nerve is somewhat serious.

When there is palmar abscess the patient is very sick indeed. The forearm is swollen and œdematous; constitutional symptoms are severe; chills; high fever and exhausting sweats. In these cases it sometimes becomes a question whether to seek for pus in the forearm. We suspect it is there. The symptoms are not relieved. The œdematous condition goes up the arm. The patient does not experience any relief from his pain. The safest place to reach it is in the centre of the wrist, above the annular ligament. Cut down until you reach the superficial fascia and come to the long flexor and palmaris tendons. Now take the dressing forceps and director and pick away between the tendons, until you come to the space upon the interosseus fascia; and there, you almost invariably, get a gush of pus. This is to be kept open and irrigated every day. Occasionally it becomes necessary to make additional openings higher up. This is good surgery. It saves the limb and life; but does not cure the member. The hand is not restored. Patients must expect, subsequently, some adhesion and stiffness of the tendons. If such adhesion and stiffness result, it occurs from the long continuance of the inflammation; from the fact that gluing together of the tendons has occurred, and contraction of the parts with a comparatively useless hand, in many cases; in no sense is this to be ascribed to anything the surgeon does; but wholly to the progress of the disease, before the surgeon was called in. You will find, often, the physician or surgeon blamed for consequences about the usefulness of the hand and arm, where really he saved what could be saved; but could not cure the part.

BUNION.

Bunion is usually upon the great-toe joint and is an enlarged bursa. Usually it is there for the purpose of protecting from friction against the side of the boot. When irritated and inflamed by pressure; when the joint is thrown out of its normal position by shoes which are too short; the end of the toe begins to be thrown in; the joint projects, and it becomes inflamed and tender. A sac is evident upon the surface of the bone; fluctuation can be felt. This sac is an inflamed bursa. Occasionally, by careful treatment, it may be made to subside without suppuration. This treatment should consist in the taking off of pressure; either by cutting the shoe; or by wearing a very large or thick corn plaster, which encircles the joint and allows it to ride free beneath the plaster. Applications may be used at night to allay the inflammation in the part itself. Sometimes a poultice is very useful. You must not be carried away with the idea that we always apply a poultice to produce suppuration. It sometimes prevents suppuration; softens the skin; allays the heat; sweats and foments the part; and frequently produces absorption instead of suppuration. When suppuration exists and is unavoidable, it bursts and discharges through a minute opening. Then it is a long while in healing, because you have a little thickened sac or cyst, which continues to secrete, and it is most speedily cured by laying it open. You must investigate the sac and see whether it goes into the joint. If it does, it must be laid open freely and irrigated; and the part put on a splint. If it does not, the sac may be laid open, scraped out and forced to heal, just as any bursa would. The most important point in treating the early stages of bunion is to get the great toe on a line with the inner border of the foot as it was intended to be by nature; and as you see it in all the old statues. The old sandal prevented the possibility of bunions; dragging the great toe out by a strap between the great toe and second toe. It is a good practice to put between the great toe and next toe a thick piece of paino felting, which can be inserted to keep the toe out, while the patient walks. The shoe must be made on a straight last; and with these means, a great many persons can get along, and prevent the formation of bunions.

ANTHRAX FACIEI: REPORT OF A CASE.[1]

BY S. E. WYMAN, M.D., CAMBRIDGE.

The occurrence of such cases is sufficiently rare to justify the publishing of notes connected with this dread malady; and a brief *résumé* of the history of anthrax as it occurs in animals and in man will form a fitting introduction to this paper. Anthrax, charbon, milzbrand or carbunculus contagiosus, as a disease in animals, is perhaps the one whose knowledge by man dates back to the earliest period. This is the disease referred to in Exodus, ninth chapter, third verse: "Behold, the hand of the Lord is upon thy cattle which is in the field, upon the horses, upon the asses, upon the camels, upon the oxen, and upon the sheep: there shall be a very grievous murrain." And in the sixth verse: "And all the cattle of Egypt died."

Among the Greek and Roman veterinarians it was known as Οὐδημα. The name of "anthrax" was used by the Greek, and "carbunculus," by the Roman physicians. The Arabians described anthrax in man with even greater accuracy as *Atshac*, *al Humrah*, or Persian fire.

From the fourteenth to the eighteenth century the disease of anthrax was covered up under different names given to various diseases; and only toward the end of the last century was it shown that these manifold diseases were, in reality, only different forms of the same disease.

Chabert, in his monograph,[2] brought order out of

[1] Read before the Cambridge Society for Medical Improvement, May 22, 1883.

[2] Description et traitement du charbon, Paris, 1780.

chaos, and grouped what had been hitherto considered many and various diseases as one malady with varying manifestations; and his classification has been adhered to, not only in France, but in all countries even to this day.

No infectious disease in man or animals (with the exception of tuberculosis) has been more generally recognized, and cases of the same reported, as has been the case with anthrax. Heusinger,[3] in his work on Milzbrandkrankheit, has found the evidences of its presence in almost if not all countries, whether in the most northern or most southern latitudes, in the Old World and in the New. It seems, at first thought, strange perhaps that, although the contagiousness of anthrax has been abundantly proved by numerous observations in the eighteenth century, authors in the beginning of this century should have denied that there was any contagion in anthrax; as, for instance, Delafond, who, in his particular study of anthrax in sheep (*maladie de sang*), considered the rennet, stomach and intestines the special seat of the disease, and ascribed as its chief causes overfeeding and the condition of the soil.

Among animals anthrax is found most frequently where agriculture is in its most primitive condition; and while it may occur in all soils, yet those most favorable to its growth and propagation are soils which are close, impervious, clayey or peaty, and such as are habitually over-manured. Anthrax occurs most often among herbivora; least often among carnivora; omnivora being less susceptible than herbivora, and more so than carnivora.

It would exhaust your patience and time to go further into these details, for which the reader is indebted to the articles by Bollinger, in "Ziemssen's Cyclopædia," Vol. III; James Law, F.R.V.C.S., in "Pepper's System of Medicine," Vol. I; and E. M. Moore, M.D., in "Ashhurst's International Surgery," Vol. II.

As to the etiology of anthrax, Pollender,[4] in 1849, found in the "blood of animals suffering from anthrax a countless mass of fine rod-like bodies, which in appearance and figure resembled vibriones, and in their micro-chemical behavior were seemingly of a vegetable nature." Brauell[5] (in 1857), independently of Pollender,[6] "found the same little bodies in the blood of men, horses and sheep which had died of anthrax." Davaine,[7] however, was the first who associated the presence of these bodies (which, after experiments, he pronounced in 1863, to be bacteria and later bacteridia) as standing in the relation of cause and effect in producing anthrax. Later investigations have substantiated his theory, and to-day the bacilli anthracis and their spores are the recognized cause of anthrax.

The bacilli anthracis in the blood are found to be in the form of fine rods, straight, only occasionally bent or angular, from 0.007 to 0.012 mm. in length, devoid of motion (a valuable aid in their differentiation from the motile bacteria of putrefaction); smaller forms, minute ovoid or oblong bodies are found. The smallest (micrococci) under the highest powers of the microscope are seen, but always with clear-cut, even margins, thus distinguishing them from the normal irregular granules of the blood. Spores are never found in the blood of the living animal; but when the bacilli are grown in organic infusions outside the body, the anthrax germ develops from bacillus or micrococcus into a long, branching filamentous product, which, if oxygen be present, develops into spores. The anthrax germs are very tenacious of life, and the spores to a much greater degree. "Meat cooked for hours, or broth boiled similarly, when taken from anthrax-infected animals, has caused symptoms of anthrax in persons partaking of such food."[8]

In man, Fournier[9] was the first who was able, in 1769, to trace the cause of anthrax to the consumption of anthrax-diseased meat, and to the handling of the wool of such animals.

With the course, symptoms and other interesting topics naturally suggested by internal anthrax, nothing can be presented in this brief article. It is with the external form, which has usually been relegated therefore to the domain of surgery, of anthrax carbunculus, to which attention is specially directed.

Theoretically, man might be infected, as are herbivora, from the soil; but practically such is not the case. The principal ways of infection are immediate and mediate. Of the former may be cited cases caused by handling hides, wool, hair, flesh and other parts of diseased animals. But as to the mediate causes, we have to deal with a more extended number of possible sources of infection. Bites of insects, mosquitoes, blue-bottle flies, and others of a like nature (blood-suckers), which have been previously in contact with anthrax-diseased carcasses are among the well-known causes. Well-attested cases are reported where men or animals, themselves not infected, have been the carriers of the anthrax germs to others. Other ways of catching the infection are by handling harnesses, stable utensils, hay, fodder, the surgeon's knife, etc.; drinking contaminated water; and, in animals, the feeding on meadows containing the buried remains of anthrax-diseased animals.

It is very interesting to note in this place that the site of the primary seat of infection (the anthrax node) is constantly on the exposed parts of the body. Bourgeois[10] long since called attention to the fact that this was most frequently the face, neck, hands or arms and almost never on the trunk. Dr. A. W. Bell,[11] of Brooklyn, in 60 cases reported by him, found that 56 were on the face, two on the hands, one on the wrist, and one on the forearm; and that often the disease had started from the bite of a fly or a mosquito in many of these cases. Bollinger[12] has found in the stomach of such flies as feed on the flesh and blood (horse-flies, blue-bottles, etc.,) the bacillus anthracis, thus completely showing that bites from such insects may cause anthrax.

As to the symptoms, these usually appear within twenty-four hours after inoculation. The patient complains of a stinging sensation in some spot to which previously his attention has been called by an itching. When examined, a small red spot, like a mosquito bite, is seen, but with a small, central, black spot. The further description, taken from the standard authorities, of the *natural* progress of the local manifes-

tation was not watched in the case of the patient, whose history will soon be given. "This speedily increases to a small round swelling (papule), which in fifteen hours is surmounted by a minute vesicle with dark-red or bluish contents. This increases from the size of a millet-seed to that of a pea, and in thirty hours bursts spontaneously or under friction, forming a dark-red, indurated, comparatively painless nodule (parent nucleus of Virchow). The areola is swollen, livid and red, and on this appear vesicles similar to the first; these pass through a similar stage, leaving a doughy, gangrenous or hard, livid surface. By this time the surrounding skin is shiny red and livid, and the disease spreads by the same method of extension."

Constitutional symptoms vary: fever at first is slight, but may reach a high point, attended with occasional chilliness, pains in back and loins, languor, great prostration; in fact, such symptoms as are met with in cases of general blood-infection.

The disease lasts from six to ten days.

As to the diagnosis, it must be remembered that the anthrax nodule begins with a small red papule having a dark central point, from which the disease extends as above described. The simple furuncle lacks this black centre and the rapidly rising elevated red areola. Simple carbuncle tends to appear on covered parts of the body, anthrax on uncovered places. In carbuncle, simple, several boils rise and burst simultaneously, and break into one sore; whereas, anthrax extends by separate, isolated nodules like the "parent nucleus." The finding of the anthrax bacillus by microscopical examination would be conclusive if resorted to.

The disease anthrax is very rare: Bilroth says, "Even simple, benignant carbuncles are so rare that in the extensive surgical policlinic in Berlin, where every year 5,000 or 6,000 patients presented themselves, I only saw a carbuncle once in two years or so. In Zurich, also, they were rare." Bryant, in his "Practice of Surgery" (p. 408), says, "Malignant pustule, or charbon, is a disease with which I have no personal experience."

As to prognosis, much if not all depends on the early recognition of the true nature of the malady. In anthrax districts, where the physicians are familiar with its appearance, astonishingly good results have been attained. Nicolai[12] reports a mortality of five per cent, Lengyel and Koranyi nine per cent. (There is no statement made as to the site of the nodule in these reports.) But the prognosis in other districts where anthrax is not so general is worse, the mortality reaching forty to fifty per cent. In considering this part (prognosis), it must be borne in mind that anthrax of the face, especially of the upper lip, is almost always fatal.

As to treatment, the most approved method consists in the excision of the parent nucleus, or cross incisions with the subsequent use of the most powerful germicidal agents, cauterization or local germicidal lotions, injections and applications. The constitutional treatment must also simultaneously be carried out by stimulants, and carbolic acid internally to the extent of fifteen drops daily.

CASE. The patient who forms the basis of this paper was a young man of stocky frame, American born, and nearly twenty-five years of age. He was a teacher, and absent from his school at that time, November, 1886, on a vacation. On the night of November 19th, when going to bed, he noticed a pimple on his upper lip on the left side, just below the ala nasi and at the upper part of his mustache. This pimple he pricked with a needle, and applied cuticura soap to the spot.

November 20th, he was one of the spectators at a football game on Jarvis Field, during which game he sat on the ground, but with thick wraps under him. After returning to his temporary home the spot began to grow painful, and the lip to swell toward bedtime. Sleep was somewhat disturbed, and he presented himself for advice on the following morning. At that time the upper lip throughout its entirety was much swollen; the mucous membrane tense and shiny; the local papule was hard, with a black central spot, tender to the touch and surrounded by a raised, livid areola. Only a minute drop of pus followed the introduction of a grooved needle. The patient was sent to his room, and seen later at 11.30 A. M. At this time free crucial incisions were made through the base of the nodule, and corrosive sublimate solution (1 to 1000) freely injected with a hard-rubber syringe. Thorough washing of the parts with bichloride solution (1 to 1000), was ordered at each application of hot flaxseed-meal poultices.

The wound on the next morning was found tending toward union, and had to be reopened. His sleep had been bad; he was nervous, and had slight chills. The night visit showed the wound more inclined to gape; the central part, which had been kept from closing by the insertion of a plug of cotton saturated in corrosive sublimate solution, was necrosed, and a very small amount of thick, inspissated pus was extracted by means of forceps. There was no fever as yet, and the pulse was only 84; opium was required in order to obtain rest.

On November 24th, the symptoms were more grave; and our esteemed fellow-member, Dr. J. T. G. Nichols, saw the case in consultation at 11 A. M. The swelling had, through its extension by the subcutaneous cellular tissue, formed a second nodule just above the ala nasi, with the swelling and induration extending upwards toward the left eye. As there were evidences of nervous and general weakness, brandy (two drachms every two hours) was ordered. The swelling extended further at night, and the whole side of the face was markedly red and shiny. For the first time the temperature was elevated to 100.1°, with the pulse at 90.

On the morning of November 25th, the fourth day after seeking advice, all the symptoms were so greatly aggravated that Dr. R. M. Hodges kindly consented to give his services and advice in the case. The pulse in the morning early was 90, the temperature 99.4°. Dr. Hodges saw the patient at 11.15 A. M., and considered the case very grave, with the probability of a fatal termination. The pulse at that hour was decidedly irregular and weak, and it was plain to Dr. Hodges that the patient was less strong than he seemed. Radical operation was however advised, and agreed to by the patient and his friends.

Under ether, Dr. Hodges performed the operation, which may be designated as the subcutaneous one, of cutting up thoroughly all the diseased tissue (then occupying nearly the whole of the left cheek) by inserting his knife into the original wound between the outer skin and the mucous membrane and carrying the blade by generous sweeps throughout the whole territory. The hæmorrhage, which was considerable, was stopped, and disinfection accomplished by plugging the

[12] Nicolai: Pepper's System of Medicine, vol. i, p. 943.

entrance wound with cotton saturated with corrosive-sublimate solution.

The patient rallied well, and in the afternoon seemed fully as comfortable as before the operation. The cotton plug was removed, the wound syringed with corrosive-sublimate solution, and plugs of necrosed tissue removed by forceps. There had been some sweating. His pulse varied from 88 to 90, and was rather weak; temperature 100.2°. When a night visit was made on this same day, little change was noticed, except that the left eye (which the swelling had succeeded in closing in the early morning) was even more tightly closed.

On the following day the patient was no worse; in fact, there was scarcely any change. Plugs of necrosed tissue were removed, and the same treatment carried out.

The symptoms were improved on the following day. The patient had slept without opium, and the necrosed tissue came away more freely. It was a disappointment to learn at the visit in the afternoon (3 o'clock) that a third focus had started on the left cheek on a level with the angle of the mouth. This was hard and tender. The breath was offensive, but the general condition was good. This spot extended in its progress along the lower border of the inferior maxilla, involving the lower lip as far forward as the median line. The area which at this time was involved measured two and one-half by three inches, practically the whole of the left side of the face.

No further cutting was done, but by forcing lines of communication from one focus to another, by means of a director and probe, it was possible to reach the whole diseased area by injection with the syringe; and later the necrosed tissue was pressed out from the lower angle of the jaw through the opening first noticed.

His recovery was gradual. He was able to sit up for a while on November 30th, after which date convalescence was rapid, so that he was discharged well, December 3d. Almost no scar remained, and none which is not now covered by his mustache.

PUERPERAL ECLAMPSIA.[1]

BY T. E. CUNNINGHAM, M.D.

IT must be conceded, I think, that this is one of the most dangerous and alarming conditions to be met with in the practice of obstetrics. It destroys more lives than any other puerperal affection, in proportion to frequency. Statistics are not very reliable on this subject; but taking a moderate estimate, it probably occurs once in four or five hundred deliveries, with a mortality of about thirty per cent. for the mothers and fifty per cent. for the children, although some authors place it much higher.

In an experience of two thousand obstetric cases, eclampsia was encountered three times, twice at the commencement and once before labor, and all were primipara who were suffering from albuminuria. One of the patients was very dropsical; and owing to the difficulty of re-establishing the function of her kidneys, complications rapidly followed, which caused her death. The other two slowly but perfectly recovered; one has been delivered since of twins and enjoys good health, whereas the other, who was delivered last December, and apparently made a good recovery, is suffering from chronic parenchymatous nephritis, which, judging from a recent examination of the urine, is in the inactive stage. Two of the children were born dead, the other dying on the third day. This is not a very brilliant showing; and yet it would seem that, in the light of modern science and with the wisdom of the ages to guide us, one ought to be able to cope more successfully with this terrible malady.

Our literature is replete with theories relating to the mysteries which surround its etiology and therapy; but considering that the questions are still *sub judice*, we take up each new journal wondering what the next speculator will have to say. From the repletion and depletion theory of Hippocrates to the bacteriological theory of Gerdes is quite a lapse of time; but it requires very little knowledge to enable one to appreciate the clinical value of the ancient as compared with this modern view of the subject. From a study of the works of different authors and a limited bedside experience, it would seem that we are in possession of all the theories for the explanation of the obstetric phenomena. The difficulty all along appears to have come from trying to make one or two factors do what it takes several to accomplish. We have been taught so long to consider eclampsia as closely allied to albuminuria, that disturbance of functions, other than those of the kidneys, has received but indifferent attention until within a comparatively short time. It is not to be inferred that this is not an important factor, but that the renal affection alone rarely is sufficient to produce convulsions. It is only a part of a whole, a collective cause, the other parts consisting of pregnancy — usually the first — a watery condition of the blood, and high nervous tension. It is a matter of common observation that women looking forward to first motherhood suffer more from excitability of the nervous system and from emotional disturbances than they do in subsequent ones; and when it is realized that this state of things is kept up, perhaps for weeks, exhausting the nervous system and lessening the power of resistance, it is easy to conceive how favorable the conditions are for an explosion, particularly after the noxious elements begin to accumulate, through faulty elimination, whether it be due to pressure on the ureters, renal insufficiency pure and simple, hyperæmia, or acute or chronic nephritis.

The treatment of eclampsia is as varied as its etiology. For the sake of brevity the various means may be enumerated as follows: (1) chloral or chloroform, (2) morphine, (3) venesection or veratum viride, (4) induction of labor. Of course, other medication is called for, such as cathartics, diuretics, diaphoretics, cold to the head, sinapisms to the extremities, and proper conditions of temperature and ventilation, according to the special indications of the case. As the trouble may appear before, during, or after labor, an opportunity is offered for the exercise of good judgment in the selection of the right method or methods of treatment.

Owing to a lack of experience, the third class or post-partum form will not be discussed.

In the second class of cases, which is by far the most numerous, the consensus of opinion seems to be in favor of hastening delivery. I adopted this teaching in two cases of this class, but do not think I would

[1] Read before the Cambridge Society for Medical Improvement, May 22, 1893.

be so rash again, since nature will do the work much better than we can, if we only sustain her. It is taught that the os under these conditions is soft and dilatable; but it is not always so, and the time consumed in manual dilatation may be an opportunity lost. To allay nervous excitement and control spasms is of first importance; then the other conditions can be studied more leisurely, and the suitable means adopted to combat them.

The first patient was a plethoric young woman; and I think she might have been saved had bleeding been resorted to, since by this means the blood-tension of the cerebral vessels would have been diminished and prevented the extravasation that killed her. Routine treatment is as objectionable here as in any other department of medicine.

The second case was in an anæmic woman, with conditions just the opposite in every particular to the first; and if I had given her chloral, and waited for a natural delivery, she probably would have done better and given birth to a living child. As it was, her recovery was protracted, and much of the delay was due to unnecessary manipulation.

In the first class of cases, or ante-partum eclampsia, there are no pains, and labor may not be due for some time; and it is still a vexed question what are the best measures to adopt under these circumstances. The induction of labor is recommended by some who consider you are guilty of double murder if under these circumstances you question the procedure; whereas others, more conservative, recommend it only after all other means have failed. Lusk says, "The practice of waiting for nature proved uniformly disastrous, whilst the induction of labor furnished a certain proportion of recoveries."

Nevertheless, I took exception to this well-known teacher, and treated the third case on the expectant plan. There was an interval of a week between the first convulsion and the delivery; during the first twelve hours there were five convulsions, and the patient complained of severe headache, blurring of sight and nausea; the secretion of urine was diminished, with a specific gravity of 1,008, and contained one-half per cent. of albumen. The bowels had been constipated just before the first attack. The usual remedies for restoring the functions of the stomach, bowels and kidneys were administered; but as they did not operate by the time the fifth convulsion supervened, sixty grains of chloral were given, per rectum, with orders for half that amount to be given every four hours. During the next twenty-four hours the bowels were moved and the stomach settled; nourishment was taken, and, although she complained of headache, she was not nearly so nervous. The urine, collected after the convulsions, was chocolate-colored, had a specific gravity of 1,040, and solidified on boiling. The sediment, examined microscopically, showed renal epithelial cells, blood globules, and hyaline and granular casts. Five days from the time of the first seizure she had three more convulsions, which were controlled by large doses of chloral. In two days labor set in; as, at the end of the first stage, inertia threatened, Dr. Joseph Cunningham was called in assistance, an anæsthetic given, and the delivery of a living baby effected with forceps. The uterus contracted well, pulse 108, temperature 100°. The patient passed into a comatose state, and remained in it for four days. With the return of consciousness, it was found she was blind, and recognized her friends only by the voice. Sight returned in two weeks, and afterwards the convalescence was uninterrupted. The infant died on the third day.

Clinical Department.

A CASE OF FOREIGN BODY IMPACTED IN THE LARYNX.[1]

BY F. E. HOPKINS, M.D., NEW YORK,
Assistant Surgeon to the Manhattan Eye and Ear Hospital, Throat Department; Assistant Surgeon to the New York Eye and Ear Infirmary,

On the evening of October 10, 1892, J. R., an American, aged twenty-seven years, of slight physique and nervous temperament, sat at dinner, and while hurriedly swallowing his soup and at the same time eagerly discussing with his wife the best situation for viewing the Columbian fireworks, he drew into his larynx a piece of bone, which unhappily had been served him in his soup. The soup was made from a large beef bone, and contained chips of its cancellous structure.

There followed the usual spasm of the larynx, with the sense of impending suffocation. When he had recovered his breath a little, he attempted to dislodge the foreign body by swallowing water and then a bolus of soft bread. Failing to get relief, he called upon a physician, who, hearing the patient's story and seeing nothing in his pharynx, passed a bristle probang several times into his œsophagus. The doctor did not secure the offending piece of bone, but said it must have been driven downward into the patient's stomach. He attributed the continued pain in the larynx to the traumatism caused by the presence of the foreign body being dislodged.

The patient, although still hoarse and suffering local pain, continued to attend to his business — that of book-keeping. He, however, daily grew worse, and became so hoarse that it was difficult for those associated with him to understand him. There was increased cough and shortness of breath on exertion, and the effort to speak became more painful. When he came to me on the evening of October 15th, he complained of pain especially at the right side of the larynx, of hoarseness and of shortness of breath. He told me his story, saying that the bone had been removed, but so much pain and hoarseness remained that he feared he might be developing consumption or something equally serious. Upon examination with the laryngoscope the whole larynx was found to be congested. The left ventricular band was inflamed and swollen, concealing the vocal cord of that side. The right ventricular band was somewhat thickened, but less inflamed than the left. An ivory white body was seen upon the anterior half of the right vocal cord, extending during inspiration somewhat beyond the median line. The posterior half of the right vocal cord remained visible. The left ventricular band presented areas of superficial ulceration, since, with every movement of the larynx, it had been abraded by friction against the rough surface of the bone. In fact, because of this irritation, there was more apparent disturbance upon the left side of the larynx than upon the right, although the foreign body was impacted upon the right side. In spite of

[1] Read at a meeting of the Laryngological Section of the New York Academy of Medicine, December 28, 1892.

the evidences of irritation just mentioned, I was struck by the small amount of inflammatory reaction which had been caused by the bone, as it had been imbedded in the larynx a little more than five days. It is indeed surprising that so large and rough a body could remain so long in the larynx and provoke so little inflammation.

This remarkable tolerance of the larynx for foreign bodies is well illustrated by the case reported by Lennox Browne, before the British Laryngological and Rhinological Association on November 28, 1890. A plate of teeth had passed into the larynx during an epileptic fit in sleep and had remained in that position, unknown to the patient and unrecognized by any medical attendant, for twenty-two months. In the discussion which followed, Mr. Kendal Franks referred to a case of the impaction in the larynx, of a triangular piece of chicken-bone measuring on each side over one and one-quarter inches. It had remained in position twenty-three days; and the doctor says: "It is somewhat extraordinary that this piece of bone should have been in that position so long without being got rid of and without setting up more marked irritation." Sir Morell Mackenzie also in this discussion speaks of a case in which a piece of bone was impacted in the larynx for many months. He removed it, and the patient made a good recovery.

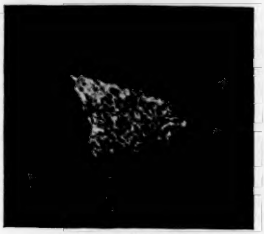
Ravenel, in the *Medical News* of March 21, 1891, reports — though on evidence which does not seem conclusive — a case of a pin retained in the larynx for thirty-eight years.

In view of such reported cases we might for a moment be led to think the condition under consideration, one of less gravity than we have been in the habit of regarding it, did we not know that in such a larynx dangerous œdema might be expected upon any added irritation, and had we not the evidence of the damage wrought by the presence of these foreign bodies, as in the case reported by the Chairman of the Section on October 22, 1889 — the case coming under his observation some time after the damage had been done. A tooth-plate measuring three inches in length and containing one tooth, fell into the laryngo-pharynx during a puerperal convulsion. It remained in this position sixteen days, and although it caused much local damage, including the destructive ulceration of the posterior third of both vocal cords, its presence was not discovered until the plate had been loosened by the ulcerative process.

We also have the statement of Mackenzie who, in his work on "Nose and Throat," says: "Sharp angular bodies of any size may cause very acute and constant pain when they become impacted so as to press against contiguous soft parts, and, of course, quickly give rise to a high degree of inflammatory reaction." He also says that "when a foreign body is impacted in one of the ventricles of the larynx it cannot generally be moved, and if it passes into both ventricles it will most likely require to be broken or crushed before it can be extracted." He refers to a case of a button-mould fixed in the left ventricle of the larynx, and extracted after six weeks by a laryngotomy. He reports a case of a man, "who while taking soup made from a sheep's head, suddenly felt choked by something going the wrong way. Examination showed a piece of bone lodged horizontally in the anterior portion of the larynx, just above the level of the vocal cords in such a manner that it completely blocked the anterior third. It could not be removed and symptoms being urgent a tracheotomy was done. The bone was then broken up and removed. It was found that it had been impacted in both ventricles. On putting the various pieces together, they made a lamina of bone three-quarters of an inch long and one-half inch wide. The long diameter had been across the larynx and about three-eighths of an inch in the right ventricle and rather less than one-quarter of an inch in the left ventricle."

Returning to the case in hand: after cocainizing the pharynx and larynx, I attempted the removal of the bone by the use of a probe bent into the form of a hook. The intruding bone stood out into the larynx with such enticing clearness, apparently just resting upon the vocal cord, that I thought it might be loosened by the probe, and the patient would then be able to cough it up. The probe grated over the projecting edge, making as little impression as it would drawn over the edge of a bowlder. I then used Mackenzie's forceps. The shape of the bone was such and it was so situated that it could not readily be grasped either by forceps closing antero-posteriorly or those closing laterally. Repeated attempts were required before it was possible to seize the bone at all, as the slightest irritation was followed by spasm of the larynx. Even when the foreign body had been caught by the forceps, it was so powerfully gripped by the contraction of the larynx, and the ragged edges of the bone gave the surrounding tissues so strong a hold upon it, that I feared to use too much force lest serious laceration should result. I did at one time lift with force sufficient to raise a weight of five pounds, without doing more than slightly to loosen the bone from its bed — so firmly was it impacted and so tightly grasped by the muscular spasm. Having loosened it, I directed the patient to take a slow, deep inspiration and then cough violently. As he did this, I had the satisfaction of hearing the bone strike the cuspidor.

An examination of the bone reveals in part the difficulty of its removal. It is of a pointed wedge shape, having a base one-quarter of an inch in thickness and one-half an inch in width and an extreme length of eleven-sixteenths of an inch. The dimensions are all a trifle greater than those given, as the sharp spiculæ extend beyond the general surface. When this body fell into the larynx, the sharp point entered the right ventricle, and was then driven deeply into the tissues by the spasm of the larynx provoked by its presence. I have tried to indicate by an ink line upon what was the upper surface of the bone, the extent to which it was covered by the right ventricular band. The portion from the line toward the base was visible upon examination. The outer side of the line is about one-half an inch from the point, and this is the extent to which it was driven into the ventricle. The right ventricular band, as already remarked, was but little swollen.



Some reaction followed as a result of the attempts at removal, and the patient slept none that night. This wakefulness was due principally to his mental condition, as he had become quite nervous about himself, and said he feared his throat would close if he went to sleep.

Two days later, on October 17th, the right cord was visible for its entire length. The left ventricular band was still much swollen, and presented two superficial ulcers at points which had impinged upon the

base of the bone. There was also a linear, vertical abrasion upon the right ventricular band, probably caused by the efforts at removal. The whole larynx was red and tumid, and the patient's voice was hardly as good as when first seen.

On October 22d, cords were both clear and intact, the ulcerations had healed, the left ventricular band was still somewhat swollen, but the patient considered his voice as good as ever.

For the accompanying photograph which gives a clearer idea of the foreign body than could be conveyed by any description, I am indebted to my friend Dr. W. P. Brandegee.

Following the report of the case, Dr. C. H. Knight, the chairman, remarked:

In connection with a report of foreign body in the larynx, I present a tooth-plate which was carried in the laryngo-pharynx of a patient for the period of sixteen days. The point of special interest which I desire to mention at this time is the fact of the reproduction of tissue on the part of the vocal cords and with it the restoration of function.

This case I reported to this Section on October 22, 1889, three months after the accident occurred. As a result of the pressure and erosion caused by the tooth-plate, the posterior third of both vocal cords had been completely destroyed — it looked as though it had been cut out with a sharp curette. In contraction of the laryngeal adductors the anterior portions of the cords approximated, leaving a wide gap at the post commissure, and the voice was only a whisper. It was my opinion at the time, and so expressed, that the impairment of the voice would be permanent.

Examination a year later, however, revealed a striking change. The scooped-out spaces on each cord had been completely filled in; and from the appearance of the larynx then, one could have no conception of the damage which had actually been suffered. With this reproduction of tissue there was restoration of function. The woman spoke with a clear, resonant voice, but of a lower pitch than before the accident — in quality it approached the voice of the male.

THE FIRST VACCINATION IN RUSSIA. — On October 26, 1768, the Empress Catherine II submitted to inoculation being the pioneer of the practice in her own dominions. The preparations for the novel function were most elaborate. The lymph was supplied by a boy of seven named Markof. This boy was ennobled under the fancy name of Ospiennyi (ospa = small-pox) and brought up under the Empress's own tutelage. His descendants occupy at the present day a prominent position amongst the Russian aristocracy.

A CASE OF HYSTERICAL HIP-JOINT SUCCESSFULLY TREATED BY HYPNOTISM.[1]

BY FRANK E. PECKHAM, M.D., PROVIDENCE, R. I.

THE case which I shall report this evening occurred at the Rhode Island Hospital, in the service of Dr. George D. Hersey; and I am indebted to him for the privilege of treating and also of reporting it.

The patient is a girl, eighteen years of age. The mother of this girl is a nervous woman, and during her younger days was subject to nervous crises which took the form of "crying spells," but she gradually outgrew them.

The patient had always been subject to "crying spells," having had them every day and often, several times a day; and was considered a very nervous child. When eleven years of age she fell over a stone wall. The foot and leg swelled, and she was laid up two months. There was complete recovery from this accident, and her usual good health continued until July, 1892.

On July 5th, while working in a woollen mill, having left her work to go across the room, she fainted away, and remained unconscious for a short time.

Upon recovering consciousness, a pail of water was standing beside her, which had probably been brought for the purpose of sprinkling her with cold water, and she at once came to the conclusion that she had stumbled over this pail. In falling, the right hip and side of the head, were injured; but patient was able to walk home. She remained in bed two days, and resumed work again on the third day.

There was no trouble from the hip until the last of August (about a month after the accident), when it began to be painful and tender, and to keep her awake at night. It was at this time that medical aid was first sought.

The hip was painted with iodine every night and morning for a week. This did not blister the skin, nor was any benefit derived. At another time a strong liniment was prescribed for the purpose of blistering. Her mother applied the liniment on herself, and the result was a blister; but on the patient it failed to act, and again there was no benefit derived from treatment.

In December she was carried to the Rhode Island Hospital, Out-Patient Department, was given medicine and advised to go home and remain in bed for ten days. She remained in bed for about a week, and at the end of the ten days returned to the hospital. There was some slight improvement. Patient could walk a little, but would fall after a few steps had been taken.

The pain was growing worse all the time. Unable to sleep at night, several "crying spells" every day, and in the latter part of December was totally unable to walk and remained in bed all of the time. The parents now gave up all hope of ever seeing her walk again. Various diagnoses had been made, namely, nervousness, fracture and hip-disease.

Finally, on April 24, 1893, she entered the Rhode Island Hospital as an in-patient in the service of Dr. Hersey. I saw her for the first time during the first week in May. She was thin and anæmic, and apparently of a very nervous disposition. On manipulating the leg she would groan continuously, but by distracting her attention and moving the leg before she was

[1] Read before the Providence Medical Association, September 4, 1893.

prepared for it, the muscular contractions were overcome and pretty free motion obtained. With the thigh flexed on the body and the leg flexed on the thigh, external rotation could be made slowly until the leg was nearly on a level with the body. With the patient lying flat on the chest there was no limitation to extension, both of which movements would be good tests for hip-disease. There was no crepitus on motion. There was no thickening around the joints. Placebos controlled pain, and produced sleep at night.

It was very evident, with the family history, and with the previous history of the patient, that the case was one of hysterical hip.

Having previously had success with hypnotism in other cases (of a different class, however), I determined to try this method of treatment.

The first *séance* was on Monday, May 8, 1893. I began by having a talk with the patient, in the presence of a third person, Dr. Perkins, the house-officer. I explained what I proposed to do, and told the patient that in order to be successful she must not oppose me in the least, and must do everything she was told. She was anxious to get well again, and promised to be obedient. I then proceeded to hypnotize, but was only able to obtain the first degree of somnolence: that is, patient remained with eyes closed and repeated after me everything she was asked. At this *séance* all the pain was made to disappear, and patient was told there was not going to be so much pain at night, and that she would sleep better.

May 9th. Slept better last night than any night since entering hospital. Complains of some pain. Again only the first degree of somnolence obtained. Pain caused to disappear, and told she was improving.

May 10th. Improvement continues; still some pain, but not enough to cause discomfort. First degree of somnolence again obtained, and the usual suggestions made.

May 11th. Did not sleep as well as usual last night. When house-officer made the evening visit, he found her quietly crying, "on account of the pain."

May 12th. Feels worse to-day than for two or three days, but is very obedient. The usual suggestions made.

May 13th. This was the sixth *séance*; and for the first time I succeeded in putting her completely under the hypnotic influence. She was told to remain asleep for a half-hour, and then to wake up and ring a bell which had been placed by her bedside. The bell was rung in about a half-hour, and patient said she had been asleep.

May 15th. Patient had now been hypnotized six days in succession, and I had steadily gained in the ability to control her. This afternoon, as previously arranged, I found the patient sitting in a wheel-chair. She was complaining of considerable pain and also of being dizzy. I was told by the house-officer that the last two days had been the worst since entering the hospital, and the pain had been so severe as to demand an anodyne. Not very encouraging certainly, after a week of treatment. Hypnotized in the chair. Pain and dizziness caused to disappear, and when all through said she felt perfectly well.

As prearranged, I found the patient dressed and sitting in the chair and feeling better than for two days. Hypnotized her, and told her to walk across the room. She opened her eyes and started across the floor. With the hand on her hip, she hobbled across the room, nearly falling two or three times. I constantly stroked her forehead, and supported her when there was danger of falling. After returning to the chair she looked very pale, but there was no groaning or expression of pain; and when the *séance* was finished, she felt perfectly well. This was the first time she had borne her own weight in about four months.

May 18th. Walked across the room easily, but there was considerable of a limp.

From this time there was constant improvement every day. Slept well and had nothing to complain of; but the limp remained.

To see her walk, it looked as if one leg was really shorter than the other; and upon being questioned, she said such was the case.

Consequently the legs were measured, both by Dr. Perkins and myself. The measurements being made over the clothes were, of course, not accurate; but we both made the leg longer than its mate, instead of shorter. Without making skin measurements I took advantage of this fact, and told her that the leg was a little longer, and that she really ought to limp with the other leg.

On May 26th, after being hypnotized in all eleven times, and having no subjective symptoms whatever, the patient was discharged cured; the only objective symptom being a very noticeable limp.

On June 2d, patient reported at the out-patient department looking very much better, not nearly so anæmic, and the limp only very slightly noticeable.

On June 9th, patient reported again without any limp whatever, feeling and looking perfectly well. At this time careful skin measurements showed the legs to be exactly equal in length.

In August, nearly three months after leaving the hospital, patient was in excellent health in every way.

I have reported this case in detail to show what hypnotism may do in these cases, even though at first they become apparently worse; and to show that hysteria, whether general or local, being a disease most intimately associated with the will and the mental faculties, may be treated through the same channels.

Reports of Societies.

CAMBRIDGE SOCIETY FOR MEDICAL IMPROVEMENT.

ALBERT H. TUTTLE, M.D., SECRETARY.

MEETING of May 22, 1893.

DR. S. E. WYMAN, of Cambridge, read a paper on

ANTHRAX FACIEI, WITH REPORT OF A CASE.[1]

DR. DRIVER: For some time anthrax was not uncommon in Dedham, where it occurred in mattress-makers. The first cases were nearly all fatal, later but few of them died. A patent smudge was invented for treating the hair before handling; and it was supposed that this destroyed the germs and was preventive of the disease. For the past five years not a single case has occurred.

DR. CLARK saw several of the Dedham cases and thought the disease took a retrograde action, the infection becoming less and less virulent until it finally exhausted itself. He thought one should accept the

[1] See page 413 of the Journal.

statement that the disease was contracted from well-cooked meat, with considerable doubt. The chances of a dirty cook contaminating articles of food after they are prepared for the table, as was long ago pointed out by Dr. Holt, are very great, and the cases attributed to the action of roasted bacilli can be more reasonably explained by this means.

DR. TUTTLE saw a case which occurred in the practice of Dr. Marcy in its later stages. Different specimens of the discharge were examined by Dr. Marcy and himself, that of the former contained the bacillus, whereas that which he examined contained only spores, a fact which shows the need of examining material from different parts of the lesion. The manner in which the disease extends in lines through the subcutaneous cellular tissue, in various directions, radiating out from the primary lesion, which usually remains small, much smaller than that of ordinary carbuncle, serves as a prominent feature in distinguishing the disease at a late period.

DR. MARCY said the patient above referred to went to Florida in full health, that a pimple developed on the left side of the face, near the nose, and ran rapidly through the stages already described, until when first seen by him on the eighth day of the disease, the whole side of the face, including both lips, the angle of the jaw and anterior temporal regions, and the orbit of the right side was involved and freely suppurating. The diseased area was cut and curetted, and large quantities of iodoform rubbed into the diseased tissues. One of the worst symptoms of the case was found in the urine which was loaded with albumen and contained casts.

DR. WYMAN, in closing, said that the disease did not run out in Russia, where it remained as virulent as ever. He also referred to Pasteur's method of attenuating the virus so that it could be introduced into animals, thereby producing immunity from the disease. Dr. Beach, of Boston, was the first in this region to inject antiseptic solutions subcutaneously for the cure of carbuncles, in 1888; but it has been done by the same method before him in similar conditions, using solutions of carbolic acid, however, instead of corrosive sublimate, by Dr. J. R. Jarnovski, of Vasilsursk, in 1876.

DR. T. E. CUNNINGHAM read a paper on

PUERPERAL ECLAMPSIA.[2]

DR. DRIVER: Six cases of eclampsia, all in his own practice, occurred during his first 1,000 deliveries. To adopt routine treatment was disastrous, yet it was frequently done by the young practitioner.

Case I was treated with chloral and morphine. The mother was unconscious for four days, during which time there was copious perspiration; but she finally recovered. In Case II, both mother and child survived. Case III was a breech presentation, and ended fatally. Case IV admitted three fingers in the os; and, following the rule to deliver when such is the case, both mother and child were saved. Case V died quickly. Dr. Driver thought, if bleeding had been resorted to, the patient might possibly have been saved. The abdomen was quickly opened, with the hope of saving the child, but without avail. The result of the remaining case was not recalled.

DR. HOOKER had two cases one of which remained unconscious four days.

[2] See page 410 of the Journal.

DR. BRYANT had seen a case where pain in the pit of the stomach, before the onset of convulsions, was a prominent symptom; and he had heard of a similar case in the practice of another physician.

DR. A. P. CLARKE had noticed that those cases where there was a great excess of albumen were apt to prove fatal, especially when complicated with retinitis and generally debility. He recommended the use of chloroform in these cases, since ether had a bad effect on the kidneys.

DR. A. H. TUTTLE had seen four cases, three in consultation and one in his own practice. The first was a multipara, in the practice of Dr. Norris. Manual dilation was begun at 7 o'clock, P. M.; but, owing to a very rigid condition of the os, it was not completed sufficiently to admit delivery until noon the following day. The mother made a good recovery, but the child died in a few hours. The second case was in a colored girl, a primipara, unmarried, and about seven months' pregnant. Medicines were given to restore the functions of the skin, kidneys and bowels; but the patient died comatose within twelve hours of the onset of the trouble. The third case was in the practice of Dr. Pidgin. She was a multipara, near term, whose urine had been examined several times for albumen during the pregnancy and just before the convulsive movements supervened, but with negative result. The os was easily dilated, and the child (alive) delivered with forceps, the mother making a good recovery. The fourth case occurred in the practice of Dr. Slayter. This was a multipara, of robust constitution, about six months' pregnant. Labor was instituted, and the patient made a good recovery.

DR. MARCY'S first case died. Two cases were saved, he thought, by bleeding, one where the convulsion occurred four days after delivery. In a fourth case, a primipara, there was rapid abdominal distention; and at eight months the urine contained casts and albumen. The artificial delivery of twins was performed, but both mother and children died. The autopsy showed fatty degeneration of the renal capillaries, with the presence of thrombi. In a fifth case, that of a young bride, eight months' pregnant, the urine was examined for albumen and casts, but negatively; yet the patient died suddenly three days later. He thought that most work in obstetrics was poorly paid for. The fee should be increased, and more time devoted to the examination of the urine and to the care of the patient during the whole period that the mother is carrying the child.

AMERICAN NEUROLOGICAL ASSOCIATION.

NINETEENTH ANNUAL MEETING, LONG BRANCH, N. J. JULY 25, 26 AND 27, 1893.

(Continued from No. 16, page 401.)

THE ANATOMICAL CHANGES IN THE SPINAL CORD IN AN OLD CASE OF INFANTILE PARALYSIS.

DR. JOSEPH COLLINS, of New York, presented numerous sections of the spinal cord, and reported the history of a case of infantile paralysis of long standing.

PROGRESSIVE MUSCULAR ATROPHY.

DR. C. M. HAMMOND, of New York, exhibited microscopical specimens, and gave the pathological report of two cases of progressive muscular atrophy, and

referred to the fact that considerable confusion is occasioned by the misapplication of the term "peroneal type" to a disease totally dissimilar to the one under consideration.

The first patient was a woman forty-six years of age, without history of gout, rheumatism or syphilis. In the fall of 1889 she stumbled over a chair, bruising the right shin slightly, and a few days afterward she was unable to walk as well as formerly. Soon after, there was marked weakness of the flexors of the foot and the extensors of the toes. By October, 1890, there was complete paralysis of the entire right leg, with reaction of degeneration, loss of power and electrical contractility of the anterior tibial muscles of the left leg, and atrophy and loss of power of the thenar and hypothenar muscles of the right hand. Gradually but rapidly the other extremities became involved, and ultimately the abdominal and intercostal muscles were affected. She died suddenly from either cardiac or respiratory paralysis. The sections of the cord showed sclerosis of the pyramidal tracts and atrophy of cells in the anterior horns, and degeneration of Gower's column throughout its entire extent. The conclusions to be drawn from the clinico-pathological study of this case would be that the muscles of the hand were supplied by the mesial group, and the muscles of the forearm from the anterior group of cells in the anterior horn. In the second case, seen in 1882, the disease only affected the muscles of the left thumb. He had the opportunity to watch the case to its termination, in 1893. It ran the usual course, and was in every way typical. At the time of death all of the muscles from the level of the arm-pits upwards, except the facial muscles, were atrophied, as well as those of the upper extremities. She became maniacal, and finally died from exhaustion. The cord and medulla were examined, and the changes were identical with those described in the preceding case.

He concluded that these cases demonstrate that progressive muscular atrophy is due to a degeneration of the cells in the anterior gray masses and the anterolateral white columns. Also, that it is superfluous to divide progressive muscular atrophy into different types, because the disease does not invariably begin in the same group of muscles.

The last two papers were discussed together.

DR. MILLS agreed with Dr. Collins's views as to the arrangement of cells presiding over the flexors and extensors. He suggested examination of the nerve roots at the extreme limit of the lesions.

DR. SACHS thought that such a careful pathological study would ultimately lead to better results than the usual clinical methods. That the Aran-Duchenne type was of spinal origin there could be no doubt, but he was not certain that the case of Dr. Hammond represented the peroneal form of progressive muscular atrophy, as described by Charcot, Tooth, Hoffman and himself. If the case were such, the findings in the spinal cord would have been of great importance. He was not yet certain whether the peroneal form represents a spinal disease or a peripheral affection.

DR. PUTNAM had a case in an adult where there was rapid destruction of gray matter throughout the cord. Despite the violence of the process, portions of the interior and lateral cell groups were preserved.

DR. PRESTON inquired as to alterations in the blood-vessels. He believed this was the primary alteration in the pathological changes. He also asked if Dr. Collins had examined cross-sections of the mixed nerves.

DR. GRAY thought it very difficult to make a positive clinical diagnosis between the central and peripheral portions of the lesion. This was often illustrated in the class of cases reported by Dr. Hammond.

DR. COLLINS, in closing the discussion, said that his investigations extended over greater ground than his paper suggested. There was diminution in the size of the vessels, but no evidence of atheroma. The mixed nerves were not examined. He thought the hæmotoxylon stain useless for a study of the cellular structure.

DR. HAMMOND concluded that the peroneal type was simply progressive muscular atrophy beginning in the peroneal muscles.

OPTIC NEURITIS, BLINDNESS, DEAFNESS AND THE KNEE-JERK IN CEREBELLAR DISEASE.

DR. F. X. DERCUM, of Philadelphia, read a paper with this title. He thought many of the symptoms of cerebellar disease were both inconstant and variable. They are difficult of explanation and frequently impossible to correlate.

He desired to call attention more especially to the optic neuritis, the blindness, the deafness and the modifications of the knee-jerks.

He related the history of seven cases in which the above symptoms were present.

It is a matter of common experience that very high grades of neuritis may exist without marked impairment of vision. It would seem, therefore, that the added symptom of blindness gives a special significance to the optic neuritis found in these cases. It would appear that for some reason if we have optic neuritis at all in cerebellar disease, that it is apt to be intense in character, and further that it is likely to be associated sooner or later with total blindness.

The proximity of the quadrigeminal bodies has naturally suggested itself as in some way explaining this blindness. The ataxia and titubation present in these cases refer us at once to disease of the vermiform process. A consideration of anatomy, as well as the autopsy of Case III, will show that if a growth be situated in the vermiform process, especially anteriorly, and that if this growth continues to enlarge, it will sooner or later press upon the superior cerebellar peduncles and very probably upon the quadrigeminal bodies themselves. When we recall the relation of the fibres of the optic tract to the primary optic centres, we can readily understand how if pressure or irritation occur at this point a neuritis should be a consequence. Further, the irritation being direct, we can, perhaps, understand why the neuritis should be of a high grade, and, finally, also why this neuritis should be associated sooner or later with total blindness.

With regard to the deafness which is present in some cases of cerebellar tumor, and which was absolute in Case III, it may perhaps be explained in a similar manner. The studies of Spitzka, Monakow and others have made it extremely probable that the posterior quadrigeminal bodies stand in the same relation to the auditory fibres as do the anterior to the optic fibres. It would simply be necessary, therefore, to our explanation that the pressure involve these structures, in order that deafness should be a symptom.

When we turn our attention to the knee-jerk, we meet with a problem of peculiar difficulty. It would

seem, that one would be justified in accounting for the loss of knee-jerk when observed in disease of the cerebellum by the loss of muscle tonus.

It is extremely probable that lesions of the cerebellum act as do lesions elsewhere, in one or two ways, that is, either by destroying tissue and thus destroying function, or by acting as irritants. It is perhaps in this way that we can account for the fact that in some cases of cerebellar disease the knee-jerk is absent, and in others present or exaggerated.

Dr. Gray hoped that Dr. Dercum's explanation of the symptoms would prove true, and asked if the pupillary reflexes had been observed.

Dr. Dercum replied that when the disease had advanced there was loss of reflex action to light.

Dr. Putnam spoke of a case of long-standing optic atrophy and practically no other symptoms. Although the optic neuritis persisted for two years, the autopsy showed a cyst and tumor of the cerebellum.

Dr. Preston asked if distinct loss of muscular sense existed in Dr. Dercum's case. He had noted this symptom in two patients. In four of his cases, the knee-jerks were irregular, disappearing and occasionally returning.

Dr. Knapp said that in all of his cases confirmed by autopsy, there was neuritis or optic atrophy. In one case where cerebellar tumor was suspected neuritis had not developed. Blindness had not been so constant. In another case the light reflex was lost when the pupils became dilated. Pressure on the corpora quadrigemina was most likely to produce blindness. He had never noted deafness. As to disease of the middle lobe of the cerebellum being responsible for the ataxic gait, he thought this view untenable.

Dr. Leszynsky, of New York, said he had observed a number of cases, two with autopsy. He thought the concomitant basal meningitis had much to do with the production of the optic neuritis, by extension of the inflammatory process along the nerve sheath. In many cases the neuritis was a late symptom. Where the neuritis or optic atrophy was accompanied by loss of light perception the pupillary reflex was always absent.

Dr. Dercum did not believe the neuritis due to pressure, but more dependent on the location of the tumor. In his cases the neuritis was always of high degree. Neuritis, blindness and deafness indicated pressure on the mid-brain. He would look for cerebellar symptoms where the knee-jerk was variable.

A NEW METHOD FOR THE REDUCTION OF DISLOCATION OF THE CERVICAL VERTEBRÆ.

Dr. G. L. Walton, of Boston, in reading a paper upon this subject, said that since the publication of sixteen cases previously coming under his notice, he has seen several of similar character, leading him to the belief that this condition is not rare, though frequently overlooked. Reduction by extension usually attempted is unsuccessful. Spontaneous reduction has occurred, showing that direction is more important than force. This fact led him to the discovery of the method theoretically correct, as shown by manipulation of the vertebræ, and by experiments upon the cadaver made by Dr. Richardson of Boston and himself. The method has been recently demonstrated in practice by Dr. Beach, at the Massachusetts General Hospital, with successful result.

In illustration of the method, suppose the left articular process of one vertebra has slipped forward over that of the vertebra below, and fallen into the depression anterior to the articular process. This bends the head to the left, and turns the face to the right. The reduction is accomplished by extending the head diagonally backward to the right, so as to elevate the articular process, after which rotation to the left replaces the displaced vertebra. The transverse processes on the right act as a fulcrum. The ligaments which hold the vertebra firmly in the false position make no opposition to this manœuvre, which requires no force. In bilateral dislocation the same movements should be made, first on one side reducing it to unilateral displacement, then on the other.

Dr. Putnam said that cases are more numerous than supposed, and cited the instance of a man injured by a fall, who died through carelessness in his removal to a hospital.

Dr. Sachs asked if this method would be practicable in other than recent cases.

Dr. Walton replied that the operation was performed in one case of about ten days' standing. A case in which bilateral dislocation was produced spontaneously, with perfect recovery, would lead him to recommend the attempt at reduction, even after a number of months, should there be no doubt as to the diagnosis.

SECOND DAY. — WEDNESDAY.

ACROMEGALY, GIGANTISM AND FACIAL HEMIHYPERTROPHY.

Dr. C. L. Dana, of New York, read a paper with this title, and reported the history of a case of acromegaly, with autopsy; also a case of gigantism, or somatomegaly, with some symptoms of acromegaly. The giant had a unilateral facial hypertrophy.

The first case was that of a full-blooded Bolivian Indian, who was exhibited as a giant. He was thirty years old; height six feet, seven inches; weight three hundred pounds. He had an enormous development of the malar and frontal bones. His thorax measured fifty inches in circumference. He died suddenly. On autopsy, the brain was found normal; weight fifty-five ounces. The pituitary gland was greatly enlarged, measuring one inch in diameter. Thyroid weighed four ounces. The feet and hands had increased in circumferential measurements. The brain presented interesting peculiarities of fissuration.

The second case was a professional giant, seven feet, five inches tall; weight three hundred fifty pounds; age nineteen years. His muscular development was feeble. He had several symptoms resembling those of acromegaly. His most curious condition was a progressive unilateral facial hypertrophy due mainly to osseous growth. It suggested an acromegaly attacking only half of one extremity. Only eleven cases of this affection are on record.

Dr. Dana said that acromegaly was sometimes associated with gigantism. He thought that many so-called giants were instances of pathological growth rather than excessive physiological development. There was much evidence to show that the pituitary gland had some function in these disorders. Among twelve autopsies, this gland was found enlarged in ten.

Dr. Dercum said that acromegaly is not associated with increase in the length of bones but in their width. He regarded Dr. Dana's case as one of gigantism with acromegaly superadded.

Dr. Gray considered it a question whether acrome-

galy and gigantism are not identical. We are still in the dark as to the pathology of acromegaly. He thought the cases presented did not warrant Dr. Dana's conclusions.

DR. COLLINS looked upon them as two separate diseases. In gigantism the changes are in the cellular structure of the diaphyses and epiphyses, principally the former. In acromegaly the changes are confined to the epiphyses. Probably the disease of the pituitary glands stands in proper relation to acromegaly. Much depends on the method of examination. He had destroyed the gland in animals to see if acromegaly developed, but all died. He thought giants may suffer from acromegaly, and regards it as a degenerative disease.

DR. BRILL, of New York, asked what structures in the brain were usually involved.

DR. COLLINS answered, the glandular structure of the pre-hypophysis.

DR. DERCUM expressed the view that as the other ductless glands are so often enlarged in acromegaly, to select a single gland as being enlarged seemed precipitate. No doubt the pituitary body may have important functions to subserve.

DR. PUTNAM said that investigators have destroyed the gland in animals, producing polyuria, thirst and debility. In view of the small number of autopsies, we cannot dogmatize. The gland was found normal in three out of nine reported cases. He had seen temporary improvement in one case under the administration of thyroid extract. We are dealing with abnormities of development, and cannot expect to discover lesions as the cause. In ten autopsies that have been made the thyroid was wasted in 77 per cent.

DR. SACHS was of the opinion that both conditions are related. Gigantism is a form of physiological excess while acromegaly is a distinct morbid condition. He did not attach much importance to the influence of the pituitary body, but thought our knowledge of the exact etiology and pathology is still in abeyance.

DR. WEBER, of New York, had seen two cases. One had symptoms of myxœdema. He was inclined to believe gigantism to be excessive physiological growth.

DR. MILLS had found at autopsy a tumor destroying the pituitary gland, but there was no acromegaly.

DR. DANA, in closing the discussion, said we did not know the functions of the pituitary gland in its relation to acromegaly, but it was certainly of some importance. He still believed in the clinical relationship between gigantism and acromegaly, but looked upon gigantism as an irregular type. He regarded gigantism as a pathological condition. The thyroid was not enlarged in his case, but the pituitary gland was.

THYROIDECTOMY IN THE TREATMENT OF GRAVES'S DISEASE.

DR. J. J. PUTNAM, of Boston, read a paper on the treatment of Graves's disease by thyroidectomy. After calling attention to the fact that this operation has been done some forty times, mainly by German surgeons, with but two deaths and a very large percentage of cures or improvements, the speaker narrated a case from his own experience.

It was that of a young woman suffering from a typical form of Graves's disease, of nine months' standing, and with a rather large goitre. The right lobe and most of the isthmus were removed .During and after the operation the patient's pulse ran up very high, and for several days she lay in an extremely prostrated and apparently critical condition. She then rallied; and now, at the end of six months, her condition is decidedly better than before the operation, though she is far from being cured. The remaining portion of the tumor has not shrunk, and still shows a marked tendency to vascular enlargement. The voice was reduced to a whisper under the immediate influence of the operation, but has now nearly recovered its natural tone. This is not an unusual occurrence.

Dr. Putnam analyzed the reported cases from the following points of view: the immediate and remote effects of the operation (including the mortality-rate after operation for goitres in general), the influence of the character of the tumor on the result, the degree and persistence of the improvement in favorable cases, the character of the operation.

Finally, the question as to the nature of Graves's disease, and the relation of the other symptoms to the goitre, was discussed. It was pointed out that this relationship was probably based on the fact that the thyroid has important vascular functions.

Strong emotions are capable of causing temporarily most of the symptoms of Graves's disease.

The reasonableness of the operation lies in the fact that in Graves's disease certain nervous centres are in a state of extreme irritability. Any means which will cut off a considerable number of excitations from reaching the unstable centres is likely to be beneficial by securing for them a partial, physiological rest. There are various means, such as complete rest, the treatment of the naso-pharynx, etc., which may do this in a measure, but no one means is so effectual as thyroidectomy. The operation, is, however, attended by a slight risk of death, and by a greater risk of considerable temporary prostration and laryngeal paresis.

DR. DERCUM had recorded the case of a man with all the symptoms of Graves's disease but the enlarged thyroid.

DR. WEBER had noted recovery in a patient possessing all of the characteristic symptoms, under the persistent use of iodide of potash. The dose was gradually increased to three drachms daily.

DR. E. D. FISHER thought it would hardly seem probable that in Graves's disease the enlarged thyroid can be considered as acting in a mechanical way in producing the symptoms. He had seen many cases in Canada, in whom apparently no symptoms were produced. These persons continued in their regular occupation without discomfort.

DR. PUTNAM, in closing, said that a large number of instances of goitre, without symptoms, had been reported with autopsies. Such children in particular had suffered from debility, and there was dilated right heart. He gave a *résumé* of our present knowledge of Graves's disease, both experimental and clinical. He concluded that we have not sufficient data to establish a physiological basis for the disease.

(To be continued.)

ECCE THYROID! — A correspondent writes to the *Medical Press* as follows: "Having been recommended to try the thyroid gland treatment for inveterate psoriasis, I ordered a thyroid gland from the family butcher. He says he knows 'what IT is because there is a demand for IT just now.'"

Recent Literature.

Appendicitis and Perityphlitis. By CHARLES TALAMON, M.D. Translated by E. P. HURD, M.D., pp. 210. George S. Davis. 1893.

Appendicitis, "the new disease," as the daily press is apt to designate it, has become a term both well understood by the physician and dreaded by the community. The numerous contributions to the literature of the subject during the past eight years form a mass of titles very discouraging to one who attempts to make a thorough investigation of what has been accomplished. It is, therefore, with gratitude that we call attention to this monograph which offers a substantial help to all who desire to acquire more than text-book information on this interesting and important subject. Dr. Talamon has no intention of giving merely an historical and analytical statement of what has been accomplished, but he is earnest in bringing forward certain personal views which will carry more or less weight. Some of them may be briefly referred to with the statement that they are given no undue prominence and form merely a part of the volume which is intended to represent a comprehensive consideration of the whole subject.

His theory of the origin of an attack of appendicitis is based upon the supposition that an intestinal concretion suddenly penetrates the appendicular canal and there gives rise to the incipient pain and subsequent disturbances. He believes that the concretions are formed in the cæcum, because they "are perfectly round." This statement is in opposition to the daily observations of elongated, oval, flattened or cylindrical concretions in the appendix, both in health and in disease.

The author apparently forgets that the hernial protrusions of the mucous membrane of the large intestine are not present in the cæcum and that when found, even in large numbers, in the usual site, the descending colon, they rarely produce any disturbance.

The important distinction is rightly made between a relapsing and a recurring appendicitis. In the former the intervals between the attacks are so short that the disease is always present; it is a chronic appendicitis with exacerbations and remissions. In the recurring appendicitis each recurrence takes place after an interval of months or years of freedom and has all the characteristics of the original attack.

It is in this connection that the author's consideration of appendicular colic is so important. This symptom has often led to the diagnosis of an acute appendicitis, to an immediate operation and to the extirpation of an appendix free from any obvious anatomical change. The mistaking of appendicular colic for perforative appendicitis should be the bugbear of the surgeon as its opposite should be the dread of the physician. According to Talamon "chronic relapsing appendicitis is rather an infirmity than a malady menacing to life."

The treatment of appendicitis should depend upon the belief in an existing or threatening perforation. Our author says that in the immense majority of cases our knowledge as to the presence or absence of the perforation is made clear by the third or fourth day. He believes, however, that it is almost impossible, during the first week to decide with certainty upon the presence of pus. Hence the surgeon should not be called for till the seventh or eighth day. This rule, however, is not absolute as he recognizes the importance of considering each case by itself.

"*Theoretically*, surgical interference is indicated as soon as the diagnosis of perforative appendicitis is made. *Practically*, this interference should be immediate in the forms attended with peritonitis which becomes general from the outset. . . . It ought, in our judgment, to be put off till the eighth or twelfth day in the forms with partial peritonitis, as the diagnosis of suppuration cannot be made certain during the first week, and the chances of recovery seem to us the greater the more thoroughly the purulent collection is encysted."

It is satisfactory in a book written by a foreigner to find the author more than willing to show an appreciation of the work of American physicians and surgeons in redirecting attention to the appendix as the frequent cause of serious and fatal disease. His monograph bristles with American names and full credit is assigned for their work.

Dr. Talamon has given an admirable statement of our present knowledge of the subject, and Dr. Hurd is to be complimented on the excellence of his translation. If the volume had been better published, its cost would have interfered with its usefulness.

The Law of Cremation; An Outline of the Law Relating to Cremation, Ancient and Modern. By AUBREY RICHARDSON, Solicitor. London: Reeves & Turner. 1893.

The primary and special purpose of this book is to state in explicit terms the legal status of cremation in the various civilized countries where it is practised, and the regulations which have been instituted to govern its administration. The work is something more than this, however, for it gives a concise history of the whole subject, showing the widespread adoption of the funeral pyre by the earliest nations of antiquity for the disposal of their dead, the distinct influence of Christianity in opposing the custom and in favoring inhumation instead, and the more recent reaction toward a return to the earlier practice of incineration, but with greatly improved methods and ampler safeguards. The regulations which have been ordained by various governments, or by the cremation societies themselves, to reduce to the lowest terms the possibility of destroying evidence of crime when a dead body is incinerated, are fully set forth and appear to be in every instance entirely adequate. The volume is a seasonable and interesting contribution to the literature of the subject and will prove particularly acceptable to those who advocate the reform which cremation is designed to bring about.

The Throat and Nose and their Diseases. With 120 illustrations in color, and 235 engravings by the author. By LENNOX BROWNE, F.R.C.S.E., Senior Surgeon to the London Throat and Ear Hospital, etc. Fourth edition, 734 pages. Philadelphia: Lea Brothers & Co. 1893.

The fact that the third edition of this book was so soon exhausted that it has been out of print for nearly two years is sufficient indication of its popularity.

The principal additions in this edition are in the chapters on nasal deformities, and on the membranous affections of the mucous membranes. The number of pages has not been increased, and the book will undoubtedly still hold its position as a safe and practical text-book, well arranged and of convenient size.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 26, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PHYSIOLOGICAL CHEMISTRY AS A PART OF MEDICAL EDUCATION.

IN a paper read before the Section in Pedagogy of the Pan-American Medical Congress, Prof. R. H. Chittenden makes an earnest plea for a more thorough training in physiological chemistry as a part of medical education. Biological studies are the essential substructures on which the study of medicine rests, for the profession demands at present, men, not alone trained in the art of medicine, but of high intellectual attainments, of broad and scholarly habits of thought and observation, and endowed with the power of logical reasoning. No training is better fitted to educe these traits than the careful study of biologic processes — not by the reading of books or lecture-notes, but by actual observation and appreciation of the processes as seen in laboratory work. The important and close relation of biology to medicine is more appreciated every year; and each year the common changes of animal and vegetable processes are found to depend upon definite and fundamental chemical formations.

At present the study of physiology in many medical schools is incomplete. It consists mostly of muscle and nerve physiology, with demonstrations of blood-pressure and kindred experiments designed to illustrate mainly the mechanical side of physiology. Important and needful as this is there is another side of physiology which, in this country, has not been cultivated as it should be — namely, the chemical side of physiology, or physiological chemistry. It deals with quite a different series of problems from those pertaining to so-called pure physiology, but they are as fundamental, if not more so, than any other single line of physiological work.

Physiological chemistry means more than the mere application of chemical analysis to a determination of composition, it is the study of the processes of functional activity going on in the body. "The unsymmetrical development in medicine, especially of the last twenty years, by which the sovereignty of morphology has been attained, giving undue weight to anatomical methods of investigation, has reached its climax, and the clinicians even are now looking to physiological chemistry to aid them in unravelling many of the hidden processes of life, thus hoping to gain clews to clearer methods of diagnosis and more rational lines of treatment."

As the teaching of medicine has become each year more clinical and direct, so should the study of physiology, particularly in its chemical relations, be taught by practical laboratory work in small sections, each with a trained instructor. A course, to be worthy the name, should extend at least through six months, with an average of fifteen hours of laboratory work a week. Such a course can be advantageously taken only by men who already have knowledge of general, analytical and organic chemistry, physics, anatomy and histology, together with more or less familiarity with general physiology.

To the plea that medical students cannot afford so much time for a study only indirectly connected with medicine, Prof. Chittenden replies that the time is well spent, especially at present, when there is need of more properly trained physicians rather than of men holding diplomas of medicine.

The details of such a course will vary with the instructor; but the more thorough and general the work, the better for the student. The various albumens and their changes and decomposition products, the reactions and composition of muscular tissue, "in nerve tissue the chemical characteristics of the various elements and the chemical differences between the gray and white matter, are to be noted; the neuroglia, neurokeratin and brain proteids are studied, while chemical and anatomical relationships are compared in this as in all other tissues examined." In digestive and excretory functions, the range of study opened is wide and directly applicable to the practice of medicine. Such laboratory work is perhaps best accomplished before the student begins his medical course proper.

"But the medical school itself can well afford to establish a thorough course in this subject; indeed, no medical school at the present day can afford to be without such a course of study if it hopes to rank with the leading institutions of the land, or aims to provide instruction of the highest and fullest type."

MAY TYPHOID FEVER ARISE *DE NOVO*.

DR. HUBERT WORK, of Pueblo, Col., writes to the *Medical Record*, September 9, 1893, his experience with typhoid fever on the cattle ranches of Colorado. He has known severe outbreaks of this disease under circumstances where he believes a *contagium vivum* could not be traced. At the same time, pollution of the drinking-water seems in all cases to have been a factor. In one instance, twelve persons in one locality took the fever in a grave form; all these had used drinking-water from a well adjoining a pit in which a quantity of decaying vegetables, a dead cow, etc., had been buried. In other instances the well

water was known to have been contaminated by the washings of manure heaps. In two cases, typhoid fever was contracted after eighteen months' residence on a newly-located ranch; the water-supply, reported as good, was taken from new wells fifty feet deep.

Dr. Work is inclined to reject all modern germ theories of typhoid fever and to commit himself to the belief in the *de novo* origin.

The Eberth bacillus has now been found too constantly present in the fæcal matters, intestinal lesions, spleen, etc., of typhoid patients to render probable the theory of accidental concomitance, and had Dr. Work been able to search for these organisms in the cases he reported, he would doubtless have found them in abundance, if they were genuine cases of typhoid and not merely cases of septic fever. Without such an examination and without autopsies, the diagnosis itself must remain in some doubt.

Dr. W. R. Cushing, of Dublin, Va., relates a similar case[1] of a patient living on a mountain side remote from other people, who was said not to have been out of the neighborhood for weeks, who breathed the purest of mountain air, drank from a mountain spring, where the drainage was apparently perfect. The case was a solitary one, no other member of the family was attacked, although using the same water, etc.

Whether Eberth's bacillus is pathogenic, may not be regarded yet as absolutely proved, although the evidence that it is the essentially procuring cause of typhoid is sufficient to convince nearly all pathologists. The bacillus produces a toxine to which the specific symptoms are believed to be largely due. There is increasing proof that this bacillus is propagated in drinking water, and that it develops in decaying vegetable and animal matter, in sewage, etc. Where it originates is a question applicable in common to this and all other forms of life, and one which is not yet solved.

It is now almost axiomatic that no living contagion arises *de novo*. In what preëxistent form, then, does the typhoid bacillus live?

Some bacteriologists at one time entertained the opinion that the Eberth bacillus is identical with the bacillus coli communis which it morphologically resembles. The latter is under ordinary conditions an habitual, harmless inhabitant of the intestines, only manifesting malignancy and becoming pathogenic in circumstances of impaired and lowered vitality. The ingestion of decaying, putrefying substances in water or in food offers one of the conditions of the development of virulence. Though the Eberth bacillus be not identical with the coli communis, it has been suggested that it may yet, like the latter, be a normal inhabitant of the intestines, ready on suitable occasions to become virulent. It is now known that the pneumococcus inhabits normally the saliva of many people, and the pyogenic streptococci and staphylococci have been found in the mouths and other mucous passages of persons in health.

Isolated instances of apparently autochthonous typhoid fever have not infrequently been observed and reported in the past, and will continue to be in the future. In regard to some there is legitimate doubt about the diagnosis; in regard to others the fact that the connection between the one case and a preceding case was not traced, cannot be regarded as sufficient proof that it did not exist. But, however that may be, a *de novo* origin is the least philosophical refuge from the recognized absence of exact knowledge at certain points. We as yet know very little of the life habits of most of the pathogenic bacteria.

[1] Record, October 14th.

MEDICAL NOTES.

Sir Andrew Clark Paralyzed. — Sir Andrew Clark was striken with paralysis October 19th at his residence in London. He was talking with a patient when he suddenly fell to the floor insensible. Later in the day he partially recovered, but much anxiety is felt regarding him. On the 18th he presided at the Royal College of Physicians during the Harveian oration.

Legal Effect of Pregnancy on Damages. — The Supreme Court of Wisconsin has ruled that when a married woman sustains a personal injury, and her physician does not caution her to avoid pregnancy, and there is no evidence that her injury was such that he should have done so, her pregnancy occurring after the accident, even if it prolong her injury or delay her recovery, is not necessarily, and as a matter of law, sufficient to justify a reduction of damages.

Alvarenga Prize of the College of Physicians of Philadelphia. — The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1894, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1894. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within it the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

A Physician's Bequests. — The late Professor Olivieri, of Naples, left a very large estate which he had acquired from his practice. By his will he made several most munificent bequests: to the Naples Blind Asylum $40,000; to the Pellegrini Hospital $60,000 and his instruments; to his friend and pupil, Dr. Mottola, who attended him in his last illness, he left $20,000.

HEART DISEASE. DISEASE. — A French physician calls attention to a new remedy, the result of accidental, among many experiments, which is the use of a supposed to be cast absorbent of a cardiac stimulant, followed by active stimulant of the heart. These remedies have been employed in the treatment of angina, and have occasionally given complete relief which is usually recognized in the history there for. The patient is ordered to abandon tobacco and to take abstinence of a diet.

JEWISH METHOD OF SLAUGHTER. — Considerable interest has been aroused in England over the method employed among the rabbis of Israel in killing beef, according to the Jewish ritual. Recently the Jews has in London [illegible] a petition against the considerable use of the new knife which is in use in the Jewish method of slaughter, called a [illegible] knife. It is claimed that the animal which [illegible] suffers [illegible] seen. Lately [illegible] testimony has given has the Jewish method has [illegible] and has a method that has been [illegible] Allen, [illegible] and other [illegible] the difference [illegible] among the sheets, has the charge [illegible] rabbis [illegible].

BOSTON.

RELAPSE AND NOT YELLOW FEVER. — The steamer Alpheus arrived in Boston from Progreso, Yucatan, on October 9th with sheets of her crew ill with what was supposed to be yellow fever, as has been reported in Boston when the vessel reached her wharf. Two men on her in the voyage. She was immediately on the sea in quarantine. No other cases have been reported. It is supposed to be relapse of yellow fever was taken in the vicinity of West Street, as in these the appears to have been malaria.

SCARLET FEVER AND DIPHTHERIA. — Since the 1st of October there has been a large increase in the number of cases of scarlet fever and diphtheria, reported to the corresponding number as month. While 18 and 17 now be urged number of cases of diphtheria, while Wards 15, 17, and 19 have no cases scarlet fever. The number of cases fever cases for the whole of the month was 173. From October 1st until the 9th the number is 167. Of diphtheria there were 9 cases in September. To the 9 October, 102 cases are entered in the ward of health's books.

REMOVAL SERVICE. — A removal service in the [illegible] of the late Dr. Hedges was held in the Boston City Hospital on Sunday afternoon. About two hundred persons were present, including members of the board of trustees of the visiting staff and the present members of the house staff, nurses and others, as well as the immediate family of Dr. Hedges. The service, which was conducted by Rev. P. S. Allen, consisted of address by Dr. D. W. Cheever, Dr. E. W. Taylor and Dr. Howe, singing of a quartette and the reading of a poem by Whittier by Miss Thaxter.

NEW YORK.

SMALL-POX. — From January 1st to October 7th, 81 cases of small-pox were reported in the city. Seven cases are recently developed on Blackwell's Island, and all the inmates of the institutions there have been vaccinated. Throughout the city vaccination is being carried on, among various classes of the community, to a large one has the Board of Health as ever before attempted.

PHYSICIANS TO CONTAGIOUS HOSPITALS. — Drs. W. H. Nettleton, S. T. Armstrong and Albert T. Sinnott have been appointed to be [illegible] to the hospitals where contagious diseases are treated. It is announced has the Board of Health will establish [illegible] in the Riverside Hospital on North Brother Island for the use, under suitable precautions of advanced [illegible] and [illegible]. All the various contagious diseases will be treated here except typhus fever, be large [illegible] which a separate is so great.

DEATH FROM SWALLOWING A SPONGE. — During the performance of an amputation of a foot at St. Joseph's Hospital, October 8th, the patient died of asphyxia [illegible] by swallowing of a piece of sponge. On account of the accumulation of [illegible] it was almost impossible to [illegible] as, and while [illegible] the sponge [illegible] was [illegible] from the [illegible] and was swallowed. After a [illegible] attempt to extract it, tracheotomy was performed, but this also proved [illegible] to [illegible] life.

Miscellany.

DR. REEVES AND THE "LEPROSY CURE."

THE courage of Dr. Reeves is really astounding. He knows the consumption merits the approval of all honest persons. The return of the grand jury [illegible] all [illegible] that will have the effect of restraining [illegible] evil [illegible] still pending. The career Dr. Reeves has shown to the cause of [illegible] deserves the support of the whole profession.

At a meeting of the Philadelphia County Medical Society held October 8, 1887, the following preamble and resolutions were unanimously adopted.

Whereas, Dr. James B. Reeves of Chattanooga, Tenn., having announced [illegible] "leper," under the "consumption" [illegible] and [illegible] that is responsible [illegible] of [illegible] to [illegible] and [illegible] of criminal [illegible] and *Whereas*, he [illegible] has published [illegible] and

Resolved, That the Philadelphia County Medical Society condemns Dr. Reeves as [illegible] and immoral [illegible] on the [illegible] and [illegible] the [illegible] to which he has been subjected.

Resolved, That the action was taken [illegible] of advertising a cure [illegible] that is to say, a [illegible] the composition [illegible] which [illegible] and [illegible]

a physician in good and regular standing; because such action is *ipso facto* sufficient to work forfeiture of membership in this or any other county medical society governed by the laws of the American Medical Association.

Resolved, That a copy of these Resolutions, duly attested with the signatures of the President and Secretary and with the Seal of the Society, be forwarded to Dr. Reeves, and that they be handed to the press for publication.

De Forest Willard, *President.*
T. B. Schneideman, *Secretary.*

A NEW DIAGNOSTIC SIGN IN TYPHOID FEVER.

Dr. Filipovich, of Odessa, calls attention to a hitherto unmentioned sign which he has observed in all the cases of typhoid fever under his care during the last two severe epidemics of typhoid in Odessa.[1] It consists in a peculiar callous appearance, of an orange or saffron yellow color, upon all the prominent portions of the palms of the hands and plantar surface of the feet, taking the place of the rosy appearance of those parts in health or the bluish tinge seen in cyanotic patients. This condition is explained by the feeble heart-action, the incomplete filling of the capillaries and the dryness of the skin in typhoidal patients.

In view of its constant and well-marked appearance in all the cases of typhoid under observation, Filipovich thinks it may well serve as a diagnostic sign of typhoid fever, in the absence of other pathognomonic signs.

Dr. Skibnevsky has also observed the constant appearance of this palmo-plantar sign during an epidemic in Moscow. The sign disappears rapidly on the establishment of convalescence.

PERSISTENT SINGULTUS RELIEVED BY LAVAGE OF THE STOMACH.

Two interesting cases of persistent singultus have been reported recently by Gallant [2] and Coleman,[3] in which other remedies failing immediate relief was obtained by washing out the stomach. The first patient, a man aged twenty-three years, after an attack of acute indigestion began to hiccough on the evening of May 29th. The paroxysms were frequent and continued for the two following days except during sleep. A saline and the administration of small doses of cocaine gave relief for two days, when the paroxysms began again and continued until the afternoon of June 6th, when the stomach was washed out with three quarts of warm water. The singultus at once ceased, and did not return.

Coleman's patient was seventy years old, and the hiccough had resisted household remedies for several days, and had been unrelieved by musk, bromides, chloral or opium. Hiccoughing continued under profound narcotism, and when the patient was seen at the end of the ninth day he was exhausted and oblivious of his surroundings. The stomach was washed out, the current bringing back no food but a quantity of dark tenacious mucus, with patches of separated mucous membrane, very much thickened. The singultus ceased immediately and the patient rapidly recovered.

Gallant, in reviewing the literature of singultus, found no previous mention of this method of relief.

Correspondence.

LETTER FROM CHICAGO.

World's Fair Congress of Public Health, and Meeting of the American Public Health Association, October 10–14, 1893.

Chicago, October 15, 1893.

The meetings of these organizations, just closed, were jointly held in the Art Institute in this city, beginning on the morning of Tuesday, October 10th. It was at first intended to begin the sessions on Monday; but the overpowering interest attendant upon Chicago Day at the Fair, not only prevented an early beginning, but very largely affected the attendance at all the meetings. The average attendance at the meetings was not more than one hundred and fifty, and there were scarcely any delegates or visitors present from transatlantic countries, so that the meetings could in no sense be called international. The meeting in Mexico last year, however, had created an unusual interest among the Central American Republics, and a large number of physicians who were present at the Pan-American Congress at Washington, visited Chicago, and remained to attend this meeting. More than one-third of the papers presented were by Central and South American delegates.

The meeting was organized at 10 A. M., as a meeting of the World's Fair Congress of Public Health, and was opened with a brief address by Hon. C. C. Bonney, President of the World's Fair Congresses.

He was followed by a further address of welcome by Mrs. Charles Henrotin, Vice-President of the Woman's Branch of the World's Congress Auxiliary.

In the absence of Mayor Harrison, Dr. A. R. Reynolds, Health Commissioner of Chicago, gave a brief address.

Dr. E. Liceaga, President of the Superior Board of Health of Mexico, then addressed the Congress in Spanish, his translated remarks (in English) being distributed among the audience.

Mrs. Dr. S. H. Stevenson spoke briefly of the importance of individual attention to hygiene as one of the essential elements of success in public sanitation.

Dr. Durgin, of Boston, President of the American Public Health Association, then gave his inaugural address upon "Municipal Sanitation," which was a practical address embodying the results of twenty years long and useful experience as Chief Health Commissioner of Boston.

WEDNESDAY, 10.30 A. M.

Dr. Gihon, Medical Inspector, U. S. N., presented the Report of a Committee on "Sanitary and Medical Service on Emigrant Ships."

Dr. Gihon also read a paper which had been sent by Sir Joseph Fayrer, of London, entitled "Tropical Diarrhœa." The paper was devoted mainly to the therapeutic phase of the subject and not to the preventive treatment. His description corresponded quite closely to that of the diarrhœa which affected many of the troops engaged in the Civil War (1861–65), and which, if the records of the Pension Department may be credited, still continues to affect them. Dr. Fayrer very strongly commended a milk diet in the treatment of this disease, the milk to be used in liberal quantities.

Prof. W. T. Sedgwick, of the Massachusetts Institute of Technology, presented the subject of the "Origin and Dissemination of Typhoid Fever," in which he gave his experience in the investigations of several epidemics of typhoid fever, which had occurred in Massachusetts during 1891 and 1892. He illustrated the subject by means of elaborate maps, diagrams and heliotype illustrations. The principal conclusions to be drawn from his paper were, that a pure water-supply, a pure milk-supply, and careful attention to personal cleanliness in the management of this disease, were essential to its prevention.

WEDNESDAY. — AFTERNOON SESSION.

Mr. Allen Hazen, Chemist at the Lawrence Experiment Station of the Massachusetts State Board of Health, contributed a paper on the "Sewage-Disposal Problem in

American Cities." His paper was devoted to the rapid development of sewage-disposal in American cities, the different methods employed, and the sewage-disposal of the World's Fair (of which a more definite statement will be given in the report of Friday's proceedings).

Dr. U. O. B. Wingate, Health Commissioner of Milwaukee, gave an interesting description of the experience of that city in the "Collection and Disposal of Animal and Vegetable Waste." After several experiments in the cremation of garbage within the limits of the city, the city authorities now conducted this work at a distance of fourteen miles, the garbage being conveyed to the place of disposal in boats, by means of tight iron tanks.

Col. W. F. Morse described the process of "Disposal of the Garbage and Waste of the Columbian Exposition." All the offal of the restaurants and grounds is collected daily and conveyed to the Engle cremator near the southern border of the Exposition, where it is burned by fire.

Dr. J. Wright Mason, Medical Officer of Health of Hull, England, contributed a paper on "Cholera and its Management in Hull," a timely and practical paper written during the progress of the epidemic.

Hull is a seaport city of 290,000 inhabitants. It was visited by cholera in 1832 and 1849. In the latter epidemic one out of every 43 were attacked by the disease and 600 died. Impure water was the probable cause. At present the water is derived from wells bored in the chalk, and the other means of prevention consist of an efficient hospital for the isolation of infectious diseases, disinfecting stations, public baths, mortuary and garbage destructors, together with a system of notification of infectious diseases.

As important aids in the public management and control of the epidemic, Dr. Mason commended a cordial co-operation of the physicians, who were requested to report first cases promptly. Supplies of diarrhœa mixture were issued by the health authorities. Hospital accommodation, tents and ambulances were provided for all who should require them.

The following principles were laid down as essential to the sanitary welfare of seaport towns in regard to the possible importation of cholera.

(1) The medical inspection of vessels from infected or from suspected ports. Only the healthy should be allowed to land and these under careful supervision. Vessels should be carefully and thoroughly disinfected.

(2) The most careful attention should be given to the sanitary care of cities during the intervals between epidemics, and preparation should be made in anticipation of such epidemics, rather than during their actual existence.

A brief description of the first cases which occurred in Hull in the present epidemic was also given by Dr. Mason.

On Wednesday evening, Dr. Sternberg, Surgeon-General, U. S. A., gave a lecture upon "Pathogenic Bacteria," which was fully illustrated by micro-photographs shown by the stereopticon.

THURSDAY. — MORNING SESSION.

Dr. H. P. Walcott presented, for the Committee on National Legislation, a resolution to the effect that the American Public Health Association strongly urges upon Congress the importance of having some officer appointed by the General Government whose whole time shall be given to the supervision of the general sanitary work of the country, and that he should co-operate with the health organizations of the different States. This resolution was adopted.

Dr. Salmon, Chief of the Bureau of Animal Industry at Washington, presented a paper on "Tuberculosis and the Food-Supply," in which he stated that infected food was an important factor in the production of tuberculosis in man. He advised the inspection of all milch cows and of animals intended for slaughter.

Dr. M. Carmona y Valle, of Mexico, gave a paper on "Syphilitic Infection as a Vehicle of the Communication of Tuberculosis." He illustrated the subject by five cases which came under his personal observation. Ulceration of the throat, in his opinion, played an important part in such infection.

Dr. F. Gutierrez, of Mexico, read a paper upon the "Influence of Habitations upon the Propagation of Tuberculosis." He stated that the ratio of mortality from phthisis in Mexico to the total mortality was only six per cent., as compared with nearly twelve per cent. in the United States. He believed that the dryness of the air in Mexico was favorable to a diminished death-rate from phthisis, while the want of good ventilation, the absence of sunlight, the use of artificial light and the increased heat in the interior of hotels and dwellings in the United States, all favored the spread of the disease.

The poor in Mexico are poorly fed and have poor dwellings, but they have abundance of fresh air and sunlight and are comparatively free from phthisis.

These papers on tuberculosis were followed by an animated discussion.

Dr. Flick, of Philadelphia, opposed the theory of transmission by means of food infection as well as by means of syphilis. He believed that infected habitations were the chief source of transmission, and that such dwellings should be disinfected.

Dr. Orvananos, of Mexico, said that altitude was probably an important factor in producing immunity among the Mexican population.

Dr. Salmon expressed his opinion that the liability of taking the disease depended very considerably upon the number of germs received into the system, and that, in the case of milk, a point might be reached, where the dilution and consequent diminution of the number of germs would render them harmless. He thought that the enormous expense attendant upon the destruction of all infected animals would render such a practice impracticable. He would, however, advise a careful inspection, to ensure the prevention of the sale of infected meat.

Mrs. E. H. Richards, of the Massachusetts Institute of Technology, presented an excellent paper on the "Prophylactic and Therapeutic Value of Food."

Dr. Contraros, of Pueblo, Mexico, read a paper entitled "The Hygiene of Hair-Dressing and Barber-Shops." He referred to the possibility of the transmission of infection not only from the barber to his patrons, but also, through the medium of the barber and his utensils, from one patron to another. He specified the principal parasitic diseases of the hair and of the scalp, which are liable to transmission, and advised that all implements used by barbers should be sterilized by heat after being used in every instance.

A paper by Dr. Ernest Hart, "Objects of the National Health Society of London," was read by title.

(To be continued.)

"THE MISUSE OF DRUGS IN MODERN PRACTICE."

A REPLY FROM THE PAPOID COMPANY.

NEW YORK, October 19, 1893.

MR. EDITOR:—Our attention has been called to an article on page 239 of the Boston *Medical and Surgical Journal* of September 7, 1893, in which the author, under the caption of "The Misuse of Drugs in Modern Practice," describes and deprecates the methods of the modern pharmacist who has departed from the modest practices of his predecessors and "no longer contents himself with providing the profession with the drugs which its experience approves." Now "He aims to direct the medical art. He proclaims the virtues of new drugs, ignoring their dangers. He vaunts the superior qualities of his own wares. Imitating the business methods of his quack rivals, he scatters his circulars broadcast among the profession, containing promises of cure and certificates of results which would do credit to the advertising agents of the rival sarsaparillas." "His agents . . . enter our offices with the assurance of 'drummers' in a country grocery." "Samples are spread upon our tables." "We are told . . . that if we do not wish to be behind the times we must also give them an order." "Their medicines are always successful." They "have no use for unsuccessful cases." The writer, however, does not wish to be "understood as condemning all

advertisements of drugs." "There are some firms whose publications are always welcome." As a specimen of reprehensive therapeutic literature, the writer of the above quotes several sentences from a recent pamphlet issued by us, entitled "Papoid Digestion," and thus by inference places us in the category of quacks and nostrum venders. As this inference is totally at variance with the facts as they exist, we feel that it is not asking anything beyond the limit of fairness if we request you to kindly publish our response to your readers.

In papoid we represent a definite pharmaceutical product, the properties of which are not, so far as we are aware, possessed by any other drug thus far placed before the medical profession. Kindly permit us to say that in advertizing this product it is our province, as chemists, to state chemical truths concerning it, and we have done so in the briefest and clearest language at our command. On the other hand, we have not, either in the pamphlet referred to or in any similar literature, made statements concerning the physiological action of papoid, except such as are quoted from the reports of medical men of high standing — such reports having been culled from reputable medical journals and text-books; and we claim that we have been strictly ethical in reprinting such reports.

As to the chemical statements contained in our pamphlet they are the utterances of Professor Chittenden, of Yale College, quoted from the "Transactions of the Connecticut Academy" (Sheffield Scientific School). We assert that all such statements are strictly true, and that we stand ready to verify them at any time. The balance of the pamphlet consists mainly of articles taken from the medical journals of this country, treating of the physiological action of papoid and written mostly by physicians of wide reputation. For example, we quote from Dr. Love who is at present Vice-President of American Medical Association; one of the incorporators of the Pan-American Medical Congress; Ex-Chairman of the Section of Pædiatrics, American Medical Association; Professor Diseases of Children, Marion Sims College of Medicine, etc.: Dr. Frank Woodbury, of Philadelphia, Professor Clinical Medicine in Medico-Chirurgical College, Philadelphia; Chairman of Section on Materia Medica and Pharmacy in American Medical Association; Fellow of the College of Physicians of Philadelphia; Member of Academy of Natural Sciences, etc.: Dr. Howard Lankester, President State Board of Health, Fisher, Minn.: Prof. T. M. Culver: Dr. Thos. K. Morton, of Philadelphia: Dr. Robert T. Morris, of New York, a man who more than any other individual brought to light the value of peroxide of hydrogen: Dr. A. M. Owen, Treasurer General of the Pan-American Medical Congress; Member Judicial Council of American Medical Association; Ex-President Mississippi Valley Medical Association: Prof. Andrew Jas. Park, of Chicago: Dr. Arch Dixon, President Kentucky State Medical Society; Ex-President Mississippi Valley Medical Association, etc.: Professor Lydston, of Chicago: Professor Larrabee, of Louisville: Professor Dumesnil, of St. Louis, whose name is known on both continents, and many others. In our pamphlet we have given the titles of the articles, the journals in which they appeared, and the dates, so that those who may wish can refer to the original articles. We thus claim that these utterances are worthy the attention of progressive medical thinkers.

The statement that papoid acts in acid, alkaline and neutral media, in combination with almost any drug, and at a wide range of temperature, is, we will admit, somewhat revolutionary in character and should be read by the profession with caution — if not incredulity; for physicians already know that the animal ferments possess no such action. Our pamphlet, however, is composed of quotations from men of high standing; and a tirade against the pamphlet and its contents is at once, not only an attack upon us, but also upon the utterances of medical men who are far better qualified to write upon the subjects which they discuss than some others are to criticise.

We believe that the progressive chemist is the valued handmaid of the progressive medical practitioner. Kindly permit us to say that we are chemists only, and as such we claim the privilege of calling chemical facts to the attention of medical men — facts which we presume the average busy practitioner has neither time nor opportunity to learn through original research. We have stated facts which we believe many of the members of the medical profession were not previously familiar with; and these facts being such as to attract the attention of many progressive medical thinkers, the result has been the appearance of conclusive clinical statements in the leading medical journals showing the physiological action of papoid. These statements we claim the privilege of quoting after receiving permission from the authors; and we have freely circulated reprints, *but to the medical profession only.* They should be of interest to any physician who claims to keep pace with medical progress; and if any of these reprints have fallen upon stony ground, it is a reflection upon the receiver rather than upon the author or the sender.

It is not true that our "representative has called upon" the author of this attack. It is not true that "we have forced samples upon him"; and if he ever received any it was because he asked for them. It is not true that "we have attempted to usurp the province which belongs to the physician." And it is not true that we ever, by word or implication, gave him or any one else the right to ascribe to us even by inference the statement that "We have no use for unsuccessful cases."

Permit us to say, in conclusion, that we propose to continue strictly in the ethical line previously followed by us, and are prepared to demonstrate the absolute accuracy of all utterances appearing over our name.

Very respectfully yours,
JOHNSON & JOHNSON, Chemists.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCTOBER 14, 1893.

Cities.	Estimated population for 1893.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported 2,270: under five years of age 942; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhœal diseases, whooping-cough, erysipelas and fever) 457, consumption 284, acute lung diseases 203, diarrhœal diseases 166, diphtheria and croup 154, typhoid fever 59, scarlet fever 30, whooping-cough 19, cerebro-spinal meningitis 14, measles 7, small-pox 2.

From scarlet fever Pittsburg 8, Boston 6, Philadelphia 4, New York 3, Brooklyn and Cincinnati 2 each, Cleveland, Springfield, Haverhill, Quincy and Woburn 1 each. From whooping-cough New York 8, Philadelphia 3, Pittsburg 2, Boston, Washington, Cincinnati, Nashville, Worcester and New Bedford 1 each. From cerebro-spinal meningitis New York, Brooklyn, Malden and Gloucester 2 each, Boston, Washington, Cleveland, Worcester, Lynn and Somerville 1 each. From measles New York 2, Brooklyn, Boston, Washington, Milwaukee and Worcester 1 each. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending October 7th, the death-rate was 18.5. Deaths reported 3,656: acute diseases of the respiratory organs (London) 230, diarrhœa 193, diphtheria 88, fever 81, scarlet fever 68, whooping-cough 68, measles 30, small-pox (Bradford 10, West Ham 2, London, Wolverhampton and Birmingham 1 each) 15.

The death-rates ranged from 8 1 in Croydon to 32.2 in Wolverhampton; Birmingham 21.3, Bradford 20.2, Hull 22.2, Leeds 14.7, Leicester 16.4, Liverpool 23.2, London 17.9, Manchester 21.3, Newcastle-on-Tyne 21.4, Nottingham 15.6, Salford 21.5, Sheffield 19.8, Sunderland 23.6, West Ham 17.4.

METEOROLOGICAL RECORD,

For the week ending October 14, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 14, 1893, TO OCTOBER 20, 1893.

FIRST-LIEUT. A. N. STARK, assistant surgeon, now at Fort Clark, Texas, will proceed at once to Fort McIntosh, Texas, and report to the commanding officer for temporary duty with troops in the field at Carrizo, Texas.

FIRST-LIEUT. ROBERT S. WOODSON, assistant surgeon, U. S. A., now temporarily at Fort McPherson, Georgia, will return to his proper station, Fort Barrancas, Florida.

Leave of absence for one month, to take effect about the 20th instant, is granted FIRST-LIEUT. MERRITTE W. IRELAND, assistant surgeon, Fort Apache, Arizona Territory.

SOCIETY NOTICES.

NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS.— The third annual meeting will be held in the Academy of Medicine, 17 West Forty-third Street, New York City, Wednesday, November 15, 1893.

GEO. CHAFFEE, *President*, Brooklyn.
M. CAVANA, *Secretary*, Oneida.

THE SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY hold its first meeting at 19 Boylston Place on Wednesday evening, November 1, 1893, at 8 o'clock.

Dr. Geo. L. Walton will read a paper on "Dislocation of Cervical Vertebræ: Report of a Successful Case."

Dr. Fred B. Lund will read a paper on "Tendon Suture."

CHARLES L. SCUDDER, M.D., *Secretary*, 1 Marlborough St.

SUFFOLK DISTRICT MEDICAL SOCIETY.— The stated meeting will be held at 19 Boylston Place, on Saturday, October 28, 1893, at 8 P. M.

Papers: Dr. C. F. Withington: "Medical Teaching Abroad." Dr. R. W. Lovett; "Surgical Operations upon Young Babies; A Report of Four Months' Experience at the Infants' Hospital."

Business: Election of a committee of five to prepare a list of candidates for officers of the Society for 1894–95.

Supper after the meeting.

Members are requested to notify the Secretary, at 188 Marlborough Street, of any error or change in address.

Notice of the meetings of each section is sent to those only who have notified the secretary of that section that they wish to join it. The secretaries of the sections are appointed at this meeting.

A. L. MASON, M.D., *President*.
JAMES J. MINOT, M.D., *Secretary*.

RECENT DEATHS.

JAMES H. BODGE, M.D., M.M.S.S., of Newton Centre, died at the Boston City Hospital, October 19th, aged fifty-three years. He graduated from Dartmouth College in 1865 and from the Harvard Medical School in 1867.

CHARLES H. FISHER, M.D., Secretary of the Rhode Island State Board of Health, died at Buffalo, N. Y., October 21st, aged seventy-one years. He graduated from the Dartmouth Medical School in 1848. From his first election to the Rhode Island Medical Society in 1850, he served in the various offices and was made its president in 1877. He was several times State senator, and for some years was a member of the State Board of Education, as well as a trustee of the State Normal School from its establishment. From 1862 to 1865 he was State inspector of recruits for the Army and a member of the Board of Exemption. In 1878 the Rhode Island State Board of Health was organized and Dr. Fisher was unanimously elected its secretary, which position he filled until his death.

ALGERNON S. COE, M.D., died at Oswego, N. Y., October 18th. He served as surgeon of the One Hundred and Forty-seventh Regiment, New York Volunteers, during the war, and as brigade surgeon three years, without the loss of a single day at his post.

BOOKS AND PAMPHLETS RECEIVED.

Erotopathia (Morbid Erotism). By C. H. Hughes, M.D., St. Louis. Reprint. 1893.

How to Treat Your Own Feet, a Treatise on the Human Foot, with Illustrations. By Charles Kahler, Surgeon Chiropedist. New York: Dr. P. Kahler & Sons.

A Practical System of Studying the German Language. For physicians and medical students for self-instruction. By Albert Pick, M.D. Part III. Newtonville, Mass.: E. S. Tanner. 1893.

The French Doctor's Book, Containing a Collection of 1,200 Favorite Prescriptions, by the Most Eminent Foreign Physicians. English translation. Copyright 1893 by Wm. von Bergen. Boston: Wm. von Bergen. 1893.

The Diseases of the Male Organs of Generation. By W. H. A. Jacobson, M.Ch., Oxon., F.R.C.S., assistant surgeon, Guy's Hospital; surgeon, Royal Hospital for Children and Women. With eighty-eight illustrations. Philadelphia: P. Blakiston, Son & Co. 1893.

Lectures and Essays on Fevers and Diphtheria, 1849 to 1879. By Sir William Jenner, Bart., G.C.B., M.D., Lond., and F.R.C.P., D.C.L., Oxon, LL.D., Cantab. and Edin., F.R.S., President of the Royal College of Physicians from 1881 to 1888; Physician in ordinary to H. M. the Queen and to H. R. H. the Prince of Wales; Consulting Physician to University College Hospital. New York: Macmillan & Co. 1893.

Sterility in Woman, Causes, Treatment and Illustrative Cases. Microscopical Studies in Pelvic Peritonitis. Diagnosis and Some of the Clinical Aspects of Gyroma and Endothelioma of the Ovary. Carcinoma on the Floor of the Pelvis. Colpo-Hysterectomy for Malignant Disease. Oophorectomy in Diseases of the Nervous System. By Mary A. Dixon Jones, M.D., Brooklyn, N. Y. Reprints. 1892–93.

A Treatise on the Science and Practice of Midwifery. By W. S. Playfair, M.D., LL.D., F.R.C.P., Physician Accoucher to H. I. and R. H. the Duchess of Edinburgh; Professor of Obstetric Medicine in Kings College; Physician for the Diseases of Women and Children to Kings College Hospital; Consulting Physician to the General Lying-in Hospital and the Evelina Hospital for Children; Late President of the Obstetrical Society of London; Examiner in Midwifery to the Universities of Cambridge and London and to the Royal College of Physicians. Sixth American from the eighth English edition, with notes and additions. By Robert P. Harris, A.M., M.D., Honorary Fellow of the American Gynecological Society and of the Philadelphia Obstetrical Society; Corresponding Member of the Obstetrical Society of Leipzig and of the Royal Medico-Chirurgical Society of Naples, etc. With five plates and two hundred and seventeen illustrations. Philadelphia: Lea Brothers & Co. 1893.

Original Articles.

THE HYGIENIC ARGUMENT FOR CREMATION CONSIDERED FROM A BACTERIOLOGICAL STANDPOINT.[1]

BY A. K. STONE, M.D.

At the time when the cremation movement was in its infancy the need for some immediate change in the mode of the disposal of the dead was manifest, and the evils of intramural burial everywhere acknowledged. Thirty years ago few of the cities of the old world had any common water-supply. The inhabitants for the most part depended upon wells. These were frequently contaminated, and often became sources of epidemics; and it was much easier to lay the charge to some neighboring cemetery, than to the contamination of such wells by the sewage from neighboring houses. For, should the latter be proved, individual interests must be sacrificed and actual hard cash must be paid out by the owners of the adjoining property in order to remedy their defective drainage.

Now there are few cities of any size where there is not a general water-supply, and any contamination which produces anything like an epidemic arouses the citizens, and the boards of health are ready to see to it that the source of contamination is found and stopped, never minding the cost or discomfort of a few individuals.

The overcrowding of most of the churchyards gave great plausibility to this argument. The churchyards were usually small plots of ground around the church, and had been in use for very long periods of years. Usually they were in parts of the towns or cities where the population was especially dense, and where improvements in sanitation were slowest to make progress. Again, their use had gradually become confined to burials of the poorer classes from the neighboring parish, and single individual graves were very rare. In London it was the general custom to dig a deep grave, usually having to bore with a long augur to find a place where such a grave could be made without disturbing coffins still in a good state of preservation. When these deep common graves had been dug, they were kept open, or loosely covered with boards until such a time as it was filled to within a couple of feet to the top, the last coffin was then covered with a foot and one-half to two feet of earth. In fact, in London alone, with its immense population, the churchyard area in 1849 only amounted to about 218 acres, and in this there were annually over 50,000 people buried. Such a number would cause the whole space to be filled completely with bodies each decade.

The same condition of affairs was to be found all over the Continent, where the conservatism of the people and the scarcity of land caused the same graveyards to be used for centuries.

In this country the older graveyards in many of the cities became overcrowded early in this century, the most notable case being Trinity Churchyard in New York. Here the soil was so shallow that it was impossible to dig a grave so that the body should be more than eighteen inches to two feet below the surface. During the Revolutionary War the Hessians were employed to cover the churchyard with several feet of earth. Yet in spite of this, in the early part of this century, the stench from this graveyard was extremely bad; and during the cholera epidemic of 1849 the disease seemed to have a focus about this burying-ground. Several of the other old churchyards in New York and Copp's Hill Burying-ground in Boston became overcrowded, and had to be closed against further interments.

In spite of this horrible condition of affairs common to many places during the middle of the century, the number of epidemic diseases actually attributable to cemeteries is very small indeed. Adams, in the Sixth Annual Report of the Massachusetts State Board of Health, states that after a careful study of the reported epidemics due to graveyards, he only found two that were at all credible. One of these was in Barbary and the other in Italy; and from the account of the latter, it is doubtful whether it would stand the light of modern investigation. A circular sent at this time to five hundred physicians, evoked only eleven positive replies. Of the five in Massachusetts, four would not stand investigation, and the other could not be inquired into, because of the physician's having left the State. Of the answers to Dr. Adams from abroad, in one the deleterious influence was thought to be due to an overcrowded churchyard; but in this case no wells were involved, and the evil effects probably came from the foul air.

Dr. Cameron, Professor of Hygiene in Dublin, while having known of several cases of illness due to neighboring graveyards, and of several wells that were undoubtedly contaminated with nitrogenous material from similar sources, says: "I am disposed to believe that the injuries arising from badly kept graveyards are to be attributed to a far greater extent to the foul air, than the contaminated water. If the latter be very foul, it will, of course, produce diarrhœa, lowering the vital powers, and other effects caused by water containing simple decomposing organic material. I am of the opinion that water tainted by graveyards does not cause typhoid fever, or other zymotic disease."

Mr. Holland, Medical Inspector of Burials of England and Wales, states that in properly regulated cemeteries he has known of no sickness which appeared to be induced or aggravated by any such cemetery, though in overcrowded graveyards he had had numerous instances of mischief done to the inhabitants in the neighborhood.

In the same year (1874) Baginsky[2] could not discover a single case where the vicinity of a graveyard had caused an epidemic. Further, a series of investigations were made in regard to the chemical conditions of the water in the wells of churchyards in various cities by Wernher,[3] in which he found the water of the churchyards was purer than the wells of the town. Müller[4] also reaches the same results after a very complete investigation. Adams quotes from Professor Fleck[5] of Dresden, who in 1872, during the months of June to September, examined carefully the water from the nine wells of the cemetries, and also from the wells in the town. First, no injurious physiological effects from the cemetery water came to the author's notice, although in many instances the water of the wells was in constant use by the families of the gravediggers. In general there was no essential difference between the average well water throughout the city of Dresden and the analysis of the water from the

[5] Professor Fleck, 1893. Quoted by Adams.

nine wells in the cemetries. In Paris, water from a well near a cemetery had a sulphur-like taste, and was bottled and sold as a mineral water and obtained considerable repute.

Zulger alone, to the contrary, reports a typhoid epidemic from a graveyard in Berlin in 1873. But a sanitary committee of Berlin (1882–1885) could not find that the burial places exerted any influence either upon the production or spread of typhoid fever.

All of this goes to show that no serious epidemics have been attributable to graveyards, even during the period in which there was the best chance for such to have taken place, owing to the utter disregard of sanitary laws and to the great overcrowding of the burial grounds.

Since 1880, a period in which there has been the greatest activity among scientific men in their desire to discover sources for disease and epidemics, I have been unable to find any well authenticated case of epidemic coming from any burial place, although an epidemic of cholera in Spain is reported as coming from an old graveyard where the victims of previous epidemics had been buried. From what we know of the source and origin of cholera, it does not seem probable that this case will stand investigation.

With the development of the science of bacteriology, a new force was given to the arguments of those who believed in cremation. The bacteria were the cause of disease. The body of the person, when buried, carried with it into the earth the pathogenic bacteria. These escaped from the body, found their way into the neighboring subterranean water-ways, and carried pestilence to the wells and water-supplies. Such was the *a priori* reasoning and it seemed extremely plausible. Therefore a number of attempts have been made to investigate the condition of the soil in its relation to germ life.

The first series of experiments of importance was made incidentally in the course of experiments made to determine the etiology of the anthrax. It was found by Pasteur that in fields which had not been used for pasturage for many years on account of previous occurrence of anthrax, when new herds were again let into the fields they were soon attacked by the anthrax bacilli and the plague again appeared. He accounts for this by the fact that the bodies of the animals which had died during the previous epidemic had been buried in the field, that the spores of anthrax had formed in their bodies, and that these spores had been brought to the surface by earthworms and were then taken up by the animals feeding on the grass, etc.

Koch, however, in his article, showed by a series of seven experiments that it was very rare that earthworms acted as carriers of spores. He placed a number of earthworms in a pot of earth filled with spores of anthrax, and then with precautions against contamination, inoculated mice with the contents of the intestinal canal of the worms. The time that the worms had been in the earth which contained the spores varied from five days to one hundred and ten days. In all the control experiments where the mice were inoculated with small particles of the earth, they died on the following day of anthrax, while only one of the mice inoculated from the earthworms died, and that was on the third day. The possibility of contamination from the earth adhering to the worm must, of course, be considered in this case.

But even if the earthworms may be poor carriers of the bacteria, Koch further showed that it was highly improbable that spores could form in the lower levels of the surface of the earth, where the animals would naturally be buried, on account of the permanent low temperature. Also, while it is unusual, if indeed it ever occurs, for spores to form in the living body during life, there were plenty of chances for spore formation to take place on the surface of the soil, which was always smeared more or less with the bloody discharges of the diseased animals, if it was not soaked with the infected blood of the animals, which were rarely allowed to be buried before their hides were removed. Hence, the earth's surface and the grass could be the source of the later epidemics. It is to be remembered that dead bodies are usually buried much deeper than the ordinary habitat of the earthworm. And moreover, earthworms do not feed upon dead animal material.

All of these arguments go to disprove Pasteur's earthworm theory and we are obliged to give up the supposition that spores are brought to the surface for the infection of man and animals by any such agency.

Koch's work was later substantiated by Kitasato, who made a series of observations [6] upon the possibility of spore formation in anthrax. He took, with aseptic precautions, the blood of mice that had died of anthrax and inoculated gelatine and agar tubes and placed them in the earth at various depths. This he repeated each month in the year, and a record of the temperatures at the various depths was carefully noted. Control tubes were made and kept at the room temperature, but no spore formation was seen in any of these cultures. From the results of these experiments it was shown that the anthrax bacilli at the depth of one-half a metre during June, July and August, and at a depth of one and one-half metres during July alone, formed spores. At the latter depth only a very few appeared. Also, during July, a few bacilli grew at the depth of two metres, but they had no spores; while at three metres below the surface there was no growth at any time. In other words, no bacilli of anthrax showed any growth when the temperature was lower than 14° C. At 15° C. a few spores began to be formed. No bacilli were found alive after a stay of four weeks in the ground, and some of the cultures were dead at the end of a week, others at the end of two weeks. If bacteria of decomposition were added, no anthrax could be found at the end of a week, even during July and August, at a depth of one and one-half to two metres.

Heser [7] investigated the bodies of sheep, goats, cattle and horses buried in the ground at various depths, which after a certain time were exhumed and examined for virulent bacilli by inoculation upon other animals. In this series there was, with one exception, a negative result, although a goat was dug up on the fourth day, a cow on the seventh, and another cow on the ninth day. The exception was a sheep, which lay for fourteen days in winter at a temperature of 6° to 8° C.

V. Esmarch also made a series of experiments with the bodies of animals placed in different conditions, buried in loam, in sand, at various depths, and also kept in water, the ice chest, the constant temperature apparatus and in the free air. In only one single case did the bacilli survive the death of the animal eighteen days, and that was in the body kept in an ice chest.

[6] Zeitschrift für Hygiene, 1890, vol. viii.
[7] Zeitschrift für Thiermedicin., 1877. Quoted by V. Esmarch.

All these experiments were conducted to exclude oxygen as far as possible. To prove that spores were not formed in the bodies, a piece of meat was taken and also the body of a mouse. Into each of these spores of anthrax were introduced, with the result that after seventeen or eighteen days, inoculation showed the presence of the anthrax bacilli, thus proving that when spores were present before burial that they remained virulent.

It will be seen that all this work goes to support the original assertion of Koch, that spore formation rarely took place beneath the soil or in decomposing animals. Therefore the bodies of such animals are not a source of infection, if deeply buried.

What is true of anthrax is also true in a great measure of other specific, pathogenic organisms and the possibility of danger of infection in other diseases is lessened, because in a few of the ordinary bacterial diseases does the pathogenic bacteria form spores. V. Esmarch further concludes from his investigations that the greatest number of pathogenic bacteria probably cease growing soon after the death of their victim (though Frænkel and others had previously observed that a decided increase for a short time took place in certain cases). The disappearance occurs more rapidly the faster decomposition progresses. The specific bacteria are probably simply killed by the more vigorous growth of the bacteria of decomposition, by the absorption of oxygen and chemically by the production of products unfavorable to their development.

A similar set of investigations were undertaken by Dr. Petri,[8] and extended over a period from 1885 to 1891. It was his purpose to find out how much the dead bodies of animals, which were known to be full of pathogenic bacteria, were a source of danger to the living.

In all such cases the question necessarily arises, how far the deductions which are made from the bodies of small animals can be applied to larger animals. But so far as there has been any chance for comparison between the experimental animals and sheep, cattle, etc., there has been no great variation. Petri's experiments were made with the bodies of mice, guinea-pigs and rabbits, and were conducted with the greatest care, and, whenever possible, control experiments were made. The internal organs of the animals were examined; also the fluids in the coffins and the soil about the coffins.

Anthrax experiments were made on the bodies of mice. The first was buried in sterile earth and kept moist with sterile water. After fifty days they were disinterred and one of two mice inoculated from the internal organs died of anthrax after seven days, showing a very low state of virulence. In the other case, it was supposed that anthrax was found in the cover-glass preparations, but neither the plates nor the inoculated animals showed the presence of live anthrax. In one case, after a lapse of five years, one month and eleven days, one out of six inoculations gave a positive result, but neither feeding or plate cultures gave a similar result. In some manner spore formation must have taken place.[9]

Next, sixteen guinea-pigs were buried in wood and zinc coffins, which were exhumed and examined from time to time. These were buried in a chest, with about 15 to 20 c.m. of earth over them, and kept moist and at a temperature which varied from 5° to 19° C. Out of the sixteen experiments, three gave positive results. The first after three months, in wood; the second in a zinc coffin, after six months, two days; and the third after a period of three years, ten months (46 months). Inoculated with fragments of liver, two mice remained well, while two guinea-pigs died (!). In all the corresponding zinc coffins, the fluids and the internal organs remained perfectly sterile, so far as aërobic bacteria were concerned.

CHOLERA.

Nineteen guinea-pigs were killed with cholera bacilli and buried in wood and zinc coffins. From the wood positive results were reached on the sixth, seventh and ninteenth day, and in the zinc on the eleventh and twelfth days; afterwards negative. Also two animals were buried free, and being exhumed, one on the seventh day, and the other after three months and nineteen days — both gave negative results. Two were also put into water and allowed to stay, the first eighteen days, and the second two months and ten days; and neither the water nor the bodies showed any bacilli. An animal buried for two months and a half in very moist earth, was exhumed at the end of that time, and neither the soil nor the cadaver showed any signs of the cholera bacilli.

TYPHOID.

Twelve rabbits were killed and injected through the aorta with a bouillon culture of typhoid, and the presence of the bacilli in the extremities was demonstrated. These bodies were buried in a sandy hill in wood and zinc coffins. All the investigations gave a negative result. There was even no discoloration of the beautiful yellow sand; and though large numbers of the bacteria had been present, they could never be found, even in the fluids which could not escape from the zinc coffins.

TUBERCULOSIS.

Twelve extremely tuberculous rabbits were buried in wood and zinc. At the end of twenty-two days, and of two months and five days, the exhumation gave positive results. That which took place at the end of five months and six days gave positive results in the zinc alone, and after that the experiments were negative.

In general, it may be said that the fluids in the zinc coffins rarely contained the pathogenic bacteria. And in no case did the earth that had been soaked in the decomposing fluids, show the presence of the pathogenic bacteria. This is of special importance as regards the spread of disease through water-ways; and the question of whether the pathogenic bacteria last a few months more in a large cadaver is of little consequence as compared to this question, which can hardly be affected by the size of the animal. [This conclusion is not altogether in accord with the results of sewage filtration experiments, where it has been shown that the filter beds should be frequently renewed, or allowed to lie idle, in order to have perfect filtration. So under unhygienic conditions, where rapid decomposition takes place, it is possible to imagine a soil so overcharged with animal matter as to transmit bacteria direct to the ground-water.]

(*To be continued.*)

[8] Dr. Petri: Arbeiten aus den kaiserlichen Gesundheits Amt., Bd. vii, 1891.

[9] It may be well to note that the depth of burial was not sufficient to shut out all possibility of the presence of oxygen. Also, as post-mortem examinations were made in all cases, the internal organs were exposed to the action of oxygen to an exceptional degree, and herefore spore formation was made possible.

HYSTERECTOMY FOR CANCER OF THE CERVIX BY COMBINED ABDOMINAL AND VAGINAL DISSECTION.[1]

BY MAURICE H. RICHARDSON, M.D.,
Visiting Surgeon, Massachusetts General Hospital; Assistant Professor of Anatomy, Harvard Medical School.

THE following brief consideration of this subject, from the standpoint of a general surgeon and anatomist, will not, I hope, prove uninteresting.

In liability to recurrence after operation, uterine cancer equals, if it does not exceed, cancer of the breast. The reasons for this are to be found in the local malignancy of the uterine growth, a malignancy developing and extending as rapidly in the cervix as in the breast, and in the almost insurmountable difficulties encountered at its complete extirpation. Secondary infiltration of the broad ligaments — the earliest possible metastasis in cancer of the uterus — renders the entire removal of the disease impracticable, if not impossible; and were this invasion as universal as that of the axillary lymph-glands in cancer of the breast, no radical or dangerous operation upon the uterus would be justifiable. The surgical procedures, therefore, would be limited, and only those measures would be selected that relieve suffering and prolong life.

Clinically we do not find the broad ligaments invariably affected, even in cases of extensive local disease; on the contrary, in many instances no secondary infiltration whatever is found in separating the uterine ligaments. Not only by the absence of infiltration in these cases, but also by the numerous permanent cures following hysterectomy, are we justified in concluding that uterine cancer is infrequently associated with early metastases. Not that cancer of the cervix manifests as slight a malignancy as cancer of the lip in its early stages, for in some instances, at least, the former shows a tendency to rapid growth and invades the surrounding parts almost before its presence is known, or even suspected. Nevertheless, my experience leads me to believe that cancer of the cervix is distinctly less malignant in its early development than cancer of the breast.

In breast tumors the patient's fears lead more frequently to early consultation than in uterine disease, for the existence of the latter often remains unsuspected, the patient supposing her symptoms merely an excess of the normal physiological discharge. A natural tendency towards concealment gives us but rarely a chance to investigate and treat either disease in its earliest stage. Moreover, in both breast and uterine disease, pain is so frequently absent that no conspicuous symptom remains to call attention to these regions, so that a tumor may obtain considerable size in the breast before it is discovered, or the uterine discharges may become excessive or even offensive, before a physician is consulted. Hence, most cases of early uterine cancer are discovered by the physician in the course of treatment for symptoms in which serious disease is not suspected; while the occasional absence of symptoms allows breast tumors to become hopelessly extensive before there is any suspicion of their growth.

Cancer may extend from the cervix in all directions and invade the vaginal mucous membrane and the important structures lying in close relation with it. In fact, the epithelial infiltration must be very circumscribed not to involve also, in a hopeless entanglement, the bladder wall, the rectum or the ureters; yet the disease is occasionally limited to the internal layers of the cervix or to the body of the womb without appearing in the peri-uterine structures at all. But, unfortunately, cancer seldom confines itself in this manner; we must expect the contrary in most instances and find the disease spreading in all directions in hard and ulcerating masses.

It follows from clinical and pathological considerations that cases of cervical cancer favorable for extirpation and permanent cure are rare, that operations for relief have very decided limitations and that at best the outlook is gloomy.

From a brief consideration of the anatomy of this region, we shall find ourselves still more limited and unsuccessful in our efforts thoroughly to extirpate cancer of the cervix.

The analogy between cancer of the lip and cancer of the cervix is striking, clinically, in that both seem at first to have only a local malignancy, while both, when well under way, exhibit a rapidity of growth and area of metastases that is deplorable. In lip cancer, however, the nearest structures, the invasion of which makes interference well-nigh hopeless, are the submaxillary glands and the lower jaw, not to mention the body of the cheek. In uterine cancer, on the contrary, a peri-cervical extension of much less than an inch renders cure by excision absolutely hopeless.

A clear idea of the relations between the cervix, bladder, rectum, peritoneum and ureters is therefore of the greatest importance, not only for prognosis but for technique. The following brief description of their relations is based upon numerous dissections upon both the living and the dead subject, made with special reference to hysterectomy.

Anteriorly, the extravaginal portion of the cervix is separated from the walls of the bladder by areolar tissue, easily dissected by the finger after cutting the vaginal attachment. The intravaginal portion is separated from the bladder by the superior vaginal wall. The vagina is not so easily separated from the bladder as the uterus, being more intimately attached. When infiltrated, the vaginal mucous membrane is inseparable from the bladder wall, though the disease does not grow towards the vesical mucous membrane as rapidly as it spreads laterally.

Posteriorly, the cervix is separated from the rectum by the fold of peritoneum and vaginal mucous membrane, which together make the base of the pouch of Douglas. This interval varies somewhat in extent. Separation of the vagina and rectum is easy because they are connected only by loose areolar tissue, easily dissected with blunt instruments or with the finger. Separation of these structures, however, is not so easy as we go back, the vagina and rectum being more intimately connected near the cervix. As in the upper vaginal wall, malignant disease shows a greater tendency to spread than to penetrate; so that there may be a very extensive infiltration and ulceration limited to the posterior wall, the rectal mucous membrane apparently remaining intact. This fact I have observed frequently in advanced cancer of the cervix and vagina. The rectal mucous membrane, in many cases, is scarcely, if any, involved, so that it slips easily in all directions over the vaginal mass. Not that this is always the case, for we often find recto-vaginal fistulæ in advanced cancer; but it is frequent enough to justify us at times in operating where the vaginal mucous

[1] Read before the Obstetrical Society of Boston, June 10, 1893.

membrane alone is involved. The prognosis is very unfavorable, however, because we must literally shave the tumor in our dissection.

In the intimate relations between the ureters and the cervix, we find our most discouraging facts, both as regards prognosis and technique.

Entering the pelvis under the peritoneum, near the origin of the internal iliac artery, the ureters pass downward, forward and inward. Approaching the cervix they run directly forward on each side toward the superior vaginal wall. In their passage to the bladder they are separated from the cervix by a very short interval, varying in different subjects, but practically almost in contact with it. They are loosely placed in the surrounding tissues in this part of their course, and they may easily be isolated and drawn to one side. The distance between the ureters and the cervix may depend upon disease and upon the width of the cervix itself. In the blind manipulations of a vaginal hysterectomy, where nothing can definitely be seen, there is always danger of wounding these vessels. Vaginal hysterectomy, therefore, is not only hazardous because the ureters may be wounded, but it is also likely to fail of permanent cure, for the slightest extra-cervical infiltration must involve tissues in the immediate vicinity of these structures so essential to life.

The broad ligaments, extending outwards from the anterior and posterior surface of the uterus, are reflected at the pelvic brim, to which they are attached. Thin above, the duplication of peritoneum becomes widely separated as we approach the cervix. An antero-posterior longitudinal plane, passed through the ligament at its reflection from the uterus, makes, therefore, a triangular section, the apex of which is the Fallopian tube, and the base the lateral vaginal attachments.

Between the peritoneal folds at the apex of this triangle we have the Fallopian tube. As we descend close to the uterine body we find the peritoneal reflections gradually separated. In tying and dividing the attachments of these folds the tissues broaden, till, at the vaginal insertion, our clamps embrace a mass of considerable size. In vaginal hysterectomy the reverse is true. The most important structures involved in the operation — the arteries, veins and ureters — are situated between the lower portion of the peritoneal folds. From the position of the ureters, between these folds, always very close to the cervix, we cannot hope for a broad margin in the excision of cancer of the cervix, under any circumstances, as we may in cancer of the lip and cancer of the breast.

The dangers encountered in vaginal hysterectomy are wounding of the ureters and hæmorrhage. It is, therefore, desirable so to perform the operation that, first, the ureters may be avoided by as narrow a margin as possible; and, secondly, that the arteries and veins may be securely tied. Leaving for the present the question of septic infection, it is evident that vaginal extirpation of the uterus must be performed without a definite knowledge of the location of the ureters. They can only be avoided by clinging closely to the cervix and to the uterine body. This is very undesirable where it is necessary to remove the disease as radically as possible. In vaginal hysterectomy we grope between the ureters and not only run great risk of wounding them, but we do not give the disease as broad a margin as we otherwise might.

By the vaginal route, hæmorrhage is a conspicuous danger. If our ligatures slip, or our clamps break or come off, we may have, deep within the pelvic cavity, an alarming hæmorrhage which can only be checked with the greatest difficulty. Indeed, it is impossible at times to prevent a fatal hæmorrhage, even with the greatest skill and experience. Not that the control of bleeding is difficult in all cases, for we often find the uterus so movable that all the manipulations may be performed at the vaginal outlet. Where the uterus is large and firmly fixed, however, it is impossible to bring the broad ligaments within easy reach, and we must then apply long clamps, which are liable at any time to slip or to break. In difficult cases, therefore, we must expect formidable dangers and deplorable accidents.

The advantages of the vaginal operation lie chiefly in drainage.

By the suprapubic operation, in the Trendelenberg posture, we are able to determine the condition of the broad ligaments, to recognize a hopeless metastasis, and to dissect with precision. The slight dangers of this method are more than balanced by the thorough knowledge we may obtain of the nature and extent of the disease. In cases evidently hopeless the abdomen can be closed and a palliative operation by the vagina substituted. But if, by abdominal exploration, we find no contra-indications to a complete hysterectomy, we may proceed with much greater safety, and more thoroughly remove the diseased uterus and appendages. From the pathological standpoint, therefore, the abdominal route is preferable because we can remove not only the uterus and the cervix, but we can include the broad ligaments and the structures contained within their folds.

From the standpoint of the anatomist this operation is much preferable to the vaginal method. With the patient in the Trendelenburg position, a clean dissection with the knife or scissors may be made as far as the vaginal attachment. Starting at the pelvic brim, the structures may be successfully tied and cut until we approach the cervix, when by careful manipulations the ureter may be brought into view. The dissection from this point may be carried on as intelligently as a dissection of the common carotid. The ureters on either side may be brought into view, held out of the way by an assistant, and the vaginal attachment severed. The uterine arteries can be found by their pulsation, and tied. As we approach the vaginal attachment, however, it is very hard to tell just the limits of the disease. Up to this point the operation may be performed with great ease and with perfect safety. Separation of the vaginal attachments on all sides must now be made with great care if we would avoid wounding the rectum, the bladder and the ureters. During the prolonged manipulations necessary to avoid these errors, we run a considerable risk of a serious septic infection. It is to avoid these difficulties and dangers that I advocate the combined vaginal and abdominal dissection.

By the abdominal method the septic masses are constantly drawn toward the area that we wish to protect; by the vaginal method they are constantly drawn from that region. By the combined abdominal and vaginal operation the uterus may be delivered either through the abdomen or through the vagina. It makes little difference, however, which way is selected, because, having separated carefully the cervical attachments of the vagina below, the completion of the operation by

the abdominal route is rapid, and the peritoneum runs little if any more danger of infection than by the vaginal route alone.

The method which I advocate as the safest and most rational procedure for the radical excision of uterine cancer is first to separate by clean incision the diseased cervix from the vaginal mucous membrane by as broad a margin as possible without wounding the rectum, bladder, or ureters. The incision should be carried through the mucous membrane until the areolar tissue is reached; then dissection should be carried on by the finger or by some blunt instrument until we are close to the peritoneum, care being taken not to open the peritoneal cavity. It is, of course, necessary previously to have disinfected as far as possible the cancerous ulcerations. The hands should now be thoroughly sterilized, and the abdominal incision made with a second set of instruments. Having, in the manner described, separated the broad ligaments and isolated the ureters, we may rapidly connect the vaginal with the abdominal incision. The uterus may be delivered through the vagina or through the abdominal wound. If the mass is too large easily to be delivered by the vagina, the abdominal route should be chosen; not that it makes any great difference where the exposure is so brief, especially if the intestines, in the Trendelenburg position, are abundantly protected by sterile gauze. After removal of the uterus the folds of the peritoneum may be united by continuous suture, or a gauze drain may be provided through the vagina. In my experience there has been, by the abdominal method alone, a mild sepsis in two cases; by the vaginal method alone there has been a fatal general peritonitis in one case; all other cases have recovered without complications of any sort.

In clean hysterectomies, I think a continuous suture should be applied; in septic operations a free dependent drainage should be provided by leaving a gauze drain in the vagina.

The prognosis as to recurrence in even the most radical operation upon a cancerous cervix is bad; for, under the most favorable circumstances, the margin of healthy tissues seems utterly inadequate. A small cancerous nodule in the centre of a large breast demands excision of the whole organ, and even then recurrence is the rule. An infiltrating epithelioma of the lip requires in its proper removal the broadest possible margin of healthy tissue; and if that margin is a close one we look upon recurrence as almost certain.

In uterine cancer, therefore, the prognosis is necessarily bad if there is any extra-cervical infiltration whatever; and while under these circumstances hysterectomy is justifiable, its performance cannot be strongly urged. If the vaginal disease is extensive, only local palliative operations, performed extra-peritoneally, are justifiable.

CONCLUSIONS.

The advantages of the vaginal method are:

(1) Less liability to peritoneal contamination.

(2) More intelligent and thorough dissection of the local disease.

Its chief objection is the difficulty in controlling hæmorrhage.

The advantages of the abdominal method lie:

(1) In a conclusive investigation of the disease itself — its local extent and its possible remote metastases.

(2) In the rapidity and safety by which the broad ligaments may be tied and cut.

(3) In the ease with which the ureters may be isolated and kept one side.

(4) In control of hæmorrhage.

Its chief disadvantage is the impossibility of thorough dissection and removal of the cervical portion of the disease.

The superiority of the combined method is seen:

(1) In the intelligent and thorough dissection both of the local disease and the broad ligaments.

(2) In the certainty by which hæmorrhage may be prevented.

(3) In the protecting of the ureters.

(4) In the saving of time.

The combined method is applicable more especially to cases where the disease involves the cervix and a portion of the vaginal mucous membrane, and to cases in which the uterine body is large and fixed. It should also be employed where for any reason it may be difficult to separate the vaginal attachments.

CASES OF EXTRA-UTERINE PREGNANCY.[1]

BY CHARLES W. TOWNSEND, M.D.

THESE cases were seen within the space of six weeks.

CASE I. C. C., twenty-five years old, came to me in the out-patient department of the Massachusetts General Hospital, April 11, 1893, and gave the following history: Her previous health had been good. She had been married five months, and had never been pregnant before. The catamenia, previously regular, occurred last in the normal manner, from February 10th to 14th. Between five and six weeks later, on March 25th, she was seized with cramp-like pains in the right side, and there was a slight bloody discharge from the vagina. On April 4th, more active flowing began, which still continued. A few days ago a piece (described like membrane) was expelled from the vagina. During all this time she has had occasionally sharp pains in the right side, with a feeling of faintness.

Examination showed the uterus to be slightly enlarged and freely movable. In the right broad ligament a mass was easily felt, the size of a tennis-ball, moderately firm and tender on pressure. Tenderness was also present on the left side, but nothing definite could be felt there.

The case was believed to be one of right-sided, extra-uterine pregnancy, with beginning rupture of the tube, and was sent into the house. Here she was seen by Dr. H. H. A. Beach, who agreed with the diagnosis, and performed laparotomy at 5 o'clock the same day, removing a partially ruptured right tube, and finding a moderate amount of free blood in the abdominal cavity.

During the five hours the patient waited before getting her husband's consent to the operation, her color became perceptibly paler, her pulse rose from 80 to 96, she had several sharp pains in her right side, and it was believed, as was afterwards found at the operation, that bleeding was taking place into the abdominal cavity, showing that longer delay might have proved fatal.

CASE II. Mrs. L., thirty-two years old, also nulliparous. Had always been delicate, having had nervous prostration seven years ago, but no uterine trouble

[1] Read before the Obstetrical Society of Boston, June 10, 1893.

as far as she knew. The catamenia had been rather irregular; but she menstruated normally last, on January 5, 1893, and not again till March 2d, when she began, as she supposed, to miscarry. On March 3d, she had severe cutting pain in the pelvis, "like pleurisy pain," and she fainted. This fainting was apparently not due to the pain, as she felt easier just before she fainted. The flowing was very slight. A week later, March 10th, the pain became localized in the right side of the pelvis. On this day she passed a piece of membrane the size of the thumb, and it was supposed then that she had aborted. Since then moderate flowing continued, with occasional remissions of several days, until she was operated on April 15th. The pain in the right pelvis extending into the leg, came and went at frequent intervals.

I was asked to take charge of the case on April 3d, or a month after the beginning of the supposed miscarriage. For the last week her temperature had ranged from 99° to 100° or 101°.

Examination showed the uterus slightly enlarged and pushed over to the left side, and a mass the size of a large hen's egg was felt in the region of the right Fallopian tube. This was tender on pressure; but a few days later the tenderness disappeared, and the left side became tender, an obscure sense of resistance developing there.

Dr. G. S. Greene, of Dorchester, and Dr. W. L. Burrage saw her with me in consultation at different times, and both agreed with me in the advisability of a laparotomy. The diagnosis was obscure, and although extra-uterine pregnancy was thought of, in view of the elevated temperature purulent salpingitis following miscarriage was believed to be the more probable diagnosis.

On April 15th, at St. Margaret's Hospital, Dr. W. L. Burrage performed laparotomy, and removed a tubal pregnancy of the right tube. The following is his account of the operation:

"Assisted by Dr. Malcolm Storer. Ether. Asepsis by shaving and soap-poultice previous night, and, at time of operation, soap and water and nail-brush to abdomen, vulva and vagina, followed by saturated solution of permanganate of potash and oxalic acid.

"Curetting: A plug of yellow tenacious mucus in os uteri. Uterus well forward in pelvis, and fixed. An exudation on the right, larger, and also on the left, smaller. Moderate divulsion. Curetting brought away a small amount of tissue. Cavity of uterus two and three-quarter inches deep, seemed to be empty.

"Cœliotomy: Incision in usual situation, three inches long. Very little oozing; walls thin. Omentum found to be adherent to bladder; easily separated, and fundus uteri presented in the wound. Patient placed in Trendelenburg posture. A mass in the right side of pelvis, size of closed fist, and made up of the ovary (normal in size), blood-clots (some of them partially organized), and a firm, hard body the shape and size of a hen's egg, apparently in the outer portion of the right Fallopian tube. Adhesions were broken up gradually, and the mass, with its sac walls of organized blood-clots, freed. The tube was tied off close to the uterus, and several adhesions were ligated with stout silk. Fair amount of oozing. On the left side the ovary and tube were held together by a mass of adhesions, the tube being somewhat thickened, the ovary normal except for the adhesions. There was also much old blood, some of which had extended forward of the fundus uteri into the bladder. The tube and ovary were removed by tying the broad ligament across with interlocking ligatures of stout silk, and a gaping portion whipped with fine silk. Considerable oozing. Patient lowered from Tredelenburg posture, and the abdomen flushed several times with hot salt-solution; toilet of peritoneum. Sterilized gauze packed into pelvis, one piece into each side, and incision closed with interrupted sutures of silkworm gut. Two stitches in lower angle of wound left loose for the gauze. Wound dressed with dermatol, gauze and collodion. Length of both operations one and one-half hours. Patient put to bed in good condition.

"The gauze was removed in twenty-four hours, under partial chloroform anæsthesia. The patient pushed the bed-blanket directly on the wound; and to this was due undoubtedly the mural abscess that developed in the lower angle of the wound during the next few days. Patient passed flatus per rectum in thirty-six hours, and did well, until, at the end of a week, she developed a neuritis in the right median nerve.

"May 8th, when she began to sit up, there was no evidence of any exudate in the pelvis, the uterus was free from adhesions, except some limitation of mobility of the fundus, apparently from its being attached to the abdominal walls. The incision had closed completely, except a shallow cavity at lower angle.

"The patient left the hospital well on May 20th."

The following is Dr. W. F. Whitney's report on the specimen:

"The specimen from the case of Mrs. L. consisted of both tubes and ovaries.

"One ovary and tube (the left) was more or less glued together by adhesions and old clotted blood, which seemed to be partly organized on the outer surface of the tube, which was slightly dilated near its end. The ovary was normal in size and contained numerous small retention cysts, but no recent corpus luteum.

"The other ovary and tube (the right) were covered by adhesions and clotted blood. Near the fimbriated end the tube was enlarged to the size of a small egg, and contained a firm dark-red mass, more or less streaked by whiter and slightly fibrous-looking lines. It was quite adherent to the wall of the tube, which was more or less thickened, except along the line of attachment where the structure was loose and villous in character. Microscopic examination showed the mass to be made up of clotted blood in which were entangled irregularly formed and fatty degenerated chorionic villi and clumps of large flat cells (decidual). No evidences of fœtal structure were found. In appearance and in structure the condition very closely resembles one of the so-called "fleshy moles," the product of a uterine abortion, and is without doubt the product of a Fallopian pregnancy. The ovary was of normal size, and contained numerous small retention cysts, but no recent corpus luteum.

"The scrapings from the uterus were simply blood and a little of the mucous membrane, but with no evidences of a decidual. The other pieces were simply masses of more or less decolorized and pigmented blood-clot.

"The case is one of Fallopian pregnancy, with hæmorrhage and early abortion.

"The conditions found on the surface of the uterus was probably due to a partial organization of the blood-clot.

"The specimen is entered under E. g. 25, and is

most interesting, especially in relation to the condition of the material in the tube, which I shall study carefully after hardening."

The following case is added, presenting as it does many interesting points of resemblance with the other cases, although it was probably only a case of hæmorrhagic salpingitis.

CASE III. Mrs. T. was brought to me in the outpatient department of the Massachusetts General Hospital on May 19, 1893, by Dr. McKenty, of Waltham, from whom I obtained a very good history of the case, and had the advantage of his previous examinations, which he had carefully recorded. He had made a probable diagnosis of extra-uterine pregnancy, but had also considered the diagnosis of fibroid. The patient was thirty-six years old, a multipara, having had three children (the last eleven years ago) and two miscarriages (the last seven years ago). Her catamenia were previously regular, and from March 6th to 11th she menstruated as usual. On March 15th she again began to flow, and continued up to her coming to the hospital, the flow being generally slight, but at times copious. With the first flow on March 15th she began to have pain, sharp and cutting in character, in the right iliac region. After April 10th the pain was less severe and less frequent. She had attacks of feeling faint at the time of this pain. The pain extended down the right leg.

On April 9th she was examined for the first time by Dr. McKenty, whose record is as follows: "Uterus normal in position, and movable. Movable mass situated behind lower segment of the uterus, and connected with it by a band-shaped peduncle. At first this seemed like a prolapsed ovary, but careful examination revealed what I considered the ovary at its outer border. Left ovary in position. Sound passed full depth."

Dr. McKenty examined her again on April 18th and 26th, and on May 5th and 15th. During this time the mass grew rapidly, and it became more intimately connected with the uterus. At no time was there any fever or signs of inflammatory trouble.

My examination in the hospital, May 19th, showed the uterus slightly enlarged, and pushed over to the left side. A mass, oval in shape and of the size of a large hen's egg, was felt in the right broad ligament, connected with the uterus by a slightly smaller pedicle. The mass was rather soft, but not fluctuating, at the outer extremity; elsewhere hard, but not as hard as a fibroid tumor.

The diagnosis of extra-uterine pregnancy seemed by far the most probable diagnosis; and the patient was prevailed upon to enter the house. She entered the service of Dr. H. H. A. Beach, who considered extra-uterine pregnancy the probable trouble, and who operated three days later, on May 22d, removing the right tube, distended with blood and partially ruptured. The specimen was sent to Dr. Whitney, who was unable to find either chorionic villi, decidual cells or part of fœtal structure. By exclusion, therefore, he considered it a case of hæmorrhagic salpingitis.

All the patients made good recoveries.

THE following remarkable verdicts are reported as returned by English coroners' juries: "Man, aged forty-eight, died from stone in the bladder, which stone he swallowed when lying on a gravel path in a state of intoxication." "Child three months old, found dead, but no evidence whether born alive."

Clinical Department.

POISONING BY VANILLA.[1]

BY JAMES C. WHITE, M.D.

I WANT to make brief mention of a rare case of dermatitis venenata, at least rare in this part of the world. A man came into my room at the hospital not many days ago with a puffy face, eyes partially closed, and presenting upon one wrist and forearm various forms of inflammatory lesions — papules, general redness, and a few vesicles. I asked him what his occupation was, and he told me that he had been twice affected in the same way since he had been engaged in his business for the past two years. This business was the management of a vanilla commission house.

Now, poisoning by vanilla pods or beans, in the countries where this plant is cultivated, is reported as not very infrequent among the workmen. This plant is cultivated in Mexico, Central America and the West India Islands, and also in the East. It grows best in Mexico. The beans are collected, put through a "sweating process," are turned frequently under blankets, and sometimes submitted to artificial heat until they assume a dark chocolate or blackish color. In handling these pods many of the workmen have a dermatitis produced upon their hands and face, and this inflammation of the skin has been attributed to two causes. An acarus affects the pods, and formerly these cases were attributed to the irritative action of this little insect upon the skin. But this is very improbable, because the inflammation comes on too rapidly, and is of a different type from that produced by the presence of any animal parasite upon the skin. In the best variety of pods no artificial means are used for coloring them. When I was writing upon this subject a few years ago, I took occasion to visit the establishment of Mr. Burnett, and inquired about the workmen employed in his factory. He said that no cases of vanilla poisoning had ever occurred there, and he attributed this immunity to the fact that he used only the highest quality of pods. The greatest care is taken in the care of the highest-priced pods, and after they reach the United States they undergo often an additional treatment, if they are not quite cured. They come in sealed tin boxes. Now in the lower qualities of pods it is known that an artificial method is used for coloring them black, and that this material is the oil of the cashew nut found in the rind, called cardol. This nut is the fruit of Anacardium occidentale, and is grown in the West Indies largely, and eaten both raw and roasted. The oriental species is called the Indian marking nut, as it has the same property of turning black any substance with which it comes in contact that the juices of the poisonous forms of rhus possess, and it has likewise the same poisonous quality that they have, so that many cases of poisoning are produced by persons handling without sufficient care these nuts. Charles Kingsley, in his work on the West Indies, describes several cases where cooks and others have been poisoned by roasting them. Cardol is used to color the poorer qualities of vanilla pods, such as these upon this plate, which are a part of the box which produced the poisoning in this patient. They are of the poorer variety, and are worth about four dollars a pound, whereas the specimens in the other tray are

[1] A communication to the Clinical Section of the Suffolk District Medical Society at its meeting February 15, 1893.

worth about twelve dollars a pound. The color of both is about the same. There is no doubt, I think, that these poorer ones have been colored by cardol.

Now, as rare cases are very apt to happen together, I may state that I have this winter seen my only case of poisoning by the cashew nut. A lady living in Cambridge had received from the West Indies some of these nuts, and in opening them she was very badly poisoned about her face and hands, presenting bullæ and vesicles and intense swelling lasting ten to fourteen days. There can be little doubt that these cases of so-called vanilla poisoning are from the cardol of this nut.

You may have heard of cases of internal poisoning by vanilla. When I was a student in Vienna, Professor Oppolzer used to say that patients could have any ice cream excepting that flavored with vanilla. Now it is known that cardol taken internally produces very serious irritative disturbance of the stomach, so that it is not improbable that these poorer forms of vanilla bean may have been sent to Germany, and that a possible poisoning by cardol from the ice cream flavored with vanilla may have ensued in some cases, which gave it the reputation it had in Vienna at that time.

I have never heard of any trouble from vanilla ice cream here, and supposed that it was a notion on the part of Vienna physicians. It is Dr. Shattuck's habit, he states, in suggesting ice cream for feverish children, to take pains to suggest that they had better have vanilla, as being more innocent than other kinds.

I might add that Mr. Burnett stated that he had never known an instance of vanilla poisoning by the internal use of his vanilla. He also said that his extract was largely used as a cordial, and that he had known of no trouble resulting therefrom.

AN EXTENSIVE INJURY OF THE CHEST.

BY O. T. HOWE, M.D., LAWRENCE, MASS.

On October 28, 1892, Fred. A., eleven years old, was caught between two freight cars in South Lawrence. The train was shifting and he attempted to go between two uncoupled cars; but the engine backed at that moment, and he was caught between the couplers. The engine was immediately started ahead, and the boy taken out. Despite his injuries, he walked home, nearly an eighth of a mile, and a physician gave temporary treatment.

The case was placed in my hands, and I saw him the next morning for the first time. The patient was then in a state of collapse; no pulse; the body bathed in cold sweat; and the bed afloat with blood. With every inspiration bloody foam came from the wounds, back and front.

According to his statement, the coupler-pin had passed entirely through the body. I gave a gloomy prognosis; but under stimulating treatment he slowly rallied. A careful examination of his injuries showed that four of his ribs in front and three behind, were crushed in, forming compound, comminuted fractures. The anterior wound was about four inches long, and had been drawn together by stitches. The posterior was on the same level, but smaller.

In a few days the stitches were taken out, and a drainage-tube passed through from back to front. It was then possible to look directly through the chest, and see the lung, partly collapsed, dilate with each inspiration.

The discharge of bloody serum for the first few days was very large, soaking through the antiseptic dressings in a few hours. This was followed by an equally large discharge of pus; but the boy continued to improve. He had a slight cough, which was very painful.

Three of the ribs which were broken at the anterior angle, gradually pushed their way through the skin, and protruded about an inch from the chest wall. The patient was etherized, all the loose fragments removed, the projecting ribs cut off, and the opening in the back enlarged. It was then possible to insert the hand in the anterior opening and examine the whole interior of the chest. The lung by this time had granulated and healed, and was much collapsed.

Healing was very rapid, and by May both wounds had completely closed. The chest wall on the injured side had collapsed so that it did not seem much thicker than a two-inch plank.

At present, August 10th, the boy is in good health, fat, with no cough. There is faint respiration on the affected side.

Medical Progress.

REPORT OF PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M.D.

BIOLOGY OF FIBROMYOMATA OF THE UTERUS.

Kleinwächter[1] from the study of forty cases of fibromyomata of the uterus, where he was able at longer or shorter intervals to make repeated examinations, has deduced the following conclusions as to their growth. He is unable to find any such law of growth as would enable him to estimate the age of a tumor from its size. They may grow very rapidly, and this is the rule in the majority of cases; exceptionally they grow slowly. Sometimes they have periods of growth, followed by periods of quiescence. It is rarely the case that before the menopause a tumor ceases to grow or becomes smaller. Ergotin may help in some cases, so, too, wasting diseases. Tumors sometimes diminish after the puerperium. The disappearance of fibromata after the menopause is by no means so common as has been supposed; not infrequently they increase in size, and it seems as if, at this time, there was the greatest danger of malignant degeneration. The cause of the different behavior of these growths is not clear. It may be due to a difference in the anatomical structure, according as muscular or connective tissue predominates. Also the original seat of the tumor or its germ may be of influence. Other causes may be its blood-supply and the presence of inflammatory processes in the neighborhood.

CURE OF MASTURBATION IN A WOMAN BY NEURECTOMY.

Dr. J. S. Eastman[2] gives the account of an aggravated case of masturbation cured by resection of the pudic nerve. The patient was a single woman of twenty-six years of age, who had masturbated since she was six years old. The indulgence was one or more times a week and even as often as six times in

[1] Zeit. für Geb. und Gyn., Band xxv, Heft 2, 1893.
[2] Medical News, August 12, 1893.

one day. For a while she indulged in coitus, though without satisfaction, yet was able to resist self-abuse while the opportunity for sexual intercourse lasted.

When this was no longer the case she reverted to her former habit. She then sought medical advice. She was blistered, silver-wire sutures were placed through the labia majora, the electro-cautery was applied, ovariotomy, and finally, clitoridectomy, were performed, all without avail.

As a last resort, Dr. Eastman having found that she was more sensitive on the left side of the vulva than on the right, cut down on the left pudic nerve, and removed about three inches of it. The result was perfect. The patient gained thirty-four pounds in weight and was completely cured of her habit of masturbation.

VAGINAL LIGATION OF THE BROAD LIGAMENT FOR HÆMORRHAGE.

Dr. F. H. Martin,[3] in connection with a case where the uterine arteries as large as lead-pencils were pumping blood into a large bleeding fibroid, conceived the idea of ligating them from the vagina, where they can be easily reached. To avoid the blood being supplied by collateral circulation, he advocates tying the main artery back of the uterine branch, and by including *en masse* the whole base of the broad ligament to shut off any anomalous branches should they exist.

The article goes on to describe the distribution of the arteries in the broad ligament, and then describes the operation, which consists in an incision in the vagina one and a half to two inches long, over each broad ligament and at right angles to it, freeing it in front, laterally, and behind, then passing a silk ligature so as to include all pulsating vessels and tying it tightly, an inch or more away from the uterus and closing the vaginal incision. He gives the histories of two cases, in which he had operated, and while the immediate effect was good, it was too recent to judge of the ultimate result.

He advises this procedure under the following conditions:

(1) Acute hæmorrhage from the cervix from all acute and chronic causes, which cannot be readily controlled by mild measures, as (*a*) rupture of the cervix in childbirth, by operation or any other cause; (*b*) cancer of the cervix.

(2) Hæmorrhage from the body of the uterus as a result of abnormal growths: (*a*) fibromyomata; (*b*) sarcoma; (*c*) carcinoma; (*d*) intractable hæmorrhagic endometritis.

(3) For the purpose of changing the nutrition of myomatous tumors so that they will shrink in size, and when of small dimensions disappear altogether.

RECURRENCE OF CANCER OF THE UTERUS, ESPECIALLY BY LOCAL INOCULATION.

Winter[4] makes the statement that, even with the advances of the last fifteen years, we can show but seven per cent. of lasting cures. Recurrence is the rule, and, in the vast majority of cases, is from local inoculation, most often the result of the leaving of bits of cancerous tissue, either outside of the field of operation or in contact with some wounded surface.

To avoid such an occurrence, Winter warns against handling the diseased tissues with the fingers, against tearing the tissues and advises frequent irrigation. Where the disease is within the cervix or body, the uterus should be washed out and the os uteri sutured. Disease of the vaginal portion should be made harmless by cauterizing it and by treating it with corrosive sublimate and Paquelin. Such preparatory measures should be taken immediately before the main operation, which should be done after fresh disinfection, with new instruments.

INDICATIONS, TECHNIQUE AND RESULTS OF OPERATIONS ON THE APPENDAGES.

Schauta[5] presented a paper on this subject before the German Gynecological Association at Breslau in May, 1893, of which the following is a synopsis:

(1) The frequency of inflammatory diseases of the appendages is according to Schauta's own material, 17.8%.

(2) A permanent return to normal conditions is not to be expected when the tube as a result of inflammatory changes has become as thick as a finger.

(3) The diagnosis of the contents of the enlarged tubes (whether sterile, or containing gonococci, streptococci or staphylococci) cannot be made with accuracy either from the history, the examination, or the course of the temperature.

(4) Fever temperatures may be found before the operation, in cases of sterile contents, and completely normal temperatures where the tubes contain pus with streptococci or staphylococci.

(5) The indications for operative treatment are present when the tube is the size of the finger and severe symptoms are present; in every case, however, where pus is present in the tube.

(6) In case of the escape of pus during the operation, the immediate bacteriological examination of the pus is of great importance.

(7) Where the tumors are of moderate size, and no pus is seen during the operation, it should be performed in the Trendelenburg position, and after complete separation of all the adhesions of the tubes with the surrounding parts, and thorough unfolding of the broad ligaments, continuous ligatures should be placed through the broad ligament and the isthmus of the tube, and then the tube should be cut away.

(8) In the case of large tumors lying close to the abdominal wall the procedure is as follows: The peritoneum is opened, and if the opposite side is diseased to a less degree, the appendage of that side is removed; the large tumor is brought up against the abdominal opening and attached to the parietal peritoneum around a small circumference; the rest of the abdominal wound is closed. Then the pus tube is punctured with a fine trocar, a portion of its contents aspirated, and immediately subjected to a bacteriological examination. If the pus proves to be sterile the sac is immediately opened to the extent of the exposed surface, washed out, the peritoneal sutures separated and the sac removed in the usual way. Should the pus prove to contain strepto- or staphylococci, the operation is temporarily suspended, and only after four or five days when the peritoneal cavity is completely shut off is the incision and drainage of the tube carried out.

(9) In case of large pus sacs lying close to the vaginal vault, the opening from the vagina is indicated. Still in general the abdominal method is to be preferred since in the vaginal method one is denied the possibil-

[3] American Journal of Obstetrics, April, 1893.
[4] Archiv. für Gyn., Band 44, Heft 3.
[5] Cent. für Gyn., No. 22, 1893.

ity of seeing the condition of the other side, or of operating on it, unless the method of total extirpation of the uterus according to Péan is followed.

(10) In cases of medium sized tubes (size of an egg to that of an orange) laparotomy with careful avoidance of opening the sac is to be carried out. Should the sac burst, the pus should be immediately examined. If sterile, or containing gonococci the abdominal wound may be closed as usual; if containing strepto- or staphylococci Douglas's pouch which has been in contact with the pus should be drained after the method of Mikulicz.

(11) The draining of Douglas's cul-de-sac is effectual first by drawing off the secretions, but principally by the speedy formation of adhesions which separate the part to be drained from the rest of the peritoneal cavity.

(12) The mortality of Schauta's 216 cases from February, 1887, to April, 1893, was 13 or 6%. Two of these, however, died of pneumonia.

(13) The mortality of the cases of operations on the tubes where no pus or only sterile pus was found was 2.8% (four out of one hundred and forty-four); the mortality where gonococci were found in the pus was 9% (three out of thirty-three); the mortality where strepto- or staphylococci were found was 20% (three out of fifteen). Of the cases of the last category, with escape of pus, of six drained, one died, of five not drained, two died; of cases of laparotomy without escape of pus, and a second operation later, and of vaginal opening (four cases) none died.

(14) For the estimation of the final results, Schauta has reports of 121 cases. One hundred were free from any disturbance, in 17 cases there was marked improvement, in four cases the old troubles persisted. The percentage of cures therefore was 82.6%.

THE PALLIATIVE TREATMENT OF CARCINOMA OF THE CERVIX UTERI.

Sänger[6] says that on taking a historical view of the methods of treatment of carcinoma of the uterus, it is noteworthy that long before the total extirpation of the diseased organ was thought of, C. v. Braun was able to show 20% permanent cures with the galvano-cautery wire, a percentage which, according to Winter, has only increased to 25% after total extirpation. It is a sad fact that only one-fourth of the patients come to the gynecologist in time for a radical operation. Cases which are far advanced, that is to say, where the disease has invaded the vesico-vaginal septum, the tissues around the cervix and more remote portions of the pelvic connective tissue, can only be treated palliatively.

Palliative treatment is either operative or non-operative. The last comprises astringent disinfecting injections, tamponing with soluble specifics, or the use of powders and caustics, and medicated injections.

The most favorable method is the use of caustics after thorough curetting. The course is as follows: curetting, cauterization with Paquelin, and after the separation of the slough, tamponing with chloride of zinc. This is applied in a solution of two parts to three of water, dropped upon thin layers of cotton, these well squeezed out and laid upon the granulating surface, and the vagina filled with dry cotton.

In conclusion, Sänger gives a new method which consists in the burning out the cervix with the thermo-cautery knife, not from the surface of the cancer but from the side of the healthy tissue. The technique is as follows: a broad speculum is used for the posterior vaginal wall. What remains of the cervix is seized with forceps and drawn down. First, a circular separation of the vaginal vault, then under control of the catheter, of the vesico-cervical septum, then of one parametrium, of the retro-cervical connective tissue, and finally of the other parametrium. Gradually this is carried on up to the peritoneum, then the cervix is burnt square off, and the mucous membrane of the body of the uterus cauterized as far as it can be reached.

Occasionally must the bleeding vessels be tied. Then an iodoform gauze tampon, and after the separation of the slough, cauterization with chloride of zinc. Of five cases so treated, only one showed a recurrence, the first having been nearly three years free.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

Regular meeting, June 10, 1893, the President, Dr. Charles M. Green, in the chair.

Dr. F. B. Harrington read a paper on

INTRAPERITONEAL CYSTOTOMY,

in which he showed the great advantages of this operation in giving a large and clear view of the bladder field.

Dr. M. H. Richardson considered the operation a distinct improvement on the ordinary suprapubic method. The objection might be raised that there was more danger of sepsis. He did not believe that urine is aseptic, but in the method described of using gauze in the Trendelenburg position, he considered this danger very slight, certainly less than in operations where the alimentary canal was opened. The great advantage of the operation was that one could see to work intelligently and this advantage counterbalanced any disadvantage there might be. He intended to try the operation, and expected good results.

Dr. H. H. A. Beach said that the operation certainly seemed a very practical one. As to the septic danger, he saw no more than in salpingitis. It was certainly an important method where ample light in the interior of the bladder was needed. He suggested, in addition to the precautions advised, the use of a dentist's rubber dam slipped over the bladder.

Dr. S. J. Mixter was so fortunate as to see Dr. Harrington operate in this manner, and was impressed with the good view of the interior of the bladder and the ease with which a new growth could be removed. Some years ago he saw a case in Vienna where the bladder was opened in the same way for an enormous stone that filled up the entire viscus.

A temporary packing with iodoform gauze in the abdominal cavity might be necessary in certain cases to prevent the escape of urine, the packing being left in twenty-four hours, until first intention was obtained.

As to the septic qualities of urine it was the case that extravasation of urine, behind a stricture, was surely followed by abscess. Of course, the urine was

foul in these cases, but it generally was when the bladder had to be opened. Hence, contamination of the peritoneum would be likely to cause peritonitis.

DR. H. H. A. BEACH mentioned a case where the round of a chair entered the rectum and tore into the bladder through the prostate. Here, with a healthy bladder and urine, the patient escaped peritonitis.

DR. F. B. HARRINGTON said, that, as to the urine, there was no doubt that foul urine was septic, and he thought that any urine allowed to stay in the abdominal cavity would set up peritonitis; but where it was at once wiped away he did not think the patient would suffer. The rubber dam suggested by Dr. Beach he thought would answer very well in some cases. By this operation it was very easy to take out a section of the bladder an inch wide, as in cases of epithelioma; and he was much impressed with the ease with which the whole bladder field could be viewed and operated on.

DR. M. H. RICHARDSON read a paper on

HYSTERECTOMY FOR CANCER OF THE CERVIX BY COMBINED ABDOMINAL AND VAGINAL DISSECTION.[1]

DR. F. B. HARRINGTON said that the combined method promises increased advantages. In either of the older methods it was difficult to avoid the ureters, the cutting of which was frequently the cause of death.

DR. J. G. BLAKE said he himself was in the habit of curetting and cutting off as much of the disease as he could, keeping it thus under subjection, and relieving the distressing symptoms. This palliative operation is simple, and without risk to the patient, while hysterectomy was, at its best, by the combined method, a much more dangerous operation. Moreover, he had found, on looking up the subject, that the ultimate results were no better by the radical operation, all the patients being dead inside of five years. He would therefore prefer the simple palliative operation.

DR. J. R. CHADWICK said he had done seven or eight vaginal hysterectomies and two abdominal ones. He had found that the results, in his own and others' experience, from the abdominal operations not as good as from the vaginal, notwithstanding the greater dangers of this latter method, in which one was obliged to work in the dark, and where it was so difficult or impossible to make the vagina aseptic.

DR. BEACH said he thought comparison of statistics on these two operations was hardly fair, for the abdomen is generally opened in the severest cases.

DR. M. H. RICHARDSON said that the operation had a very limited field, He had seen an enormous number of cancers of the uterus, and of these only four where he believed the operation was justifiable.

DR. CHARLES W. TOWNSEND reported

CASES OF EXTRA-UTERINE PREGNANCY.[2]

DR. H. H. A. BEACH said that the surgical side of the interesting cases presented by Dr. Townsend demonstrated clearly certain advantages to the patient from an early diagnosis and a prompt exploration of a pelvic cavity under suspicion. It was of the first importance that an operation of the magnitude of a laparotomy, which also involved the possibility of an increase of hæmorrhage already existing, should be undertaken, if a choice could be made, at a time when the general condition promised rapid recovery. Such a condition was not likely to be associated with the anæmic and debilitated patient enfeebled by successive hæmorrhages, with or without the addition of a septic element due to the putrescence of clot which might have been effused into the pelvic peritoneum or into the broad ligament. So unfavorable an element in the case was to be avoided only by an early removal of the clot, which was as likely to complicate the healing process as it was the operation. Other important advantages accruing to the patient through early surgical treatment were the ample time afforded for critical and careful examinations, such as would hardly be permissible in desperate cases where life hung on a few moments, more or less, in the preparation for operation; and last, but by no means least, the deliberation with which the most rigid antisepsis could be applied throughout an operation. Inadequate antisepsis in these cases, unless practically impossible, was almost criminal; and we all knew the value of time in that part of the preparations. It was hardly necessary to allude to the great advantages in the use of the Trendelenburg position in these cases. The intestines were so rapidly and easily moved from the field of operation that he did not need to urge its value for those who had used it and seen it used. After the toilet of the peritoneum, the wounds were closed with deep stitches of silkworm gut, apposing the peritoneal surfaces with superficial stitches of fine silk.

In addition to the cases reported by Dr. Townsend, he added the notes of another that was sent to the hospital by Dr. J. R. Chadwick. The patient entered the hospital May 5th, with the history of pain in the stomach, and indigestion, for about a month. She had taken cold in the early part of April, while menstruating (second day). A few hours after, she noticed that the flowing had ceased, and she was seized with severe pain in the pelvis. Hot applications relieved the distress, but did not bring on flowing. She was able to go out later in the evening to the theatre. Two days later, flowing appeared, without clots. Was feverish, and feeling poorly during the rest of the month. In the last week of April the old pain returned with greater severity, and after a night of excruciating suffering she sent for her physician, who treated her during the week, and, as the pain continued severe, called Dr. Chadwick in consultation, by whom she was referred to the hospital.

Upon entrance her temperature was 101.5°, and her pulse 110. This condition quieted down to normal, with poulticing and hot douching. As soon as the tenderness had subsided so that an adequate examination could be made, there was evident an enlargement of the right Fallopian tube, and a larger mass below it and extending toward the posterior cul-de-sac. The menstrual dates were not certain. The last child was eight years old, and there had been opportunity for pregnancy. There was no history of continuous flowing. The uterus slightly enlarged. Laparotomy advised. Upon opening the abdominal cavity the right tube was seen distended by clot, which was just upon the point of rupturing backward into the peritoneal cavity. The tube was tied off and excised; as it was lifted, a second cavity was found, extending downward between the layers of the broad ligament, and forming the larger mass before alluded to. It was distended with nearly a pint of dark coagula, which were carefully removed, and the cavity sponged until it was dry, after which the abdomen was tightly closed without

drainage. The temperature rose to a fraction above 100° on the second day, and after that ranged about normal. The wound healed solidly, and all the stitches were removed on the seventh day.

Dr. S. J. Mixter reported

A CASE OF OVARIAN TUMOR WITH TWISTED PEDICLE; OPERATION, RECOVERY.

He also reported

A CASE OF FIBROID OF THE UTERUS; HYSTERECTOMY, RECOVERY.

Specimens were shown.

Dr. F. B. Harrington said he had been taught that a pregnant fibroid uterus would take care of itself; but this was not always so. He had recently seen a case of multiple fibroids of the uterus where both mother and child died. He regretted that he had not removed the uterus at an early stage.

Dr. J. G. Blake mentioned a case of fibroids that miscarried, and it was with great difficulty that he could get out the placenta and membrane, as he had to curette around corners, so to speak. The patient finally recovered.

Dr. C. M. Green said there had been a number of cases of fibroids complicating delivery at the Boston Lying-in Hospital. He recalled one case he had seen with Dr. Boardman, where the pelvis was at first entirely blocked up; but the tumor receded, and the patient was delivered. In another case the same thing happened. And in a recent case, it seemed impossible for the child to be born; but the tumor receded, the child was delivered, and by the time the patient left the hospital, the fibroid had so diminished in size there was but little remaining.

Cases of fibroid tumors might or might not go to full term. The great majority did so, and got on well. There had been probably five cases at the Lying-in Hospital where the tumors were so obstructive that an abdominal operation was thought of, but all delivered themselves through the natural passages.

He would doubt very much whether Dr. Mixter's case would have gone to full term.

Dr. J. R. Chadwick had seen fifteen or twenty cases of fibroids complicating pregnancy; and with one exception they all went to full term. There was a little tendency to uterine inertia and hæmorrhage, but he considered it a happy thing for a fibroid uterus to become impregnated, for in a large proportion of the cases the fibroids diminished in size after delivery.

AMERICAN NEUROLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, Long Branch, N. J. July 25, 26 and 27, 1893.

(Concluded from No. 17, page 424.)

TABES AND SYPHILIS.

Dr. H. Sachs, of New York, assumed that recent statistics of Erb and others proved the close relationship between syphilis and tabes. This was established furthermore by:

(1) The frequent occurrence of general paresis with tabes, and of tabes in the course of general paresis.

(2) The occurrence of symptoms in the course of tabes which are often due to syphilis: the ocular palsies, loss of pupillary reflexes and even the lightning pains.

(3) The effect of mercurial and iodide treatment upon many of the symptoms of tabes.

The writer attempted a clinical differentiation of cases of tabes which are due to an active syphilitic process; among these he considered those which exhibit complete loss of reflex contractility of one or both pupils, and ocular palsies. He reported at length a case of typical tabes, in which on post-mortem examination a more recent syphilitic process was superimposed upon an old typical sclerosis. He next referred to the way in which syphilis might cause a spinal sclerosis. He gave reasons for thinking that this was largely due to degeneration brought about by syphilitic disease of the blood-vessels to the spinal cord. Altered states of the blood might be the prime cause of the change in the blood-vessels.

Dr. Preston regarded the syphilitic process as an arterio-sclerosis. Rarely is there hyperplasia of neuroglia, without changes in the cells or nerve-fibres. The tabetic process probably begins in the blood-vessels. Traumatism seemed to be a most important etiological factor. He had seen improvement and relief of pain from the use of nitro-glycerine.

Dr. Mills looked upon the active lesions described by Dr. Sachs as probably causative of the sclerosis. Preceding the development of the sclerosis there may be lepto-meningitis and disease of the vessels, which, if attacked early, might be relieved or removed; but the sclerosis once established, recovery is impossible. Posterior sclerosis often advances at intervals by jumps, and these jumps may be sometimes coincident with, or they may follow the revival of active syphilitic processes.

Dr. Parsons referred to two cases of syphilis followed by insanity and subsequent development of spinal symptoms.

Dr. Seguin still adhered to the idea that syphilis was only a predisposing cause for the groundwork of tabes. Certain cases occur that were undoubtedly free from any history or evidence of syphilis.

Dr. Knapp mentioned a case of primary syphilis being superadded to tabes of two or three years' standing.

Dr. Spitzka did not doubt that cases of tabes existed without syphilis. He had called the attention of the Association to the same pathological condition about eight years ago.

Dr. Walton thought the frequency of trauma in the production of tabes was overestimated. The ascending degeneration resulting from transverse lesions of the cord or from fracture can hardly be regarded as a typical tabes. If we could get at the real facts in all cases, the cases in which syphilis existed without our being able to elicit the history would more than counterbalance those in which we may mistake a chancroid for a sign of syphilitic infection.

Dr. Gray said that there was an anatomical explanation for every symptom in tabes. In all cases he had seen he could differentiate between spinal syphilis and tabes.

Dr. Sachs did not claim that spinal syphilis is the same as tabes. We should never omit prescribing the most active anti-syphilitic treatment in the early stages of tabes. He did not believe every case was due to syphilis. In the large majority of cases syphilis was the prominent factor.

A NEW PEDODYNAMOMETER.

DR. WM. C. KRAUSS, of Buffalo, exhibited a new pedodynamometer. The apparatus consists of a wide heavy belt, its inner surface padded so that its adjustment around the waist will not be uncomfortable. A heavy webbing is looped through the belt passing over the shoulders, which helps to retain the belt in position. A common dynamometer is connected with the belt by means of a strong adjustable strap, permitting it to be lengthened or shortened according to the stature of the patient. Connected with the dynamometer is a stirrup, the base of which is padded for receiving the foot. Pressure exerted upon the stirrup will be registered upon the dial of the dynamometer, and the exact strength of the extensors of the leg can be thus ascertained. The apparatus can be applied either in the standing or recumbent posture. The leg should be flexed about ninety degrees at the knee. To tell the strength of the calf muscles, the strap should be lengthened and the foot flexed upon the leg.

INFECTIOUS ENDOCARDITIS WITH GENERAL SEPTICÆMIA COMPLICATED WITH MULTIPLE NEURITIS.

This paper was a joint communication by DRS. JAMES H. LLOYD and DAVID RIESMAN, of Philadelphia. It was founded on the report of two cases.

The first case was in a man who was admitted to hospital with a typhoid type of fever which had continued for three months, and was complicated with multiple neuritis. The diagnosis of typhoid fever was excluded. The neuritis was irregularly distributed. The patient gradually developed an aortic regurgitant murmur, with water-hammer pulse. Later, a purpuric eruption appeared. A diagnosis was made of infectious endocarditis with secondary septic neuritis. At the post-mortem, immense vegetations were found on aortic valves, with infarcts in the spleen and in one kidney. Sections of the spinal cord and nerves were shown, exhibiting slight posterior sclerosis in the cord and extensive inflammation in the nerves.

The second case, also in a man, simulated typhoid fever, with yellow-colored stools. At the post-mortem, multiple abscesses in the brain, a large embolus in the left brachial artery and an infarct in one kidney were found, dependent upon a giant growth of vegetations as large as a pullet's egg attached to the inner coat of the aorta, overhanging the orifices of the innominate, carotid and subclavicular arteries.

DR. DANA regarded the septic origin of neuritis of much importance. He cited the case of a young man with symptoms of rheumatism not responding to antirheumatic medication. Pyelitis developed in two or three weeks, followed by multiple neuritis affecting all extremities. It is well known that multiple neuritis in this country is most frequently due to alcohol, and not of microbic origin. These forms of neuritis have a different clinical history. Some cases have begun with a history of multiple neuritis, and have then shown symptoms of locomotor ataxia or other spinal cord affection. There is also a class of cases where the neuritis extends and ultimately involves the spinal cord.

DR. DERCUM agreed with Dr. Dana's views and believed posterior sclerosis occasionally followed multiple neuritis. He asked if septic symptoms preceded the neuritis in Dr. Lloyd's case with history of alcoholism; to which Dr. Lloyd answered yes.

TUMOR OF THE ANGULAR GYRUS.

DR. G. L. WALTON, of Boston, reported a case of tumor involving the angular gyrus and extending into the temporal, occipital and parietal regions. The symptoms were temporal and occipital headache, vomiting, paralysis of the left abducens from pressure, double optic neuritis, hemianopsia, word-blindness, aphasia and word-deafness. Operation was attempted by Dr. Richardson, of Boston. The tumor, however, proved too large and diffuse for removal. The patient lived two months with comparative relief of pressure symptoms, including abducens paralysis. Toward the end, the right hand and arm became somewhat paretic. The autopsy showed the growth to be a glioma.

DR. SEGUIN suggested that the ocular symptoms were probably not due so much to lesion of the angular gyrus as to involvement of the fibres of the fasciculus opticus which lie immediately under it. The lesion being rather deeply placed must necessarily involve the white fasciculi.

DR. WALTON agreed with Dr. Seguin that the hemianopsia was due to affection of the optic radiations on their way to the occipital lobe. The early appearance of mind-blindness together with red spots in the field of vision suggested early cortical irritation in the region of the angular gyrus.

If the symptom mind-blindness is considered due to affection of association fibres, we are justified in assuming the association fibres implicated to be those running to the angular gyrus.

CONGENITAL CEREBRAL HEMIPLEGIA WITH AUTOPSY.

DR. E. D. FISHER, of New York, read the history of a case of infantile cerebral hemiplegia of congenital origin. The symptoms were a complete right hemiplegia, with marked atrophy and exaggerated reflexes, epilepsy and imbecility. The cranial measurements showed morbid deficiency in the binauricular diameter and facial length. At the autopsy, the left hemisphere was found much atrophied. The right cerebellar hemsphere was also atrophied. The microscopical specimens showed a decrease in the number of cortex cells, but those present were not much diminished in size. There was some loss of acuteness of the angles of the cells but little pigmentary or granular changes. The cord was but slightly affected. He believed that this would seem to show that in some cases we may have a fair amount of normal cerebral structure even when there is such pronounced cerebral disease.

DR. SACHS said that in the cases in which motor areas present developmental defect, degeneration does not necessarily occur.

LESION OF THE THALAMUS AND INTERNAL CAPSULE.

DR. CHARLES K. MILLS, of Philadelphia, contributed the notes on a case in which there was a lesion of the thalamus and internal capsule.

The patient had an apoplectic attack in 1877, and died in 1892. The symptomatology of the case, summarized, was hemianæsthesia, paresis with contractures not marked, inability to recognize position of the affected limbs. Hemianopsia, and all affections of the special senses were absent, as were also athetoid and choreoid movements. Autopsy showed a hæmorrhagic cyst which had destroyed about two-thirds of the substance of the thalamus, including the entire external

tubercle and a large portion of the pulvinar. The anterior extremity and the internal and inferior surfaces of the thalamus were intact. The lesion has invaded to a slight extent the posterior arm of the capsule.

TUMOR OF THE OPTIC THALAMUS.

Dr. Wharton Sinkler, of Philadelphia, read a paper on this subject, and presented the specimen from a case with the following history:

The patient was an unmarried woman, forty-six years of age, who was in excellent health up to January, 1893. Her first symptoms were somnolence and loss of mental vigor. Her manner was indifferent and listless. In April there was some aphasia, and, later, paresis of the right side of the face, unsteadiness of gait, and awkwardness in the use of the right hand. When first seen by him, there was marked paralysis and partial anæsthesia of the right side of the face, but no impairment of sensation of the arm or leg. There was decided mental hebitude but no loss of memory. She could not walk on account of unsteadiness. The knee-jerks were exaggerated. The temperature was subnormal, and the pulse from 48 to 60. The pupils responded to light and accommodation. There was no nystagmus or hemianopsia and no change in the fundus oculi.

The symptoms increased in severity, the temperature rose rapidly, and the patient died May 25th. There had been no convulsions.

Post-mortem showed skull and membranes healthy. Cortex normal in color and consistency. The left optic thalamus was the seat of a growth as large as a hen's egg, which encroached upon the corpus striatum and posterior part of the internal capsule. The tumor has not been examined microscopically, but is probably a fibroma.

The points of interest are the hysterical symptoms which were present at the onset; the fact that the anæsthesia was confined to the face; and the question which arose as to the possibility of operation.

These two papers were discussed together.

Dr. Dana had two cases, one with tumor and another with softening in that region. Somnolence was a prominent symptom. The phenomenon of somnolence is characteristic where the posterior portion of the optic thalamus and the neighborhood of the corpora quadrigemina were involved.

Dr. Seguin observed a patient with probable tumor in this locality, with somnolence which was increased by the use of iodide of potash. He asked if such effect of the iodide had been observed by any of the members present.

Dr. Dana was familiar with a case where the iodide acted as a hypnotic.

Dr. Gray had noticed that iodide had produced somnolence in a case of cerebro-spinal meningitis.

Dr. Leszynsky thought that iodide only acted indirectly as a hypnotic by relieving the pains of syphilis.

Dr. Sinkler remarked that in his case the somnolence diminished after the administration of the iodide.

THE LOCALIZING VALUE OF APHASIA.

Dr. George J. Preston, of Baltimore, read a paper upon this subject, and called attention to the fact that aphasia has hardly commanded its proper place in the domain of cerebral localization. The centres for the speech processes, and the visual and auditory centres, were described. In connection with word-blindness, two cases of hemianopsia were related, one with autopsy, in which there was no word-blindness, as might have been expected. A case of mixed aphasia was related and the brain exhibited. The case showed absolute motor aphasia, together with word-blindness; and yet the lesion was confined to the third frontal convolution, the occipital cortex showing no disease. The general value of speech disturbance, as an aid to localization, especially in disease or injury of the brain, was discussed. A case was reported in which there was a general speech disturbance, with distinct mental symptoms; patient was at times maniacal. Upon the strength of the general disturbance of the speech processes, the skull was trephined over Broca's region, and the under surface of the dura found covered with blood. This case was mentioned to show how valuable speech disturbances may be, although very general in nature and not belonging to any recognized variety of aphasia.

SPINAL NEURASTHENIA.

Dr. Leonard Weber, of New York, presented a contribution upon this subject. He objected to any single plan of treatment, as too much routine, and not likely to be of permanent service to the patient, while a proper combination of the well-known methods based upon careful individualization were apt to be of greater benefit.

In the grave forms of neurasthenia caused by mental and physical overwork, the prognosis so far has not been good, even as to relative recovery. If the reports can be trusted, it would seem that we have in hypnotic suggestion a remedy of extraordinary power in some of these cases.

In conclusion, he related the history of some cases of severe neurasthenia brought about by protracted mercurial inunction, and another caused by prolonged daily use of small doses of Carlsbad Salts. Both recovered at the end of about a year.

THIRD DAY. — THURSDAY.

OBSERVATIONS IN A CASE OF MYXŒDEMA.

Dr. Wm. C. Krauss, of Buffalo, read a paper with this title. He reported a case of myxœdema in a woman fifty-three years old, whose mother was afflicted with symptoms similar to the patient's. The patient had always been in good health up to her forty-sixth year, although she had never perspired and the secretions as saliva, nasal mucus and milk were always scanty. Following upon an accident, her face, body and extremities became swollen, her hair suddenly disappeared from all parts of the body, and she was troubled with severe pains (especially through the temples) and a tired, all-gone feeling, incapacitating her for all kinds of manual labor. She further complained of a feeling of coldness even in midsummer. Her hands were dry, harsh and scaly; her face waxy; her eyes puffy and swollen. Her temperature ranged from 95.4° F. to 97.4° F. Her pulse, soft, regular and uniform, varied from 81 to 88 per minute. The œdema-like swelling did not pit on pressure. Urine normal; no albumen at any time. The only drug that acted beneficially was the perchloride of iron.

The author experimented with thyroid glands of sheep, feeding her for six weeks, but could detect no improvement whatever. Another case seen in consultation was being treated with desiccated thyroids, also without benefit.

SIMULATION IN TRAUMATIC NERVOUS DISEASES.[1]

DR. PHILIP COOMBS KNAPP, of Boston, in reading a paper with this title, said that although many men will simulate disease if it be to their advantage, we rarely find successful simulation of the various traumatic nervous affections. Until recently few cases have been reported by neurologists; most of the old cases were reported by general practitioners whose knowledge of nervous diseases was limited.

In non-traumatic hysteria and neurasthenia we see many symptoms which would lead us to judge that the symptoms did not really exist. Many persons unjustly accuse the victims of these diseases of pretending to be ill, when really the malady is a serious one.

Contraction of the visual field, anæsthesia, tremor, disturbances of the reflexes, circulatory disturbances and Mannkopf's symptom are to be regarded as important objective signs. Few simulators can have intelligence enough to withstand a searching examination by a skilled neurologist.

Furthermore, a man can keep his attention fixed on any subject only for a very brief time; and if he must be prepared to defend his simulation of half-a-dozen different symptoms, he will inevitably be tripped up by unexpected tests applied when his attention is diverted.

Three cases were cited in which the defence claimed that there was simulation, but in every case objective evidence proved the reality of the disease.

Out of fifty cases where claims for damages had been brought forward, only two could be regarded as simulating, and few as exaggerating, and in most of these there was little reason to suppose any deliberate attempt at fraud.

DR. MILLS believed absolute simulation very infrequent. The cumulative exaggeration of symptoms was comparatively frequent, however. A few people can simulate a type of insanity or traumatic neurosis, but cannot easily simulate all the symptoms and signs. He was in favor of the convex-lens test for amblyopia instead of prisms in these cases. He did not consider malingering of common occurrence.

DR. GRAY thought many cases supposed to be simulating are simply offering to the trained eye symptoms indicative of possible simulation. He related a case of traumatic neurasthenia cured by one one-hundred-and-twenty-fifth of a grain of atropine taken for two days.

DR. FIELD considered simulation rare. Gross exaggeration was common in these cases. In almost all there is some exaggeration of the symptoms.

DR. LLOYD regarded the symptoms of traumatic neurasthenia as nothing but the interparoxysmal symptoms of hysteria. Because a man develops hysteria after an accident, there is no reason to believe that he must be a simulator.

DR. SEGUIN said the influence of the attending physician is often pernicious to the patient. He may not actually coach him, but he suggests. Some patients take advantage of a pre-existing morbid affection. The absence of treatment is responsible for a continuance of the symptoms of traumatic nervous affections. We should be allowed to examine these cases unexpectedly, unguardedly and thoroughly, and not when sympathetic physicians or counsel are present. He protested against Dr. Lloyd's remarks about the unity of hysteria and traumatic neurasthenia.

[1] See page 318 of this volume of the Journal.

DR. KNAPP, in conclusion, said that he had seen cases with minor exaggeration, in contrast to Dr. Field's cases of the grossest exaggeration. He agreed with Dr. Seguin regarding the absence of treatment, but he had had a number of cases where treatment had been early and properly instituted. He could not agree with Dr. Lloyd's style of nomemclature.

STAINING WITH NIGROSIN.

DR. SEGUIN exhibited a specimen stained with 1 to 2000 nigrosin, a method he had used years ago, but neglected to publish. One of the advantages was that specimens may be safely left in the solution for twenty-four hours.

THE MICROBIC ORIGIN OF CHOREA WITH A CASE.

DR. C. L. DANA, of New York, read the history of a case of chorea, with autopsy.

The patient, a man of twenty-six, had had chorea since the age of fifteen. The attacks came exactly like those of ordinary chorea of Sydenham. At first there were intermissions, but the disease finally became chronic. The spasmodic movements were general and violent. There was no heart disease or rheumatism. The patient died from exhaustion. Post-mortem showed macroscopically a conspicuous chronic leptomeningitis, involving the vertex of the brain. Microscopically this was found to be mainly a proliferation process, without exudation or much cell-infiltration. In the superficial layer of the cortex there was cellular infiltration and degenerative changes. At this point a diplococcus was found. Full details were given of this by Dr. Brooks, the bacteriologist. The micro-organisms were found only in the deep layer of the pia and the superficial part of the cortex. In addition, there were found peculiar hyaline bodies in the three outer layers of the cortex, and less numerously in the basal ganglia. There were evidences of meningeal irritation, vascular disease (arteritis) and nerve-root irritation in the medulla and upper part of the cord. The lower part of the cord was not examined.

ELECTION OF MEMBERS.

The following named gentleman were elected to active membership: Dr. Brower, of Chicago; Dr. Burr, of Philadelphia; and Dr. Diller, of Pittsburg. Dr. Arnold Pick, of Prague, was elected an associate member.

PAPERS READ BY TITLE.

"The Genesis of Hallucination, Illusion and Delusion," by Dr. H. A. Tomlison, of St. Peter, Minn.; "The Diagnosis of General Paresis," by Dr. L. C. Gray, of New York; "A Report of Two Cases of Friedreich's Disease," by Dr. Frank R. Fry, of St. Louis; "The Metapore or Foramen of Magendie in Man and in the Orang," by Dr. Burt G. Wilder, of Ithaca; "Observations on the Relation of Chorea to Rheumatism," by Dr. C. Eugene Riggs, of St. Paul; "Experiences in the Use of Testiculine and Cerebrine," by Dr. J. J. Putnam, of Boston; "Peripheral Paralysis after Surgical Operations," by Dr. V. P. Gibney, of New York; "Traumatic Brachial Plexus Paralysis in Infants," by Dr. Wm. M. Leszynsky, of New York.

ELECTION OF OFFICERS.

The officers elected for the ensuing year were: President, Dr. B. Sachs, of New York; Vice Presidents, Dr. F. X. Dercum, of Philadelphia, and Dr. P.

C. Knapp, of Boston; Secretary and Treasurer, Dr. G. M. Hammond, of New York; Councillors, Dr. E. C. Seguin, of New York, and Dr. J. H. Lloyd, of Philadelphia.

In the evening a banquet was given by the Association, at which nearly thirty members were present.

Recent Literature.

A Text-Book of Medicine for Students and Practitioners. By DR. ADOLF STRÜMPELL. Second American edition, translated by permission from the second and third, and thoroughly revised from the sixth German edition, by HERMAN F. VICKERY, A.B., M.D., and PHILIP COOMBS KNAPP, A.M., M.D. With editorial notes by FREDERICK C. SHATTUCK, A.M., M.D. With one hundred and nineteen illustrations. New York: D. Appleton & Co. 1893.

The first American edition of this text-book of medicine was published in 1886. Its reception and continued popularity have justified the undertaking of the translators and editor; and its increasing use, as well as the numerous changes in facts and opinions brought about by the last six years, have demanded a second edition. The position occupied by the book in Germany is shown by the fact that it has reached a sixth edition, the fifth having been exhausted in the course of one year.

This translation is used as a text-book or as a work of reference in some twenty-eight medical schools in America. The present edition contains an entirely new chapter on influenza; quite important changes and additions have been made in the chapters on cholera, malaria, diseases of the nose and larynx, syringomelia and diabetes. In the present American edition the editor has omitted some notes, changed others, and added some new ones.

Those who know the previous edition will desire to have this one, and those who want a first-rate medical text-book, and did not have the previous edition, certainly require this. We know of no better book of its kind.

Recent Developments in Massage. By DOUGLAS GRAHAM, M.D. 12mo, pp. v, 128. Second edition, with seventeen illustrations. Detroit: George S. Davis. 1893.

This little volume of the Leisure Library is rather a supplement to the author's larger work, than an independent treatise on massage. The author has collected many new cases, showing various affections in which massage has been tried. The most important chapter is that on the use of massage in sprains, dislocations and fractures, in which considerable evidence is brought forward in behalf of the early use of massage, in place of the absolute immobilization now in vogue.

A Physician's Pocket Chart-Book. By J. A. HOWKINS, M.D. New York: Bailey & Fairchild. 1893.

This little book of charts, of a size to be carried in the pocket, will undoubtedly prove of considerable use in the keeping of clinical notes.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 2, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

SEROTHERAPY.

EGASSE discusses Serotherapy in a memoir not yet completed.[1] His article is of value rather as being a summary of progress already achieved than as containing original matter. Old cultures of human tuberculosis injected in dogs, render them immune against the strongest new cultures; the blood-serum of these dogs confers immunity against tuberculosis if injected in other dogs; in fact, it is not only preventive but curative, modifying or arresting the disease in animals already tuberculous. The animals under experimentation were dogs and guinea-pigs; the principal experimenters have been Bernheim, Richet and Hericourt. The serum of immune dogs has produced marked amelioration in all stages of tuberculous disease, and in no case was there consecutive fever, as after injections of tuberculine. Bernheim has applied this treatment to the human subject in one hundred and five cases, injecting ten cubic centimetres of the arterial serum of an animal rendered refractory; he reports favorable results from this treatment.

Richet and Hericourt have found that the intraperitoneal transfusion of the arterial blood of a dog confers on rabbits and guinea-pigs immunity, not only against bacteria, but against charbon and other germ diseases; they also demonstrated the possibility of retarding and even arresting tuberculosis by the intraperitoneal injection of the blood or serum of dogs that had been "vaccinated" and thereby rendered immune. Tuberculosis in birds also vaccinates the dog against human tuberculosis. Their article emphasizes "the salutary action exercised by the blood of a vaccinated animal on the course of tuberculosis." They also cite the case of a tuberculous patient who had been treated eighteen months by serum injections, and who was on the fair road to recovery. Stimulated by these successes, De Dominicis has been treating chlorotic and tuberculous patients by intravenous transfusions of the blood of a healthy dog. The result was excellent in the case of three chlorotic girls, who experienced rapid

[1] Bull. gén. de thérapeutique, September 15 and October 1, 1893.

amelioration. Four tuberculous patients were treated in a similar way; of these, two soon died, and the other two became speedily better, with return of appetite and strength, and cessation of fever.

Egasse affirms that the serum of the dog possesses very remarkable tonic and stimulant properties, but the salutary effects which it produces in tuberculosis "do not testify to any specific, ante-tuberculous quality." "It purifies the organism, ameliorates the general state, and thus puts the patient in better condition to resist the infection."

Tommasoli has tried local injections of the blood serum of dogs in the treatment of lupus. He has obtained some amelioration, but no cures.

With regard to tetanus, there is no need of repeating what has been before published on several occasions in this JOURNAL. The experiments of Behring and Kitasato, of Tozzoni and Cattani and others, are now sufficiently known. There is no doubt that in animals immunity has been obtained against the tetanus-poison by serum injections, but no such encouraging results have yet been experienced in man. Recently in France, Renon, Chief of the service of Dieulafoy, subjected two tetanus-patients to "repeated and large injections" of immunized serum. Both patients died. Grancher, Polaillon, Anger, Letalle and others have reported similar failures. Barth and Mayet, on the contrary, report a case of grave tetanus in a young man of eighteen years cured by the injections of the serum of an immunized horse; chloral and bromide were, however, given conjointly in large doses. The same may be said of Schwartz's patient.

More recent still is the case reported by Riccardo Gattaï, of a boy fifteen years old, in whom tetanus declared itself after a wound in the hand by the point of a compass. The ninth day, 10 cubic centimetres of the blood of an immunized hare were injected, "followed in the evening by an injection of 50 centigrammes of the antitoxine of the dog." The injection was several times repeated and the recovery was speedy and complete.

Roux and Vaillard have treated seven patients: two recoveries and five deaths. They find that the reaction under antitoxine is the same in both animals and men. The treatment has failed in grave cases of tetanus. It might have been successful if begun earlier. The prognosis depends on the extent and intensity of the lesions at the moment when therapeutic interference is attempted. These writers persist in declaring that the employment of antitoxic serum is at present the only rational treatment of tetanus, and the injections are the more successful, the earlier they are practised.

CONGENITAL DEAFNESS.

IN the care and instruction of deaf-mutes the question whether the deafness is acquired or congenital is often of great importance; and J. K. Love, in an article in the Glasgow *Medical Journal*, makes a study of the relative statistics of congenital deafness.

Even admitting that the pathology of congenital and acquired deafness differs, it still matters little whether the disease took place before birth or in the early months of life, for the latter cases soon are as dumb as the former. If surdism were always congenital the study of its pathology, though interesting, would hardly be of practical value, for congenital deafness is a finished state before it is detected. Of more importance is the amount of deafness.

The general impression that nearly all deaf-mutes are quite deaf is a decided error. On the contrary, "almost no deaf-mute is quite deaf."

The statistics as to the relative extent of acquired and congenital deafness vary much; from one series in which out of 489 deaf children 423 were reported born so, to another in which but 117 out of 279 were congenitally deaf. All the more recent statistics, German and others, show that on careful inquiry the acquired cases are found to be the more numerous.

In obtaining this information, the fact to be sure of is not whether the child ever spoke, but whether it ever heard or not. "The difficulty of ascertaining the presence of hearing in early infancy has been exaggerated; for long before speech is developed mothers have proof of the presence of hearing, and in nearly every case where the parent is closely questioned, the truth can be ascertained." The careful examination of all cases during the last two years leads to the conclusion that a majority of deaf-mutes are born hearing — the ratio being about 65.3 to 34.7.

Many interesting figures are given concerning the deaf-mute couples in Glasgow, of whom there are seventy-five; six of them have deaf-and-dumb children. Direct heredity of deafness was marked in many of the cases. The statistics of cases studied, both by the writer and others, do not prove that consanguineous marriages cause deafness in the offspring; but there is sufficient reason to discourage the intermarriage of the congenitally deaf. There is no proof that other circumstances, such as want and dipsomania, have any specific connection with the cause of deaf-mutism.

THE GOOD FORTUNE OF THE MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.

AT the Annual Meeting of this Society, on October 26th, the Treasurer announced the receipt of the first payments from a testamentary gift of the late Elisha R. Ashton of Boston. By his will, Mr. Ashton directed his executors to place in the hands of trustees a very large sum, of which the income should be paid, *in perpetuo*, to such charitable societies as he had selected as suitable objects of his bounty. The amount received by the Society as yearly income from this source is expected to be about one thousand dollars; this year it was $999.75. Twenty-five other charitable societies receive, each, the same amount.

This munificent bequest, which does infinite credit to the good judgment of the testator and to the prudent care of his chosen agents, added to the Fund already

accumulated from the subscriptions of its members and from other generous gifts by benefactors who have approved its work — places the Medical Benevolent Society in a position to enlarge the number of its beneficiaries as may become necessary.

One special feature of the Constitution of the Society, which has been highly commended, is: that its benefits are not limited to its own membership as in the great proportion of relief organizations, but are freely extended to worthy Fellows of the Massachusetts Medical Society and their families who may fall into distress, through no fault of their own. Such worthy cases are frequently brought to the notice of its Council, and are sought out and relieved, after careful inquiry, by temporary relief, or by permanent annuity, according to the exigencies of each case. At the present time there are fifteen annuitants who quarterly receive aid from this Society.

MEDICAL NOTES.

Yellow Fever. — The yellow fever epidemic at Brunswick, Ga., continues unabated, the new cases numbering from thirty to forty each day. Up to the present time there have been 750 cases and over 40 deaths. The population of Brunswick is only 4,000. At Jesup no new cases have been reported, and there are now but a few patients under treatment.

An International Chemical Congress. — The Belgian Chemical Society is organizing an International Chemical Congress, to be held at Brussels, in August, 1894. The chemistry of food-stuffs is to form the subject of special discussion.

Paris Medical Faculty. — Considerable discussion is at present going on among medical circles in Paris, both at the Academy and in the medical journals, as to the propriety of private practice by the professors of the Medical Faculty. There seems to be a growing feeling that they should not, but that their whole time should be devoted to the scientific instruction of men who are to be made accomplished physicians. The interruptions of private practice it is claimed prevent the best results of study or of instruction. On the other hand, the importance of correcting theoretic and laboratory conclusions by careful observation and experience in the care of disease is urged by the friends of the practising professor.

BOSTON AND NEW ENGLAND.

Harvard Medical School. — The legacy of $6,000 given by Claudius Marcellus Jones has been devoted to the establishment in the medical school of a scholarship bearing his name, with an income at present of $250 a year.

Diphtheria. — The numerous cases of diphtheria in the Dorchester wards, of which mention was made last week, have continued to increase. A focus seems to exist around the Mather Grammar School, some fourteen cases having occurred within 800 rods of the schoolhouse in children attending the school. The plumbing of the building is said to have been for some time in need of repairing, but so far nothing has been done to improve the condition.

New Building for the Insane at Middletown, Conn. — The trustees of the Hospital for the Insane at Middleton, Conn., have decided upon the plans for the new building for which the legislature granted $100,000 at the last session. It will be used wholly for the mildly chronic insane, and will accommodate 250 patients. It is to be built of brick and brownstone walls, with "slow-burning construction" interior. Active work will be begun in the early spring.

NEW YORK.

New York County Medical Society. — At the eighty-eighth annual meeting of the Medical Society of the County of New York, held October 23d, the following officers were elected for the ensuing year: President, Dr. Seneca D. Powell; First Vice-President, Dr. Henry D. Chapin; Second Vice-President, Dr. Egbert H. Grandin; Secretary, Dr. Charles H. Avery; Assistant Secretary, Dr. Wm. E. Bullard; Treasurer, Dr. John S. Warren; Censors, Drs. Alexander S. Hunter, Charles H. Knight, F. M. Warner, Frederick Peterson and Auguste Caille.

Examination for Appointments to the State Insane Asylum. — On November 16th there will be a civil service examination at Albany, for the positions of junior assistant physicians and apothecaries in the State hospitals for the insane. Applicants for the former must be residents of the State of New York, graduates of a legally incorporated medical college, and have had at least one year's actual experience on the staff of a public general hospital. Salary, $800 to $1,500 a year, with board.

A Long Swim.—Dr. Judson Daland, the Mediterranean deputy of Health Officer Jenkins, recently performed a remarkable athletic feat in swimming the classic Straits of Messina, from Scylla to Charybdis. He entered the sea at Faro, and after encountering much difficulty with the currents, passed the rock of Scylla and landed on the coast at Riggio, in Italy. The distance was about six and a half miles, and was accomplished in two hours and twenty minutes, and without the use of stimulants. It is not known that the feat was ever before accomplished.

Electro-Execution.—The execution of the murderer Foy, which was effected at the Dannemara prison, on October 23d, is said to have been the most successful since the infliction of the death penalty by means of electricity has been in use. At first a current of 1,640 volts was sent through the body for four seconds. The current was then gradually reduced to 150 volts, and at the end of forty-five seconds was increased again to 1,640 volts for two seconds, and then shut off. In order that there might be no delay from the possible giving out of the dynamo, as was the case at the last execution at Auburn, the electrical apparatus had been previously connected with the electric-light plant of the town.

Miscellany.

THE WATER-SUPPLY OF LONDON.

THE Royal Commission appointed last year to inquire into the water-supply of London has lately made its report.

The city is at present supplied by eight metropolitan water companies and sixteen others within the limits of Greater London, that is, within a circle of a radius of fifteen miles from Charing Cross, an area of 701 square miles. These extra metropolitan companies obtain their supply from wells sunk into the chalk stratum, with the exception of two companies which draw daily a total of 4,000,000 gallons from the Thames.

It is estimated that in 1931 the population of London will be at least 8,526,054, and the daily supply required will amount to 253,529,686 gallons. The capacity of the water companies to provide this quantity is returned as follows: — From the Thames, 300 million gallons daily; from the Lea, 52½; from wells and chalk springs, 87 million gallons; making a total of 439½ million gallons a day. To ensure these results from the Thames and Lea it will be necessary to make vast storage reservoirs, and impound all the storm and flood water, to be drawn upon when required.

It is feared that this storage water will be of such quality as to be of considerable danger to consumers for there is at present much filth discharged into the rivers; a large proportion of which is preventable and distinctly illegal, the Rivers' Pollution Prevention Act being to a great extent a dead letter. The Commission urges that "all possible vigilance be exercised to prevent unnecessary contamination of the Thames and Lea and their respective tributaries, to ensure the thorough treatment of all sewage, before it is allowed to pass into the rivers, by the most efficacious methods that science and experience may dictate, and to enforce the adequate storage and filtration of such water as is abstracted at the intakes."

LOOKOUT MOUNTAIN AS A HEALTH RESORT.

LOOKOUT MOUNTAIN is recommended most enthusiastically as a health resort by Dr. Deitrich,[1] who has found there a cure for his own case of phthisis. Its reputation for climate has, until the last few years been only local, but is deserving of further notice. The plateau summit, which is seventeen hundred feet above the Tennessee River, and two thousand and eighty above tide-water, is an undulating surface beginning at the northern end and gradually widening out to the south until it is over a mile in width. It extends into Georgia, but only the Tennessee portion is easy of access. "The soil is light and sandy, absorbing moisture with great rapidity. Since the war there has been no cultivation, and the plain has now grown up with pine and oak forest.

"The meteorological records, which have been taken only within the last twelve months, show a mean annual temperature of 54° F., with an annual range of 17° F. During the winter there is seldom freezing weather; and only once in five years has the thermometer been as low as 2° F. The maximum last summer was 88° F. The average number of clear, fair days was twenty-four each month. There is abundant sunshine and a breezy atmosphere."

[1] Medical Record, October 14th.

It is stated that no case of consumption has been known to occur among the native mountaineers. The water-supply is abundant and pure, there being both freestone and chalybeate springs. Aside from the wonderful views to be had from the summit, there is the advantage of easy access from the city of Chattanooga. The accommodations for invalids, which are so important and so lacking in many of the Southern health-resorts, are said to be most excellent.

VENOUS MURMUR IN CIRRHOSIS OF THE LIVER.

MARTINI reports[1] three cases of atrophic cirrhosis of the liver in which there was a constant blowing murmur to be heard in the sixth intercostal space in the right axillary line. The murmur was always increased during inspiration, but in one case diminished after an attack of hæmatemesis. The cause seemed to be in the altered position of the ascending vena cava, which was crowded against its opening in the diaphragm by the contracted liver and the ascites, causing a venous eddy at the point of obstruction. In one case which came to autopsy there was a distention of the vein below the opening.

ANTHROPOMETRICAL DESCRIPTIONS.

ONE of the interesting studies which has arisen in connection with criminology is the means by which criminals may be identified without mistake. The adoption of the photograph was a great gain in every way, but the large collections of rogues' likenesses have been growing to such proportions in our great cities that it is now impossible to search through them all. In Paris, alone, there were 100,000 persons photographed in ten years. The changes of feature possible, and the distortions even of photography were also objectionable.

In a recent number of the *Humanitarian*, Dr. Bertillon describes the method which under his name is now used in France. It exemplifies most remarkably the time saved by system and order in the arrangement of statistics. The description of each person is made by recording the length of various bony parts, always the same, and taken in a regular order. Under each measurement there are made three divisions, long, medium and short. And as each new factor is introduced under the proper sub-class of the division before it, the case under consideration is rapidly localized.

The measurement of height is not used as the basis of the first great division as might be expected, for it is found impossible to measure closer than 1.18 inches, while by commencing with the less changeable measurements a greater accuracy of classification is obtained.

The length of the head is the first taken, by means of compasses so accurately adjusted as to show a variation of a millimetre. The three classes are short, 7.2 inches; medium, 7.25 to 7.4 inches inclusive; and long, those over 7.4 inches. Next is measured the breadth of the head, from one parietal bone to the other. This again gives three classes, narrow up to 6 inches; medium, 6 to 6.22 inches; broad, over 6.22

[1] Gazz. degli Ospitali, 2, 21, 1893.

inches. Following these there come in order, each with three divisions, the length of the middle finger of the left hand, one of the very best indications, the maximum length of the left foot, not of great accuracy, length of extended arms, height, color of the eyes, for which a special table of seven divisions is used. These figures alone divide the number of cards to be examined by a very large divisor, and the addition of a few more measurements, as the measurements of the ear, sternum, or other fingers, would reduce the number of cards, each criminal having one, still further. Finally, as a last and absolutely determining check is the record of particular body signs, as scars, moles, etc. Three or four of these would suffice to enable a man to be identified out of a million. These special marks are much less deceptive and costly than photographs, and are a better guarantee for identification than measurements; and would entirely replace the latter, if only it were possible to make use of them as a basis for classification.

The number of divisions, all equally probable, which are furnished by the twelve indications, combined and divided by the three categories (small, medium, large) exceeds *One Million.*

Correspondence.

LETTER FROM CHICAGO.

World's Fair Congress of Public Health, and Meeting of the American Public Health Association, October 10–14, 1893.

(Concluded from No. 17, page 430.)

THURSDAY. — AFTERNOON SESSION.

Dr. A. R. Reynolds, Commissioner of Health of Chicago, and Mr. Allen Hazen, Chemist of the Water Department at the Exposition, presented the subject of "The Water-Supply of Chicago." Dr. Reynolds stated that the new water intakes or cribs four miles distant from the shore had been in operation for several months, and that since the water had been drawn from that distance the death-rate from typhoid fever in the city had been greatly reduced. For the year ending September 30, 1892, the number of deaths from typhoid fever in Chicago was 1,790 in a total of 26,646, or a percentage of 6.72. For the year ending September 30, 1893, deaths from typhoid fever were 712 in a total of 26,977, or a percentage of 2.64. It is most unfortunate for this comparison that the old supplies were partly in use during the first few months of the latter year, before the four-mile tunnel was opened. We may believe that if this had not been the case, the comparison would have been still more favorable to the improved supply. It is a well-known fact that people using a water-supply to which they are not accustomed are often more susceptible to any infection which it may contain than are those using such water regularly. A striking illustration was furnished by Philadelphia in the Centennial year, when the typhoid death-rate was nearly doubled; while in Chicago the present year, for the first five months of the Fair period the rate has been less than half as high as for the corresponding months of the preceding year. For the entire year under consideration, in spite of the vast number of visitors continually present, there has been a reduction of over 60 per cent. in the typhoid fever death-rate. This reduction is most striking, and it can hardly be doubted that the improvements in the water-supply have been the chief, if not the only, cause.

The mortality percentages from typhoid fever in a number of cities may be compared as follows: Chicago, 1892, 6.72; in 1893, 2.64; Philadelphia, 1892, 2.22; Boston, 1.22; Paris, 1.01; New York, 0.90; Brooklyn, 0.80; London, 0.49; Berlin, 0.42. The cities having the lowest typhoid fever death-rate, London and Berlin, use only filtered water. London draws nearly all its water from the two grossly polluted rivers, the Thames and the Lea, and after filtering it, supplies it to a population that is almost free from typhoid fever. Another improvement which will eventually still further protect the purity of Chicago's water-supply may be mentioned — the drainage canal. In the meantime it may be a question worth considering by the engineers whether filtration would not be as cheap and effective a means of improving the water-supply as the farther extension of the tunnel.

Mr. Geo. W. Fuller, Biologist at the Lawrence Experiment Station, presented a paper on the "Removal of Pathogenic Bacteria from Drinking Water by Sand Filtration." He described the experiments which had been made at the Lawrence Experiment Station, the results being summarized in a series of tables, in which it was shown by the results of 11,000 examinations that it is entirely practicable to construct filters for city water-supplies which will remove more than 99 per cent. of the bacteria. He stated that the large filter just finished for the filtration of the water for the city of Lawrence was already removing from 96 to 98 per cent. of the bacteria after a few days of use.

The remainder of the afternoon was devoted to the subject of "Quarantine."

Papers were read by Drs. Liceaga and Orvananos upon "Quarantine in Mexico."

Dr. Montizambert, of Quebec, described the system in practice at Grosse Isle, the Quarantine Station of the St. Lawrence River, where more than 100,000 pieces of baggage of immigrants had been disinfected during the past season.

Dr. Swearingen, of Texas, described the quarantine system of the Texas sea-coast, and severely criticised the laxity of the Mexican laws in allowing people infected with yellow fever and small-pox to cross the Rio Grande.

A vigorous discussion followed in which Drs. Baker, Hewitt, La Chapelle and others participated, the points at issue related to the disinfectants in use, the articles to be disinfected and the methods of treating them, and the diseases to which quarantine should be applied.

EVENING SESSION.

Mrs. Dr. Sarah H. Stevenson, of Chicago, spoke upon "Municipal Sanitation," her remarks being chiefly devoted to the importance of a proper disposal of the dust of dwellings and of streets.

Dr. Abbott, of Massachusetts, read a paper entitled "National Registration a Necessity." [1]

FRIDAY. — MORNING SESSION.

Dr. Miguel Marquez, of Chihuahua, Mexico, presented a paper entitled "Animal Vaccine: Why it should be Preferred to Human Vaccine," in which it appeared that epidemics of small-pox had been more frequent during the past half-century in Mexico than in the United States. The conclusions of his paper were as follows:

That to continue the use of human vaccine, is attended by grave inconveniences that are advantageously avoided by the use of animal vaccine; that the latter is adapted for distribution; that its beneficent influence may be felt even in the smallest villages, hamlets and ranches, by distributing great quantities of vaccine points; that an intelligent person can inoculate without the least danger; that we should not trust to the judgment of any individual to determine whether a child is or is not well, or if the lymph should be taken from it (with the possibility of transmitting syphilitic virus) and that, of course, the adoption of animal vaccine will suppress forever the custom of vaccinating from arm to arm.

Summary: The animal vaccine should be preferred to human vaccine, because:

(1) It does not transmit syphilis and preserves more efficiently against the small-pox.

(2) It can produce at a given moment large quantities of lymph, fresh, pure and genuine, at a very small cost.

(3) Its administration can be trusted to any intelligent person without the least danger.

[1] To be published in the Journal.

Dr. Jerome Cochran, of Alabama, presented the results of an experiment in disinfection for the preventive treatment of pneumonia. He stated his belief that pneumonia was infectious, but was not aware of any previous attempt to limit its spread by means of disinfection. A brief description of outbreaks in prisons and among miners in Alabama was given. The epidemic occurred in May, 1893. The total number of cases was 93. Disinfection of the prison hospital was begun on May 14th, and completed in six days. There were only seven new cases after the disinfection; and he thought that these might have been contracted before the completion of the disinfection. This was accomplished by drenching the walls and floors with sublimate solution. Mattresses and clothing were introduced into a steam-chest for six hours. Convicts were required to take a bath. In one week the epidemic had ceased.

Dr. C. N. Hewitt, Secretary of the Board of Health of Minnesota, read a brief paper entitled "The Best Way to Restore the Practice of Vaccination to its Proper Place as a Preventive of Small-Pox," in which he presented the results of his experience in dealing with a hundred outbreaks of small-pox in Minnesota. He successfully conducts a State vaccinal institute, and distributes lymph from this establishment. He believed that the work of propagating vaccine lymph should be freed from the harmful influence of commercial and trade methods to which it is subjected in this country.

Dr. Lee, of Pennsylvania, presented a resolution endorsing the practice of vaccination in the strongest terms; which was adopted by the Congress by a unanimous vote.

As one of the committee on yellow fever appointed at the last meeting of the American Public Health Association at Mexico, Dr. Liceaga, President of the Supreme Board of Health of Mexico, presented a "Contribution to the Study of Yellow Fever." The following is a *résumé* of the chief points in the paper of Dr. Liceaga:

(1) The places where yellow fever reigns, and which can be considered as *centres* of infection, are in the Gulf of Mexico, Vera Cruz, Frontera, Campeche and the districts on the northern coast of the Yucatan Peninsula, the last named separated by the Yucatan Canal from the Island of Cuba, where the fever also reigns.

On the great Pacific Coast, which belongs to the Mexican Republic, there is not a single yellow fever centre.

(2) All the Mexican territory on the Gulf of Mexico and on the Pacific Coast is well adapted for the disease when imported.

(3) Yellow fever has become epidemic in the following places on the gulf coast: Matamoros, Altamira, Tampico, Tuxpam, Papantla, Misantla, Nautla, Alvarado, Coatzacoalcos, Minatitlan, Lagang and San Juan Bautista de Tabasco.

(4) The epidemic has extended into the interior, but never into places situated more than 1,008 metres over sea level.

(5) On the Pacific there is not a yellow fever centre, but it has been imported into the following places: On the Peninsula of Lower California, La Paz and Todos Santos; on the Continent, Guaymas, Altata, San Blas, Manzanillo, Santiago, Acaponeta, Acapulco, Puerto Angel, Salina Cruz, Tonala Soconuzco, Tapachula and San Benito, and in the interior in Hermosillo and Culiacan.

(6) Immunity against yellow fever is obtained after having had the disease in any of its forms.

It is possible that this immunity may be lost at times, but it is seldom the case, as it happens with typhus, small-pox and scarlet fever, which may be had by a person who has had them.

(7) The vaccine of Jenner against small-pox and others which science has discovered, authorize us to look for the one that will prevent the yellow fever.

The inoculation against this fever which Dr. Carmona y Valle has practised with success should be tried on a large scale, in an uniform manner, in order to be able to find out if they are efficacious or not. If this experience confirm it then they should be made compulsory in the countries where the fever reigns.

If they should not prove worthy, then the inoculation of blood serum, as proposed by Dr. Sternberg, from persons enjoying immunity, should be tried on a large scale and in a uniform manner.

(8) The purification of the drinking-waters used by persons who have to expose themselves to contract the disease, should be recommended.

The purification of the water used on board the ships leaving or calling at infected ports should be proposed.

(9) The sanitation of the places which are yellow fever centres should be done at once.

(10) To prevent, by means of Sanitary Police measures, the importation of fever into places where it can be developed.

Dr. Mendizabal, of Mexico, read a paper upon "La Grippe in Mexico."

Dr. Roque Macouzer, of Mexico, presented the subject of "Diphtheria in Mexico." He stated that the disease was imported into that country by the French Army in 1863, that it was now decreasing in severity, and he believed it would finally disappear. He regarded notification and isolation as important measures in restraining its spread.

Dr. Macouzer presented the following resolutions, which was referred to the Executive Committee.

(1) That educational institutions he recommended to devote more time to the study of hygiene.

(2) That governments should appoint to sanitary positions only those persons who are experts in sanitary science.

Dr. Marin, of Pueblo, read a paper on "Scarlet Fever in the City of Mexico."

Dr. Hewitt reported, in behalf of the Executive Committe, that Mr. Henry Lomb, of Rochester, New York, already well known as a generous benefactor of the Public Health Association, had offered a new prize of $500 for a treatise on "Public Hygiene," for use in the public schools, with a further prize of the same amount for a treatise or essay on some special topic which would be announced in future.

Dr. W. Oldright, of Toronto, read a paper on "Unrest, and its Effect upon the Nervous System." He urged the importance of recreation, and regular relaxation from work, especially for brain-workers. He advised occasional complete abandonment of work and change of employment, as a means of rest. He especially plead for a better observance of Sunday as a day of rest for workingmen.

A prominent paper in the afternoon session was that of Dr. Benj. Lee, Secretary of the State Board of Health of Pennsylvania, entitled, "How shall our Lepers be Cared for?" The following abstract is given:

The State Board of Health of Pennsylvania and the Board of Health of the City of Philadelphia have had some unpleasant experiences with lepers, which have led both of these bodies to appeal to the general government to establish a colony or colonies, where these unfortunates might be provided with the comforts of home, medical care and nursing, and, at the same time might cease to be a horrid menace to the health of those with whom they were thrown into close contact. In order to arrive at a somewhat definite opinion as to first, the need for the adoption of such a measure, and secondly, the general drift of opinion on the part of those who had given the subject thoughtful attention, in December, 1891, I addressed circular letters of inquiry to the secretaries of all State and Provincial boards of health in the United States and Canada, and to prominent dermatologists.

Replies to these inquiries have been received in twenty-three instances. They indicate, briefly, that cases of the diseases have been recognized and made the subject of official report in seventeen States and Provinces. In ten States or Provinces cases exist at the present time under the observation of the authorities, namely, New Brunswick twenty-two, British Columbia seven, New York six, Pennsylvania four, Illinois two, Iowa one, Minnesota seven, Wisconsin four, Louisiana forty, California twenty-four; making in all one hundred and seventeen cases.

At the well-known Lazaretto at Tracadie in the Province of New Brunswick, provision is made for the comfort, care and treatment of these unhappy beings in a manner in harmony with the dictates of humanity and the requirements of modern science, while, at the same time, they cease to jeopardize the health and happiness of others. The United States has only gone so far as to make the affection quarantable at the seacoast, and to order those found suffering from it on arriving vessels, to be at once returned to the ports from which they came. In the different States of the Union, the widest diversity prevails, both in theory and practice. The only place in which segregation is practised, and at the same time humane provision is made for the shelter, maintenance, medical attendance and nursing care of lepers, is the City of Philadelphia. The manner in which the county authorities, who have the care of the other cases in Pennsylvania, discharge that duty is by no means in keeping with the dictates of humanity or the laws of sanitation.

While their numbers are few, no little rural community (very few States even) feels justified in going to the expense of establishing a lazar-house or colony. Is it wise to wait until State after State finds itself compelled by their increasing members to take this step? Or is not rather the duty of the central government to gather them all into one properly supervised community where they can have the companionship of their fellows, the comforts of a thoroughly furnished home, and the advantages of the best medical and surgical skill?

Such is the distinctly expressed opinion of nineteen of the twenty-one eminent dermatologists who favored me with replies to my circular of inquiry.

In conclusion, I desire to say that in determining the importance of this question and the necessity for governmental interference, the numerical method is entirely misleading. One case of leprosy outweighs a hundred of any other disease. If there were but ten lepers in the land instead of more than ten times ten, it would be equally the duty of Congress to initiate measures to prevent, if possible, a single addition to the horribly afflicted company.

In the afternoon many of the members went to the Exposition for the purpose of visiting the exhibits of the State Boards of Health in the Department of Hygiene and Sanitation. The exhibit of the Massachusetts Board of Health, to which reference has already been made in the JOURNAL, received much commendation.

Visits were also made to the sewage-disposal works and the garbage crematory. The former is conducted very nearly upon the plan adopted in several German cities (Essen and Dortmund), and known as the Rockner-Rothe process. The sewage of all the Exposition buildings is received into a building at the further extremity of the grounds, where it is collected in four large iron tanks open at the top. As it enters at the top, it is treated with chemicals which precipitate the sewage, the tanks acting as settling reservoirs for the sludge which gradually falls to the cone-shaped bottom where it is pumped out and conveyed to a press and deprived of much of its water. The compressed sludge is taken to the crematory and burned, together with the garbage and refuse which is collected each day from the restaurants and grounds.

Near the Department of Hygiene is the Rumford Kitchen, established by Mrs. E. H. Richards, of the Institute of Technology, where practical illustrations of food preparation and food economy have been given daily. The members were hospitably entertained at the kitchen.

The following officers of the Public Health Association were elected for the ensuing year: President, Dr. E. P. La Chapelle, of Montreal; First Vice-President, Dr. M. Carmona y Valle, of Mexico; Second Vice-President, Dr. J. N. McCormack, of Kentucky; Secretary, Dr. I. A. Watson, of New Hampshire; Treasurer, Dr. H. D. Holton, of Vermont.

It was decided to hold the next meeting at Montreal in October, 1894.

DIFFERENTIAL DIAGNOSIS OF DIPHTHERIA.

BOSTON, October 28, 1893.

MR. EDITOR: The accompanying circular letter has been sent out to a number of gentlemen, but, as it appears, has not reached some of those who would be glad to co-operate in this work. If there are any who are willing to furnish material, we shall be very glad to have them consider this letter as especially directed to them.

Very truly yours,
HAROLD C. ERNST, M.D.

HARVARD UNIVERSITY MEDICAL SCHOOL.
BACTERIOLOGICAL LABORATORY,
Boylston and Exeter Sts.

BOSTON, October, 1893.

MY DEAR DOCTOR: It is desired to secure information as to how many cases of mild sore throat are or are not diphtheritic. This can only be done by bacteriological examination of cases in private practice, and your co-operation in securing evidence upon the point would be very valuable. Nutrient materials and directions for making the cultures will be furnished at this laboratory every afternoon except Sundays, between three and four o'clock, and at other times by special appointment. The cultures will be carried on and the examination concluded without further trouble to you, and a report will be sent you as soon as the work is finished.

If you are willing to help in the investigation, we shall be very glad to receive a notice to that effect, and further instructions as to methods will be given you here.

Very truly yours,
HAROLD C. ERNST, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCTOBER 21, 1893.

Cities.	Estimated population for 1893.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Consumption.	Diarrhœal Diseases.	Typhoid fever.	Diphtheria and croup.

Deaths reported 2,460: under five years of age 925; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 444, consumption 273, acute lung diseases 230, diphtheria and croup 161, diarrhœal diseases 142, typhoid fever 70, scarlet fever 20,

cerebro-spinal meningitis 18, whooping-cough 12, malarial fever 10, small-pox 5, measles 4, erysipelas 2.

From scarlet fever New York 6, Pittsburg 3, Philadelphia and Boston 2 each, Brooklyn, Cleveland, Lowell, Lynn and Springfield 1 each. From cerebro-spinal meningitis New York 5, Brooklyn 3, Cleveland, Somerville and Chelsea 2 each, Washington, Lowell, Cambridge and Lynn 1 each. From whooping-cough Philadelphia 5, New York 4, Boston 2, Brooklyn 1. From malarial fever Brooklyn and Nashville 3 each, New York and Charleston 2 each. From small-pox New York 3, Brooklyn 2. From measles New York 3, Fall River 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,527,846, for the week ending October 14th, the death-rate was 18.2. Deaths reported 3,599: diarrhœa 164, diphtheria 111, fever 98, scarlet fever 73, whooping-cough 54, measles 35, small-pox (Bradford 3, London and Birmingham 2 each, Liverpool and Burnley 1 each) 9.

The death-rates ranged from 9.1 in Huddersfield to 25.5 in Preston; Birmingham 19.6, Bradford 14.8, Croydon 12.9, Gateshead 19.5, Leeds 19.6, Leicester 18.1, Liverpool 22.7, London 17.9, Manchester 21.7, Newcastle-on-Tyne 18.3, Nottingham 18.4, Portsmouth 15.6, Sheffield 18.3, Swansea 17.8, West Ham 18.1.

METEOROLOGICAL RECORD,

For the week ending October 21, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 21, 1893, TO OCTOBER 27, 1893.

LIEUT.-COL. ALBERT HARTSUFF, deputy surgeon-general, is relieved from duty at Fort Omaha, Nebraska, and ordered to report in person to the commanding general, Department of California, for duty as medical director of that department to relieve COLONEL JOSEPH R. SMITH, assistant surgeon-general.

COLONEL SMITH, on being relieved by LIEUT.-COL. HARTSUFF, will proceed to Governor's Island, N. Y., and report in person on December 4th, to the commanding general, Department of the East, for duty as medical director of that department.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIVE WEEKS ENDING OCTOBER 21, 1893.

FESSENDEN, C. D., surgeon. Granted leave of absence for thirty days. October 4, 1893.

BAILHACHE, P. H., surgeon. Detailed as delegate to meeting American Public Health Association. October 5, 1893.

VANSANT, JOHN, surgeon. Granted leave of absence for thirty days. September 23, 1893.

HUTTON, H. H., surgeon. Detailed as chairman, Board to inspect Gulf Quarantine Station. October 17, 1893.

HAMILTON, J. B., surgeon. Granted leave of absence for three days. October 2, 1893.

GASSAWAY, J. M., surgeon. Detailed as member, Board to inspect Gulf Quarantine Station. October 17, 1893.

MEAD, F. W., surgeon. To rejoin station (Washington, D. C.). September 19, 1893.

CARTER, H. R., surgeon. To proceed to Way Cross, Ga., for temporary duty. October 4, 1893.

KALLOCH, P. C., passed assistant surgeon. Granted leave of absence for twenty days. October 9, 1893.

BROOKS, S. D., passed assistant surgeon. To proceed to Chicago, Ill., for temporary duty. September 19, 1893.

GOODWIN, H. T., passed assistant surgeon. Granted leave of absence for thirty days. September 27, 1893.

COBB, J. O., passed assistant surgeon. Granted leave of absence for thirty days. October 11, 1893.

GUITERAS, G. M., passed assistant surgeon. Detailed as recorder, Board to inspect Gulf Quarantine Station. October 17, 1893.

WERTENBAKER, C. P., passed assistant surgeon. Granted leave of absence for seven days. September 26, 1893.

PERRY, J. C., passed assistant surgeon. Granted leave of absence for seven days. October 5, 1893.

GARDNER, C. H., assistant surgeon. To proceed to Port Townsend, Washington, for temporary duty. October 7, 1893.

NYDEGGER, J. A., assistant surgeon. To proceed to Way Cross, Ga., for temporary duty. October 8, 1893.

NORMAN, SEATON, assistant surgeon. Granted leave of absence for four days. October 4, 1893.

SPRAGUE, E. K., assistant surgeon. Granted leave of absence for three days. October 7, 1893.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at 19 Boylston Place, on Monday, November 6th, at 8 o'clock.

Readers: Dr. J. H. McCollom, "Some Remarks on Diphtheria." Discussion by Dr. A. L. Mason, Dr. Durgin, Dr. F. H. Williams and Dr. Jackson.

Dr. J. W. Farlow, "Some Remarks on Hypertrophy in the Post-Nasal Space." Discussion by Dr. F. I. Knight, Dr. A. Coolidge, Jr., and Dr. F. L. Jack.

JOHN C. MUNRO, M.D., *Secretary*.

APPOINTMENTS.

DR. ROBERT T. EDES, of Jamaica Plain, has been appointed Shattuck Lecturer before the Massachusetts Medical Society for 1895. The Shattuck Lecture for 1894 will be given by DR. THOMAS DWIGHT, of Boston.

RECENT DEATHS.

DR. RICHELOT, the founder of L'Union Médicale, died recently in Paris, aged eighty-seven years.

PROFESSOR LEFORT, Vice-President of the Académie de Médicine of Paris, died at Paris, October 19th, aged sixty-one years.

BOOKS AND PAMPHLETS RECEIVED.

A New Material for Surgical Splints and Jackets, with a Method for Applying it. By Edward A. Tracy, M.D., Boston, Mass. Reprint. 1893.

A Novel Proposition; Revolutionizing the Distribution of Wealth; Farm Products Moved as Mail Matter at a Uniform Rate for all Distances. By David Lubin, Sacramento, Cal. Reprint. 1893.

Transactions of the American Surgical Association. Volume the Eleventh. Edited by De Forest Willard, M.D., Recorder of the Association, Philadelphia: Printed for the Association and for sale by W. J. Dornan. 1893.

Sarcoma of the Pia and Brain, Simulating Brain Tumor; Mono-Spasm and Mono-Paresis; Operation; Death on the Third Day. Some Points in the Diagnosis and Treatment of Intra-Cerebral Hæmorrhage and in the Treatment of Chorea. By J. T. Eskridge, M.D., of Denver, Col. Reprints. 1893.

A Manual of Diseases of the Nervous System. By W. R. Gowers, M.D., F.R.C.P., F.R.S., Consulting Physician to University College Hospital; Physician to the National Hospital for the Paralyzed and Epileptic. Second edition. Revised and enlarged. Vol. II. Diseases of the Brain and Cranial Nerves, General and Functional Diseases of the Nervous System. With 182 illustrations, including a large number of figures. Philadelphia: P. Blakiston, Son & Co. 1893.

Chirurgie des Voies Urinaires Etudes Cliniques. Par le Dr. E. Lournean, Professeur Libre de Clinique des Maladies des Voies Urinaires; Professeur d'Anatomie a l'école des Beaux-Arts; Ancien Chef de Clinique Chirurgicale a la Faculté de Médicine; Secrétaire de la Société de Médicine et de Chirurgie. Second edition. Revue augmentée et accompagnée de cinq planches hors texte noires et chromo lithographiées. Bordeaux: Feret et Fils. 1894.

SUDDEN DEATH DUE TO THE HEART.[1]

BY WILLIAM T. COUNCILMAN, M.D., BOSTON.

IN this paper I shall not consider the cases of death due to the actions of poisons on the heart nor the effect of traumas, although both of these are subjects of great interest. The action of the heart in keeping up the circulation of the blood is one which is absolutely essential to the maintenance of life. Anything that interrupts the continuous circulation of the blood through the lungs and through the systemic circulation brings about at once a cessation of the life of the individual. We are not yet fully informed as to the conditions under the influence of which the heart beats with its normal sequence and regularity. It was for a long while supposed that the action of the heart depended upon the nervous ganglia contained within it. These ganglia are abundant in the mammalian heart, and are situated along the large veins emptying into the heart, in the walls of auricles, in the auriculo-ventricular grooves and in the basal portions of the ventricles. It was generally supposed that from these ganglia motor impulses passed to the muscular fibres of the several parts, causing rhythmic contraction of these fibres, the sequence and co-ordination of which were due to a co-ordination between the several ganglia in regard to the generation of impulses. There were various experiments which seemed to prove this. It was shown that when the frog's heart was divided in such a way that each segment contained portions of the ganglionic cells, that the segments in connection with the ganglia would continue to pulsate, while those segments in which there was no connection with ganglia would remain quiescent. Thus, if the lower portion of the ventricle of a frog's heart be cut away, it will cease to pulsate, while the auricles and the portion of the ventricle remaining attached to them continue to contract. The heart may be bisected longitudinally without any loss of its contracting power; and the auricles, which in the frog's heart contain the most ganglia, may be cut into small bits, and they will continue to contract.

Recently, however, a number of experiments have shown that this dependence of the heart-beat on nervous impulses proceding from the ganglia cannot be held without reserve. Portions of the heart, and even strips of its muscular substance, will continue to beat with regularity while immersed in blood-serum. The reluctance of portions of the ventricle to execute spontaneous contraction when severed from the auricles seems to be peculiar to the frog. In the tortoise, for example, portions of the ventricle containing no nerve-cells will beat spontaneously and with a natural rhythm when separated from the auricles. A consideration of all that can be learned experimentally as to the cause of the natural rhythmic contraction of the heart would seem to show that it is independent of nervous action and due to changes taking place in the muscle itself. In various ways the muscular substance of the heart differs from that of the skeletal muscles. It is not so completely differentiated. The striation, although present, is not so distinct, and the closer division of the fibres into cells, and the anastomosis of these cells with one another, is different from the other muscles; and it is possible that the continuous rhythmic contraction is due to this close anastomosis of the fibres. What part the ganglia play in the contraction is uncertain. It may be that they exercise some trophic influence, or they may serve as depots to distribute to all portions of the heart nervous impulses, reaching them from without.

It is not possible to apply to mammals without reserve the result of the experiments which have been made on the hearts of frogs and tortoises. In these animals the substance of the ventricle is very much looser, and the blood from the ventricular cavity can bathe almost all portions of the muscles. In mammals the case is different, because here, owing to the greater amount of muscle and the closeness of its texture, its nutrition can in nowise be kept up by the blood within the ventricle. In order that the proper amount of blood for nutritive purposes should reach the muscle, the circulation in the coronary vessels is necessary. We shall see that the functional activity of the heart depends more on the integrity of the coronary circulation than on any other factor; and when any impairment of this circulation reaches a certain degree, the action of the heart ceases. The proper function of the heart seems further to be in some way dependent on the proper functioning of all its parts. Impairment of one portion of its muscle by degeneration is frequently followed by sudden cessation of function in all other parts.

We can divide these cases of sudden death coming from the heart into two classes. We can consider, first, conditions arising within the heart which render the circulation of the blood through it impossible; and, secondly, those conditions coming from the heart which interfere with its function, no impediment being given to the circulation of the blood through the heart by these conditions. We will first consider those conditions which arise within the cavities of the heart, interfering with its circulation. We may have, in the first place, as a very rare condition, thrombi of such size formed within the heart that the passage of blood through its cavities is obstructed. The formation of smaller thrombi within the heart is a comparatively common event. They may be formed in either one or both sides of the heart, and the most common place for their formation is within the auricular appendages of the heart. These may become entirely occluded by the formation of thrombi. The thrombi formed in the ventricles, are, as a rule, small, and are seated usually in the trabecular tissue of the apices. These do not give rise to trouble in the heart itself, although when carried from the heart they may produce various troubles, and even sudden death, by occluding the arteries going to parts essential for life. The thrombi formed in the auricles are, however, rather more extensive. The most extensive formation of thrombi is usually associated with chronic endocarditis and stenosis of the mitral valve. This plays an important role in the first formation of the thrombi. The great dilatation of the auricle and its imperfect emptying leads to the stagnation of the blood in certain parts, especially in the appendices. There may be an enormous formation of thrombi in the auricle, and the mouths of one or more of the pulmonary veins may be occluded by the thrombi, without causing immediate cessation of the cardiac action.

Mural thrombi may be formed at the openings of

[1] Read at the meeting of the Massachusetts Medico-Legal Society, October 4, 1893.

the heart, and may be sufficiently extensive to prevent the entry or the exit of blood. The specimen which I present and which I owe to the kindness of Professor Draper, illustrates this. The specimen comes from a young man of twenty-five who died suddenly. There is an acute endocarditis with vegetations on the aortic valve. In the sinus of Valsalva, behind the anterior segment of the aortic valve, a thrombus has formed which terminates in a large globular mass. It is very probable that during life this floated freely in the aorta. At the autopsy, it was found as it is now, below the valves within the ventricle. It is possible that it may have been forced into the ventricle at the close of the systole, and then on the next contraction of the ventricle may have been wedged into the orifice by presenting a longer diameter, thus closing the orifice and instantly stopping the circulation. The condition is an exceedingly interesting one, and in looking over the literature of heart thrombi I have not found a similar case. It would be difficult to explain the sudden termination of life in any other way.

Of most importance in this connection are the so-called free thrombi in the heart. This condition was first observed by Von Rechlinghausen,[2] and described by him in his treatise on the general pathology of the circulation. He describes two cases of marked mitral stenosis in which there were free thrombi the size of small walnuts in the left auricle.

Cases have since been described by Macleod[3] and Hertz,[4] and lately another case has been reported by Arnold.[5] Hertz first brought forward the idea that the free thrombi in the auricle could occlude the auriculo-ventricular valve, acting as a ball valve and so produce severe symptoms, or in some cases sudden death. Von Recklinghausen,[6] in a criticism of the paper of Hertz in which he gives the clinical history of his two cases, takes ground against the ball-valve theory of Hertz. In both of his cases death was not sudden, and there were no symptoms during life which denoted any sudden impediment to the circulation. In one of the cases which Hertz reports there was sudden death, and in the other there were several attacks of collapse which he was inclined to attribute to temporary occlusion of the valve. The same was true in the case reported by Macleod. In the afternoon the patient was seized with convulsions and shortly after became unconscious. The pulse was very small, weak, and the cyanosis extreme. This condition was gradually recovered from, and at nine o'clock in the evening of the same day there was a similar attack which lasted until death, which took place the following morning. In the case reported by Arnold, although there was some evidence of sudden impairment of the action of the heart, orthopnœa and intense cyanosis three weeks before death, the manner of death was not such as could be attributed to a sudden cessation of the circulation. These free thrombi in the heart are always round, their roundness being probably due to their motion within the auricle and probably to their increase in size by the continuous addition of new masses of fibrin. Their origin appears to be always the same. They are associated with the presence of adherent thrombi either in the auricular appendices or elsewhere in the auricle. Long thrombi, sometimes projecting to a considerable extent from the surface with a small base of attachment, are sometimes found adherent to the wall of the auricle. These form the so-called heart polypi of the old writers. These masses can become detached, and from their continual motion rolling round and round in the auricle can acquire a round shape. They are necessarily always associated with stenosis of the mitral valve, for with a valve of normal width the masses separated from the mural thrombi would pass through into the ventricle. That they can become a cause of sudden death by closing as a ball valve the narrow auriculo-ventricular orifice appears evident from the case of Hertz and from a case which I observed at the Johns Hopkins Hospital. The case was that of a woman with a history of previous attacks of rheumatism, and the clinical evidences of mitral stenosis. She came into the hospital for the relief of her symptoms of dyspnœa, dropsy, etc., and after being there for a short time died suddenly, falling back in bed when about to arise from it. At the autopsy, the usual changes in the other organs due to mitral stenosis were found. In the heart itself there was a considerable hypertrophy of the right ventricle, with some dilatation. The left auricle was greatly dilated and hypertrophied. The mitral orifice contracted to a button-hole which would only admit the first joint of the little finger. There were large thrombi masses in the auricular appendices, and a round free thrombus which was lying on, and occluding the mitral orifice, and partially pressed into this. The thrombus was of circular shape, the surface slightly irregular, and at no point was there an irregular surface showing that it had been recently broken away. There can be little doubt, however, that it had originated from the thrombi in the appendices, and that it had been free in the auricle for some time. The condition is one which is rare, and the cases which I have mentioned are the only ones which I have found in the literature.

The cessation of the circulation may also be due to the stoppage of emboli in the heart. According to Terrillon,[7] emboli carried to the right heart from the systemic circulation do not always pass through the heart into the pulmonary circulation, but may remain in the heart producing there an impediment to the circulation. In this case, he says that the heart does not cease instantly, but its beats become gradually smaller and scarcely perceptible, and a condition of extreme cyanosis, followed by death, results. In such a condition the embolus must be an extremely large one, and it is probably caught in the ventricle, and from the continuous addition of thrombi to it, it may occlude the orifice of the pulmonary artery.

These seem to be the only conditions which interfere with the circulation of the blood through the heart by obstructing its orifices. We must now consider those cases in which the mechanism of the heart itself breaks down. We may divide these into the cases in which pathological condition is seated in the muscular substance of the heart or in the valves. There are a number of cases reported in the literature of the heart of the sudden rupture of a valve. Generally, the aortic valve is the one ruptured; and the rupture is generally due to sudden and severe muscular effort, and may take place in a perfectly normal individual. The condition is one which may be

produced in a dog by passing a sound into the aorta from the carotid, and tearing away one of the aortic valves. There is usually sudden collapse, which is recovered from when the heart's action increases to meet the sudden demand thrown upon it. I have seen one case in which sudden rupture of several of the chordæ tendiniæ of the mitral valve was sufficient to instantly stop a diseased and hypertrophied heart. The case was that of a man with extensive visceral syphilis and Bright's disease. He rode to the hospital in a car, and after leaving the car and walking up the few steps leading to the dispensary, he fell dead. At the autopsy, there was found an acute and chronic endocarditis which had affected the chordæ tendiniæ, and several of these belonging to the aortic segment of the mitral valve had ruptured, allowing the valve to flap back into the auricle and destroying its functions. It is difficult to see how such an accident could happen in a normal heart; and even should it take place it would probably not result in sudden death.

A very much larger number of cases of sudden death are due to conditions affecting the integrity of the myocardium and its power of contraction. It has been shown by numerous experimenters that a normal circulation in the coronary vessels is essential to the function of the heart, and those pathological conditions of the heart itself which lead to sudden cessation of its action are in the main or entirely to be referred to diseased conditions of the coronary arteries. That sudden death is common in heart disease is a widespread belief among the laity. As a rule, in cases of heart disease of the ordinary type in which there are marked evidences of the condition during life, chiefly shown by the results in other organs of impairment to the circulation, death does not take place suddenly, but is generally to be referred to the gradual increase of the conditions brought about by the impairment of the circulation. Cases in which the trouble lies in the mitral orifice, whether stenosis or regurgitation, or both, rarely or never die suddenly. Sudden death, though not common, may take place in cases of stenosis of the aortic orifice.

In stenosis of the aortic valves the intraventricular pressure must be greatly increased in order to overcome it, and with this there is probably a greater degree of hypertrophy than is met with under any other circumstances. Moreover, stenosis of the aortic orifice is frequently accompanied by, and often the result of changes in the arteries, which in themselves lead to hypertrophy. It is possible that the greatly hypertrophied and dilated ventricle may suddenly have an amount of work thrown on it which it cannot accomplish. In consequence of sudden exertion, or some pschychical influence quickly increasing blood-pressure, the ventricle cannot contract on its contents and there is an end. More often, however, the sudden death which takes place in aortic stenosis is due to conditions of the myocardium which may accompany the disease of the aortic valves. Those cases of aortic stenosis which arise after the fortieth year, and have not been preceded by an acute endocarditis are generally due to an extension to the aortic valves of arteriosclerosis of the aorta. The same process also very generally affects the coronary arteries, and death, in cases of aortic stenosis, is more often due to this affection of the arteries and the changes in the myocardium following it, than to the aortic stenosis in itself.

It is only of late that the important part which the coronary arteries play in the physiology and pathology of the heart has been fully recognized. The two arteries have few or no anastomoses with one another and are distributed to definite sections of the heart, being terminal arteries in the sense of Cohnheim. There is, of course, capillary anastomosis between the various arterial tracts, but there is little or no connection between the larger branches. There is a difference between the various authors as to the presence of and degree of this anastomosis, and there seems to be a marked difference in different hearts. In some cases abundant anastomoses between the right and left coronaries certainly exist as was shown by a case reported by Welch.[8] In this case the right coronary artery was occluded at its origin by a dense sclerotic patch in the aorta. Beyond this the artery was open and it must have received sufficient blood from the left coronary to suffice for its circulation. Stevens[9] found by making injections that communication between the two main arteries and between the various branches of each was sometimes found but does not think that this anastomosis is sufficiently well marked to compensate for the closure. Sternburg[10] studied by various means of injections the territories supplied by the different arteries. He finds that a large portion of the right auricle, the entire posterior part, and a large portion of the anterior part of the right ventricle, a large part of the inter-auricular, and the inter-ventricular septum, the posterior part of the left ventricle, and the posterior papillary muscles are all supplied by the right coronary artery. All other portions of the heart are supplied by the left.

The coronary arteries are among the arteries most liable to disease. They may be occluded by thrombosis or embolism or have their lumen narrowed or occluded by arterio-sclerosis and atheroma. There is a difference between the two arteries in the liability to disease. The left coronary is more frequently affected than the right, and the descending branch of the left coronary more frequently than any other single branch. If a very small branch of the artery be occluded the circulation in the territory supplied by it may be kept up by anastomosis through the capillaries, but this only holds for a very small branch. Occlusion or narrowing of a large arterial branch is followed by the same result which takes place in any other portion of the body where the arteries are terminal, as in the kidney or spleen. The portion of the tissue supplied by the affected artery will, if the occlusion be complete, be cut off from its supply of blood. This will produce necrosis of the tissue elements and of the walls of the blood vessels. The area will be pale, anæmic and we have the conditions of the white infarction. In some cases a large amount of blood will flow into the previously anæmic area from the capillaries of the surrounding tissue. The injured blood-vessels will allow free hæmorrhage to take place from them into the tissues and the condition known as hæmorrhagic infarction is produced. In other cases we have a mixture of the two, an infarction with an anæmic central territory, surrounded by hæmorrhage. The infarctions rarely take place except when the occlusion of the artery is sudden and complete as by thrombosis or embolism. The condition which is more common than infarction

is one of imperfect nutrition of the heart followed by degeneration of the muscular substance, and produced not by a total occlusion but by a gradual narrowing of the artery. This is due to the ordinary arterio-sclerotic changes sometimes accompanied by atheroma. The nutrition of the tissue may also be affected by arterio-sclerosis without any narrowing of the lumen. The calibre of an artery always conforms to the needs of the tissue supplied by it and varies with the requirements of the tissue. The variations in calibre are produced by contraction of the muscular coat. The essential pathological change in arterio-sclerosis is destruction of the muscular coat, and its substitution by a dense unyielding connective tissue. This converts the artery into a rigid tube which, although performing the mechanical work of bringing blood to the tissue, cannot vary the lumen to meet the demands of the tissues.

Coronary arteries stand in causal relation with the pathological condition known as fibrous or chronic myocarditis. This condition is characterized by the presence of smaller or larger whitish opaque masses of fibrous tissue which is substituted for the muscular tissue. In most cases it may be seen in the endocardium, and extends from this into the muscular tissue; in other cases it does not extend into the endocardium, and the evidence of its presence is only obtained by making sections of the muscle parallel with its surface. Although spoken of as myocarditis, it probably is not an inflammation but the fibrous tissue simply takes the place of the previously degenerated muscular tissue which has been absorbed. The process is one which is rarely found in the right ventricle, and is usually confined to the left side of the heart where it affects the apex of the ventricle and the papillary muscles. It is nearly always due to arterio-sclerosis of the coronary artery distributed to the area, its distribution in the heart conforming to the distribution of the artery most frequently affected.

Most authors agree that fibrous myocarditis is exclusively due to the disease of the coronary arteries. I have recently, however, seen a case which shows that it can be due to other conditions. The case was that of a man who died suddenly a few days after entering into the hospital. He had previously been treated for syphilis, and at the time of his death there were evidences of a slight papillar syphilide on his body. His chief complaint on entering the hospital was dyspnœa. At the autopsy there was found obliteration of the pericardium and the formation of dense sclerotic masses of connective tissue in both layers of the pericardium. The pericardium was adherent in its whole extent, and here and there in the thickened tissue some slight caseous material was found. The right ventricle was enormously dilated, being fully as large as a normal heart. All the valves of the heart were normal. Throughout the right ventricle there were numerous masses of fibrous myocarditis, some of which were two centimetres in diameter. They were distributed not only throughout the outer surface of the ventricle, but along the septum. There was also a patch of fibrous myocarditis in the left ventricle, in the septum and a few small patches at the apex. The coronary arteries were normal with the exception of a perfectly circumscribed patch of endarteritis in the left coronary artery around the mouth of a large branch going into the septum. The intima here was thickened and roughened but the calibre of the artery was very slightly affected. Microscopic examination showed that the patches of fibrous myocarditis in the right ventricle were in every case closely connected with the fibrous pericarditis, and it seemed to be due merely to an extension of the fibrous tissue from the pericardium into the myocardium. It was accompanied by a well marked arteritis of the smaller arteries. There was clear evidence of syphilis given in a fibrous orchitis in both testicles. There is little doubt that in this case the myocarditis was directly due to the pericarditis which was very probably in close relation with the syphilis. The marked disease of the small arteries in the affected foci would point clearly to this. The dilatation of the ventricle was due to the fibrous myocarditis, and the sudden death to the same cause.

Although this formation of fibrous tissue is essentially conservative in its action, supplying a firmer tissue than the degenerated muscle, it is infinitely less resistant than the normal tissue of the heart. It gradually gives way before the pressure in the ventricle and is the cause of aneurism of the heart. These aneurisms of the heart are essentially the same as aneurism of any of the arteries. They frequently contain a large amount of laminated fibrin in their walls. They may form in any part of the heart, but are much more frequent in the apex of the left ventricle. Rupture of the heart, leading to sudden death in a large percentage of the cases, may take place through the walls of such an aneurism.

Death from non-traumatic, the so-called spontaneous rupture of the heart, cannot be regarded as extremely uncommon. I have seen four cases and there are a great number of cases reported in the literature. It would not be within the purpose of this article to enter fully into the literature of the subject. The fullest accounts with statistics are given by Bottger,[11] Barth [12] and Meyer.[13] It may be regarded as certain that rupture, even under the greatest sudden increase in pressure, never takes place in a normal heart. The various conditions of the heart which precede rupture are those due to coronary artery disease. The connection between rupture of the heart and disease of the arteries was first recognized by Barth, and since then has been noted in all cases in which the arteries were examined. The pathological conditions of the myocardium which may lead to heart rupture, are fibrous myocarditis, with or without aneurism formation, circumscribed fatty degeneration, necrosis and fatty infarction.

The only condition of the heart not connected with disease of the coronary arteries which may be followed by rupture is fatty infiltration. In this condition there is a development of fat on the outside of the heart, beneath the pericardium, which may penetrate beneath the muscular fibres, thus weakening the heart. In the earlier literature several cases of this have been reported, but since the condition of the coronary arteries has received careful attention, there has been no report of this. It must be very exceptional to have such a degree of fatty infiltration that it can lead to rupture of the heart.

With regard to the frequency of rupture of the heart, Devergie [14] reckons it as producing two and one-half per cent. of the cases of sudden death. Aran

[11] Bottger: Ueber die spontanen Rupture des Herzens, Arch. d. Heilkunde, 1863.
[12] Barth: De la rupture Spontanée du cœur, Arch. gen. de Med., 1871.
[13] Meyer: Zur Kenutriess der spontanen Herzruptur, Deutsches Arch., Bd, 43.
[14] Devergie: Médicine Legale, 1840.

(quoted from Bottger) found in 202 cases of sudden death with changes in the organs of circulation, 113 produced by affections of the heart without rupture, and 88 by rupture. To both traumatic and spontaneous rupture of the heart the male sex is more disposed than the female. Elleaune [15] found in 18 cases of rupture of the heart, 16 in males and only two in females. In the traumatic rupture the greater frequency in males may be explained by their greater exposure to danger. And in the spontaneous rupture of the heart to the fact that men are more disposed to lesions of the vessels than women.

With regard to the seat of rupture, Ollivier [16] found in 47 cases that the seat of the rupture in 34 was in the left ventricle; in eight the right; in three the right auricle, and in two the left auricle. Bayley has found in 19 cases the seat of the rupture was in 16 the left ventricle, and in three the right ventricle. In 62 cases collected by Bottger, the rupture in 47 was in the left ventricle, in five the right, in five the right auricle, in one the left auricle, one the intraventricular septum, one in both ventricles and in one extending from the right auricle into the right ventricle.

As might be expected the condition is one which is most apt to be found in the later years of life. In 50 cases which Bottger has collected in which the age is given, there were found

Between	20 and 30 years	1
"	30 and 40 "	2
"	40 and 50 "	6
"	50 and 60 "	7
"	60 and 70 "	18
"	70 and 80 "	11
"	80 and 90 "	4
"	90 and 100 "	1

This is clearly due to the greater frequency of vascular diseases as age advances.

In most cases the rupture is a perfectly clean one making a straight passage through the wall of the heart. This is especially the case when the rupture is preceded by an aneurism. In other cases the rupture does not take place directly through the wall of the heart, but the rupture into the pericardium may be at some distance from the rupture into the endocardium, the blood burrowing into the wall of the heart and making a fistulous passage. In some cases in which the rupture has been preceded by a hæmorrhagic infarction, the hæmorrhage into the muscular tissue is very extensive and from this it appears to penetrate both into the endocardium and into the pericardium. Mettenheiner [17] reports a case in which there was rupture of the myocardium with extensive hæmorrhage beneath the pericardium, which had not penetrated into the pericardial cavity. The pericardium for a considerable distance was separated from the myocardium by the hæmorrhage. Such a case is analogous to a dissecting aneurism. The rupture of the heart sometimes takes place when the patient is quiet and there is no excitement of any sort. In other cases the rupture appears to be due to some sudden increase of the blood-pressure, either brought on by muscular exertion or excitement of some sort.

Wadman [18] reports a case in which in a man, sixty-four years old, rupture took place during coitus, and a number of similar cases have been collected by Bottger. Geo. II, of England, is said to have died from rupture of the heart while at stool, and Philip V, of Spain, on hearing the report of the defeat at Piazensa.

Death is not always instantaneous in rupture of the heart. If the rent be a considerable one and a large hæmorrhage takes place at once into the myocardium, death is instantaneous. A number of cases have been reported in which the beginning of the rupture was apparently marked by fainting and death followed several hours afterwards.

The same effect as rupture of the heart itself may be given by rupture of any of the great vessels within the pericardium. The rupture may take place here, either through an aneurism or through a degenerated spot in the aorta.

In the four cases of rupture of the heart which I have seen, three took place in the left ventricle. One of these was preceded by an aneurism. In two, death was immediate, and in one in which there was a long passage between the endocardium and the myocardium, death was gradual. In another case in which an aneurism of one of the sinuses of Valsalva burst into the right ventricle, the manner of death was also slow. I have also seen one case in which death was due to rupture of the aorta within the pericardium. In all of these cases death is not due to the hæmorrhage. The amount of blood found within the pericardium is never sufficient to have produced death. The amount of blood which is found depends upon the rapidity and extent of the rupture. The pericardium is a distensible cavity, and if the pressure be slow it may be gradually distended to a considerable degree before an amount of blood accumulates within it which will be fatal. The death, of course, is due to an increase of pressure within the pericardium, preventing the entry of venous blood into the heart and so stopping the circulation.

In rare cases sudden death may take place from pericarditis. When the pericardial pressure is suddenly increased by the rapid accumulation of an exudation, death may be sudden. In a case autopsied at the City Hospital during the past year in which death took place suddenly, there was a large hæmorrhage into the pericardium which had evidently come from hæmorrhage from the greatly-distended vessels of the pericardium. This case, however, was complicated by an acute myocarditis which may have contributed greatly to the effect of the pericardial exudation.

Rupture of the heart does not seem to follow cases of ulcerative endocarditis even when the ulceration is extensive. In rare cases the rupture may be due to the presence of new formations in the heart or to parasites. Berth found one case in which rupture had first taken place into a large echinococcus cyst of the heart and then into the pericardium.

Although a circumscribed fatty degeneration of the heart due to coronary disease may lead to rupture, this does not take place in the general fatty degeneration of the cardiac muscle, which comes on in the acute infectious diseases. Probably in such cases there may be combined with fatty degeneration a diminution in the force of the cardiac contraction and the intraventricular pressure.

A much greater number of cases of sudden death is due to disease of the coronary arteries without rupture of the heart. This fact is one to which attention has only recently been directed when greater attention has been bestowed on the pathology of the coronary

arteries. It is probable that most of the cases of sudden death without apparent cause, which have been reported, were due to diseased conditions of the coronary arteries which were overlooked at the autopsy. Death from this may be the most sudden of any of the forms of death, whether proceeding from the heart or elsewhere. The individual often falls as if struck with lightning. As in rupture of the heart, death may be preceded by some muscular or psychical disturbance, or it may come on without any immediate exciting cause. The cases are usually those of individuals who have passed the fortieth year, and who have not denied themselves the pleasures of life. All the conditions which favor the development of general arterio-sclerosis favor the similar process in the coronary arteries. In some cases death has been preceded by attacks of angina pectoris, and it may take place in such an attack.

In almost all cases we find that the arterial disease has produced lesions in the myocardium before death. The most common of these are the more or less extensive patches of fibrous myocarditis. Rare cases are seen, however, in which there is considerable disease of the arteries without any macroscopic evidence of degeneration in the myocardium. Microscopic examination in such cases will usually show rather diffuse hyaline degeneration with slight connective-tissue increase. We can easily understand, supposing the circulation in the coronary arteries to be necessary for the function of the heart, that the instant closure of a main artery or a large branch by embolus should be followed by an instant cessation of the heart's function. But it is more difficult to understand the sudden stopping of the heart without any previous symptoms, in those cases in which the closure of the vessel takes place gradually. Cohnheim[19] has shown that tying off a large branch of one of the coronary arteries for a time produces no symptoms, and then there is a great fall of blood-pressure, and, after a few convulsive movements, the heart stops. There is no doubt that disease of certain of the coronary vessels is more serious in its consequences than others. Sudden death is more frequently associated with disease of the descending branch of the left coronary than any other. The gradual closure of the arteries, with degeneration of their walls and nutritive changes in the myocardium, may go on for a long time with but little impairment of function. The last straw, however, is finally laid on the back of the overloaded camel and the back breaks suddenly.

THE HYGIENIC ARGUMENT FOR CREMATION CONSIDERED FROM A BACTERIOLOGICAL STANDPOINT.[1]

BY A. K. STONE, M.D.

(Concluded from No. 18, page 435.)

THERE remain to be spoken of only the various experiments that have been made to determine the number of bacteria in the soil. The first of these were open to serious error because of faulty technique. But Fränkel[9] and Reimer,[10] the former working on the sandy soil of Berlin, and the latter on the heavier soil of Jena, have arrived at practically the same conclusions in regard to the bacteria in the soil, namely, that the number on the surface was very large, and the diminution from this amount was very rapid, especially after the depth of three-fourths of a metre was reached; and at one and three-fourths metres the numbers were very small indeed. Or, as Reimer puts it, to a certain depth the number of bacteria is very high, but always less than are to be found on the surface. With increasing depth there is a sudden and sharp decrease of the number. The zone in which this sudden diminution takes place is, in both Berlin and Jena, between one and two metres. The exact position of this zone depends on the condition of the soil, as, for example, the line is deeper in cultivated than in virgin soil. At a depth of two metres the soil can be germ free (of ærobic bacteria). More rapid growth is observed in specimens taken from the upper strata than in those from lower.

The ground-water seems to have various influences upon the condition of things. In some cases the regular diminution took place in spite of the presence of the ground-water; in other cases there was a marked increase in the number of germs when the ground-water was reached. So that the conditions of the porosity of the soil and the amount of foul matter poured upon it probably influence the number of bacteria to be found in the ground-water.

An interesting portion of Reimer's investigations is that made in the cemeteries of Jena and Little Jena. Examinations were made in seven graves, which have been in use for from one and one-half to thirty-five years; also a set of control experiments were made in the ditches in neighboring gardens. It was found first: That the number of bacteria in the ground of the graveyards and the gardens was practically the same, though in both cases larger than in ground that had never been disturbed. As soon as a depth was reached where the earth had never been moved, the figures promptly fell to correspond with those of similar depths of virgin soil. The earth immediately below the coffins in the exhumation, showed a marked increase in the number of bacteria over the average of similar depths, yet considering the circumstances, the increase was smaller than was to be expected: while at a distance of half a metre below the coffins, the number of bacteria returned to the average that was to be expected at that depth. At a level of the upper surface of the coffins there was no increase from the average in the number of bacteria found.

Beumer (although his technique is open to criticism) has also similar results to those of Reimer. He did not, however, carry his investigations as far as could be wished, for he made no examination of the earth below the level of the coffins, that is, six feet.

Gärtner[11] also derived similar results from an investigation of two cemeteries.

In 1890, investigations were begun to determine the hygienic condition of the cemetery of the Charité Hospital[12] in Berlin. No burials had taken place since 1859, and the government wished to find out whether the cemetery could justifiably be used for building purposes. Proskauer was detailed by Koch to conduct the investigations, and the results of his work are briefly as follows:

[1] Read before the Warren Club.
[9] Fränkel: Zeitschrift für Hygiene, vol. ii. 1887.
[10] Reimer: Zeitschrift für Hygiene, vol. iii, 1889.
[19] Cohnheim and Reclberg: Ueber die Folgen d. Kranzarterienverschliesiung für das Herz, Virch. Arch., 85.
[11] Gärtner: Tageblatt der Naturforscher-versammlung, Heidelburg, 1889. Quoted by Prokann.
[12] Proskauer: Zeitschrift für Hygiene, vol. xi, 1891.

At a depth of 1.70 metres the soil is rich in human remains and remnants of coffins. The decay of these human bodies has been so complete in the last thirty-one years that in the upper layers of the earth there was no difference to be discovered, either chemically or bacteriologically, from earth that had never served for graveyard purposes. The chemical investigation at a depth of .5 to 1.50 metres, that is, directly at the level that the coffins had occupied, showed that the earth was in no ways overladen with rotting organic material, and that on the contrary it was poorer in nitrogenous material than Flüge had found in the *aufgeschütteten Boden* — heaped-up earth — of Berlin. From 1.70 metres or from two to six metres in depth, the condition of the soil was similar in all respects to what would be expected in similar soils. There was not the slightest trace of nitrogenous matter and no micro-organisms.

The ground-water of the graveyard and the well-water had the same chemical properties as the water from the surface wells of Berlin, all of which contain large amounts of nitrogenous compounds, particularly nitrates. But Proskauer is of the opinion that the ground-water is already contaminated before it reaches the cemetery, and that there is no increase in the amount of organic matter during its stay within the boundaries of the old graveyard. The ground-water also showed itself free from micro-organisms; and finally Proskauer concludes, after taking everything into consideration from a hygienic standpoint, that there is no reason why the Alter Charité Kirchhof should not be used for dwellings or for hospital purposes.

The work of Domingos Freire, of Brazil, in his investigation of the causes of yellow fever, is frequently quoted as giving strong arguments in favor of cremation. He has stated that he has surely found the micro-organisms causing yellow fever; that he has recognized the same organisms in the earth of cemeteries in which the yellow-fever patients have been buried; and he has also claimed to have found a method of vaccination.

Sternberg,[13] Deputy Surgeon-General of the United States, after a series of investigations into the etiology of yellow fever, was not able to agree with Freire. And in his report, 1888, he states that no such micro-organism as described by Freire, or as shown by him to Sternberg, is to be found in the blood and tissues of yellow-fever patients. In later reports he concludes that the specific infectious agent of yellow fever has not been demonstrated. The most approved bacteriological methods fail to demonstrate the constant presence of any particular micro-organism in the blood or tissues of yellow-fever cadavers. This position is supported by Cormil and Babes in their work on "Les Bacteries," who do not consider that, at the date of their publication, 1890, any specific bacteria of yellow fever had been discovered. Therefore, we are forced to the position that, until further work has been done, Freire's work cannot be taken as authority.

Professor Graucher, of the Faculté de Médecine de Paris, and Professor Richard made a report to the International Congress of Hygiene and Demography, on the Action of the Soil on Pathogenic Bacteria. They reached the following conclusions:

Pathogenic bacteria are everywhere deposited only in the superficial layers of the soil; from .5 metres to 1.5 metres there are very few present. They multiply with difficulty in the ground, though in the spore state they may remain for a long time.

The pathogenic germs are destroyed, partly by the action of the saprophytic bacteria, and partly — when they are on the surface — by the action of the sun; the latter must be considered a powerful destroying agent. Continuous cultivation of the soil, which tends to bring bacteria from the lower depths to the surface, is the very best means to bring about the destruction of the pathogenic bacteria.

Disturbances of the earth's surface — for example, extensive excavations — put in circulation a large number of pathogenic germs. A solid layer of two or three metres of earth is usually sufficient to protect the ground-waters against contamination of pathogenic bacteria.

All the investigations above quoted correspond in a remarkable degree; so that we are justified in saying that, from a purely bacteriological standpoint there is no evidence that a buried body is a source of special danger to the living.

On the other hand, there can be no doubt that water and air are frequently contaminated by the presence of putrefying animal remains, as instanced in the analysis of well-water from cemeteries; as we see by reports of the well near Paris, which became distinctly foul shortly after the interment of the bodies of a large number of Prussian soldiers who had died of typhoid; or the story of the well in Paris where the water, contaminated by cemeteries, had a distinct taste of sulphur, so that it was bottled and sold as a mineral water; or from the undoubted cases where epidemics were of the greatest intensity in the near vicinity of overcrowded graveyards.

Why these occurrences have taken place, and what effect the decay of animal matter has upon the human being, we have at the present time no accurate means of knowing. Such data as we have can only be obtained when we study the subject of putrefaction. We cannot hold the old explanation that putrefaction is simply oxydation — the burning of the animal, in the same way that a bit of the animal would act if it were exposed to the flame. But decay, and the return of the body to its final elements, is not a simple chemical process, as is usually imagined, but a very complicated process, induced for the most part by the action of various bacteria upon the organized tissues, converting them into mid-products. The first stages, according to Flügge, consist in the change of the albumens into peptones, and this may be effected by a large number of bacteria. Among the products of putrefactive fermentation are carbon dioxide, hydrogen, nitrogen, hydrosulphuric acid, phosphoretted hydrogen, methane, formic acid, acetic acid, butyric acid, valerianic acid, crotonic, glycolic, oxalic, succinic, propionic, lactic and amidostearic acids, leucin, ammonia, ammonium carbonate, ammonium sulphide, trimethylamine, propylamine, indol, skatol, tyrosin, neuridin, cadaverin, putrescin, cholin, neurin, peptotoxin and various other volatile acids and ptomains.[14] These special products are not necessarily all present in any given body in the process of dissolution, but vary according to the place where the body may be put, or according to the presence of certain varieties of bacteria.

The nitrification of the organic products is also due to the presence of bacteria; and within a short time

[13] Sternberg: Manual, 1892.

[14] Sternberg: page 134.

two observers, quite remote from each other, have isolated a bacterium, which if not identical, is at any rate of the same species. I refer to Jordan's work at Lawrence, and Winogradsky's at Zurich. Similar work has also been done by Frankland and Warington. Thus far, bacteriological investigations have been confined to those bacteria which accomplish their work in the presence of oxygen, or to the aërobic bacteria; and but little attention has been given to those which work only when oxygen is excluded, the anaërobic bacteria, although it is known that the foul odors of putrefaction belong, for the most part, to the latter class. In none of the investigations above quoted were there attempts to discover the number of anaërobics that might be present, with the exception of the work of Proskauer, who said that some of the human remains were examined for anaërobic germs, but with negative results.

It is believed by men interested in sanitary questions, that sewage containing excreta and animal impurities, and micro-organisms, is best rendered pure by pouring it out on the soil and allowing it to percolate slowly through the upper layers, where it is met by the bacteria of decomposition which are present, as has been shown above, in great quantities. The retrograde changes then take place with great rapidity, and the whole process is hastened by the action of the sun and by the cultivation of the land; the plants seizing upon the particles of decomposing matter, as soon as it is reduced to the stage where it can become their food.

The difference between this process, which is advocated by many of the best sanitary authorities at present, — as instanced by the many sewage farms in operation, among which may be mentioned Berlin, Paris, and the towns of Framingham and Marlboro in this State, and the Experiment Station of the Massachusetts Board of Health where so many careful experiments have been carried out, — and the process that takes place where a body is buried in six feet of earth, is that in the case of the former, oxygen is always present, while in the case of the dead bodies oxygen is practically excluded; the argument being that the decomposing changes in the case of the sewage take place rapidly, because the bacteria have plenty of oxygen, which is necessary for their development. On the other hand, the dead bodies are buried so deep that all supply of oxygen is cut off, and decomposition does not take place,[15] or takes place so slowly that more of the poisonous mid-products of decomposition are allowed to form, and hence the body becomes a source of danger to the living by those soluble products of decomposition designated by the general name of ptomains, or appearing in the chemical analysis combined under the general heading of albuminoid ammonias.

The only experiment which I have been able to find, that bears directly on the occurrences which take place when a body is buried, is the one which is reported by the State Board of Health.[16]

A tank twelve feet in height was taken and filled to a depth of six feet with layers, first of coarse gravel, then of sand and loam from a cemetery. This was watered weekly, and the condition of the water noted. In December, 1889, the body of a dog weighing eleven and one-half pounds was put into the tank and buried beneath similar soil for the remaining six feet. This tank was watered regularly with an amount of water slightly larger in amount than what would correspond to the average rainfall on the same area. The outlet was tapped, and the escaping water was examined monthly for the space of two years. For six months practically no nitrification of the body had taken place. At the end of that time, there was an increase in both the nitrates and nitrites, and the free ammonia increased rapidly for the next five months, showing 26.625 parts per 100,000 by November, 1890. It then gradually fell off, but at the end of twenty-four months the amount was still 4.75 parts per 100,000. The albuminoid ammonia, in which the dangerous mid-products are represented, if present, increased but little for seven months, and then increased some for two months, after which it increased very rapidly, and for November, 1890, averaged 2.8000 parts per 100,000. From this time on there has been a steady fall, until December, 1891, there was but .1200 per 100,000.

The odor at the effluent grew very strong and offensive through April, May and June, and was most nauseating during the first part of July. Since then it has decreased, but all through the second year it had a strong, offensive odor. In December, 1890, the outlet was trapped, and in this way all possible supply of oxygen entering from below was cut off. The most important effect of this proceeding was, that the number of bacteria per cubic centimetre in the effluent water immediately fell off, and from 4,319 in September, 18,360 in October, 4,796 in November, the number became 96 in December, 362 in January, 10 in February, 52 in March, and has since never been above twenty; and for several months in midsummer was sterile.

This experiment bears out what has been said above, and tends to shift the burden of proof upon the chemists, calling on them to explain what the deleterious effects of drinking-water, which is contaminated with decomposing animal matter, may be.

I conclude, from a study of the effects of bacteria contained in dead bodies upon the health of living persons, that there is no good evidence whatsoever to show that, if the bodies are suitably buried, the bacteria which are probably the cause of the so-called zymotic diseases, can in any way contaminate the ground-water. The harm which decomposing human bodies may exert upon the living must be due, not to the specific pathogenic bacteria, but to poisoning of the air and water by the presence of volatile and soluble substances, which probably have the effect of depressing the general vitality of the persons subjected to the influence.

Under suitable conditions, the earth, with the assistance of the "bacteria of decomposition," appears to be a rapid and sure means by which bodies of persons dying of zymotic diseases may be rendered harmless and converted into material suitable for the maintenance of higher vegetable life.

Experience goes to show that the pathogenic bacteria are unable to resist for any length of time the chemical changes set up in the dead body by the bacteria of decomposition, excepting in the few rare cases, where spores are formed. These are able to resist the putrefactive changes for an indefinite period of time.

At the request of a gentleman who is much interested

[15] Seymour Haden reported that in 1875, when removing corpses from St. Andrew's Churchyard to level Holborn Hill, London, the bodies were in much the same state as when first buried, and decomposition was unadvanced and unadvancing; and little or no difference was discernable between the interments of yesterday and of King Charles II's time. International Congress of Hygiene and Demography, 1891.

[16] Massachusetts State Board of Health Reports. Purification of Sewage, 1890-1891.

in cremation, I undertook the task of going over the literature which has accumulated upon this subject and have tried to find out from a bacteriological point of view what arguments could be advanced in favor of cremation. The conclusions reached are not at all in accord with my preconceived ideas, and it appears as though it belonged to the chemists and not to the bacteriologists to prove, if possible, that cremation is a hygienic necessity. Of course economical and æsthetic arguments are entirely uninfluenced by the lack of evidence to support any given hygienic argument.

Clinical Department.

DIPHTHERIA: TRACHEOTOMY, PERSISTENT AND INCREASING DYSPNŒA, SYSTEMATIC CURETTING OF THE TRACHEA; RECOVERY.

BY CHARLES L. SCUDDER, M.D.,
Assistant in Clinical Surgery, Harvard Medical School, Boston.

A BOY, four years old, ordinarily in good health, had been ill with diphtheria for two days. His brother, one year younger, had died of the same disease one week previously. He was referred to me by Dr. T. M. Rotch, of Boston.

Very little disturbance of the tonsils and pharynx existed at the time of the first examination, the end of the second day's illness. The breathing was slightly difficult. The alæ nasi dilated a very little, the retraction of the supra-clavicular and epigastric regions with each inspiratory movement was just beginning to be apparent. In short, breathing was slightly embarrassed. The lungs were normal. The heart was in good condition. The temperature was low. The indication *par excellence* for operating was present, namely, increasing difficulty in breathing.

Tracheotomy was done. The relief, of course, was instantaneous. The boy was kept in a cot-bed covered by a hood of sheets, which was constantly filled with steam from two boilers.

All went well until the second day after the operation, when the secretion from the tube became a little sticky and slightly diminished in amount. The character of the secretion improved upon the use of a spray close to the tube, and the boy had a comfortable night. The third night, however, there was serious trouble. The secretion became very slight, the respiration rapid and labored, and the child cyanosed and extremely tired by the tugging for air.

In spite of the removal and cleansing of the inner tube and the removal, cleansing and replacing of the outer tube; the removal of both tubes and the dilatation of the wound; the use of the catheter through the wound, and the introduction of a feather, and later a pair of properly-curved forceps, — notwithstanding all of these ordinary manœuvres for the relief of obstruction below the tracheotomy wound, no relief was afforded. The child was fast losing strength, and was becoming rapidly asphyxiated. It then seemed necessary to resort to a very radical procedure. Having at hand a dull wire intra-uterine curette, this was introduced into the wound, gently carried to the bifurcation of the trachea, and all sides of the trachea — its whole circumference — systematically and thoroughly curetted. As the curetting continued, pieces of membrane, one of which made a complete cast of the circumference of the trachea, were withdrawn through the wound. The hæmorrhage was slight. The relief to the dyspnœa was immediate.

The tube was replaced; and the boy made an uninterrupted recovery. One or two pieces of membrane came away the following day.

Two years have elapsed since the tracheotomy and curetting of the trachea. The boy is well and strong.

This case is recorded to emphasize the importance of systematic curetting of the trachea for obstruction by diphtheritic exudation. The manœuvre was suggested in a conversation with Dr. Wheeler, of Chelsea, Mass., regarding a case which he had likewise curetted. A careful search of medical literature fails to find a similar case recorded.

In the case in hand the diphtheritic inflammation was probably quiescent. The product of that inflammation was separating from the walls of the trachea. Resolution had begun. It was an opportune time to curette.

No general rule can be deduced from a single instance, but it would seem wise to resort to thorough curetting, if, after tracheotomy, dyspnœa increased in spite of all the ordinary procedures, and if the patient is in good general condition.

Intubation would have been of little aid in this instance.

It has been my experience that these cases operated on early in the course of the disease and when the laryngeal symptoms are slight, even though progressive, do better than the cases operated on when the child is exhausted by difficult breathing and by sepsis.

HINC ILLÆ LACHRYMÆ.

BY DAVID COGGIN, M.D., SALEM, MASS.

TEAR-PASSAGES that are by no means thoroughfares are, as is well known, frequently encountered in our latitude and especially during cold weather. It is likely that more females than males seek advice because of this trouble — whose victims range from infancy to age.

When seen early, the epiphora ordinarily yields to treatment, as by dropping a lotion within the conjuntival sac (such as acid zinci sulph. 0.10, acid boric. 0.50, aqua menth. p. 10.0, aqua camph. 20.0).

Naturally, if the sac is distended, its contents should be squeezed out before using the lotion. Large shade glasses worn out of doors afford relief in some instances.

Rarely the catarrhal trouble is located at the inferior extremity of the nasal duct, and it may subside on applying within the naris a solution of Seiler's tablets, or the like.

Frequently the lower punctum is so small as to be barely visible. In such a case, and also when it is somewhat everted, it is often sufficient to dilate it, as well as the canaliculus, with a small conical probe, and then to inject an astringent lotion with a Meyer's syringe (which has a bulbous tip and is therefore less liable to injure the mucous membrane than is Anel's).

If the fluid passes through the corresponding nostril it is most reassuring to the patient. The country practitioner, who is frequently forced to extemporize apparatus, can make blunt the points of a large darning-needle and of a hypodermic syringe and he will thus have instruments that will be of material aid in treating this trouble.

Even if the nasal duct is closed so that no water passes down into the nose, the frequent use of the syringe is ultimately likely to be of benefit.

But in cases of long standing it is ordinarily necessary to incise (somewhat inwards towards the eye) the outer third of the lower canaliculus, and to make two or three vertical cuts through the narrowed portions of the nasal duct with a probe-pointed knife, which has a long, malleable shank, such as Agnew's. Afterwards, the passing of probes is the routine, but by no means always satisfactory, course of treatment.

Some ophthalmic surgeons prefer large probes — three millimetres to four millimetres in diameter.

My usual practice is to use a Bowman 5–6 (having William's olive tip), and bent to form an arc. I pass the probe and immediately withdraw it, in accordance with the advice once given at Moorfields by the late Sir Wm. Bowman, Bart. Cases occasionally occur where a member of the patient's family learns to pass a probe most deftly. Assuredly, the frequent emptying of the sac by pressure and the use of an eye-water are to be preferred alone rather than in connection with harsh probing by whomsoever done.

In acute inflammation of the lachrymal sac (abscess of the tear-passage), on using cocaine and introducing an Anel's probe through the lower canal into the sac, it is often possible by an in-and-out motion, in conjunction with gentle pressure on the distended sac, to evacuate so much pus as to relieve the tension and pain. On applying moist heat for ten minutes every hour, and on repeating the emptying of the sac two or three times, resolution may occur.

Several timid patients have been thus relieved — the last one quite recently. One was a man who declined to have the abscess punctured, and on three occasions, at intervals of, perhaps, as many years, a probable perforation through the skin with a resulting disagreeable fistula of the lachrymal sac was apparently avoided by performing this little manœuvre.

In chronic dacryocystitis with great distension of the sac-cavity, so an unsightly tumor was a cause of annoyance to the patient, after opening and appropriately treating the passage to the nose, ordinary contractile collodium (U. S. P.) was painted on the external surface of the tumor, renewing it every day or two, till the swelling had quite disappeared and the capacity of the sac had been restored to its former limits, while the epiphora was no longer present.

It has never been my fortune to either apply caustics to cause obliteration of the sac, or to excise it.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

LOCAL ANÆSTHESIA.

VON HACKER[1] has published his results relating to the use of cocaine and æthyl-chloride for purposes of local anæsthesia. The preparation of cocaine found most satisfactory was:

R	Cocaine	0.1
	Sodii Chloride	2.00
	Aquæ	100.00

Of this solution 10 grammes, the amount usually used, contains 0.01 gramme of cocaine. The solution should be injected into and under the skin so as to create an œdematous-like condition. Distinct wheals are formed. When so used, von Hacker found that minor surgical operations were absolutely without pain. The method is not suitable for extended operations. The chloride of æthyl spray was also found to be quite efficient for small operations and quite simple in application.

SURGICAL SIGNIFICANCE OF DUST.

The interesting editorial of Warbosse,[2] in which he describes at length the important work of Hægler,[3] deserves a careful perusal. The article is too long to report in detail. The results reported have an important relation to operative work and wound treatment. The work seems to show that the important factor in atmospheric infection is dust; that this contains the germs; that air in a room unagitated contains few germs; that the atmosphere of an unclean room in a state of rest is freer from germs than that of a comparatively clean room in a state of commotion. Dry dressing and dry treatment of wounds allow a greater distribution of germs into the atmosphere than moist ones. It is true that the danger of infection from air containing pathogenic microbes is much less than from other sources. Still, it is of enough importance to be considered when one is striving for complete asepsis. Hence attention should be paid to diminishing or eliminating the harmful effects of dust. Also to prevent the conversion of infectious material into dust, as by the dessication of pus, agitation of dry discarded dressings, or in similar ways. The methods proposed for the removal as far as possible of this liability of infection during operative work or the dressing of wounds were to avoid agitation of the air at such times or to precipitate all dust by charging the atmosphere with moisture, so that during its precipitation the dust is carried down with it and the air is thus cleared as during a shower. The moist surface thus produced holds such precipitated dust fast for a time, and prevents its renewed circulation by air currents. The article is an important one, and is a valuable contribution to the knowledge of asepsis.

SALINE INFUSION.

The value of this method of treatment of severe surgical shock as well as for cases of severe hæmorrhage, with or without strychnia, is emphasized by Dr. Sternberger,[4] who reports two severe cases of collapse, which were apparently rescued by the infusion. Three pints were syphoned into the median cephalic vein. In one case the infusion was repeated at the end of fifteen hours. The six-tenths-per-cent. solution was used at a temperature of 117° and 118° F. Dr. Sternberger considers the high temperature of the infusion and the after-use of strychnia important factors to his success; also the amount of infusion (three pints).

The saline solution can also be used subcutaneously for the same purpose, or by enema. The former method has recently been described by Dr. Farrar Cobb.[5] The apparatus used was a metal aspirator trocar with stop-cock and side entrance connected by rubber tube with a glass or hard rubber funnel. The trocar is sterilized by heat, the tube or funnel with

sublimate solution (1 to 1000). The sterilized salt solution was kept at a strength of twelve parts in one thousand, so that the addition of an equal amount of boiling water makes a solution of the strength usually used (6 to 1000) and of the right temperature for instant use. This arrangement is good for emergency work. The preparation is simple and rapid. The solution is syphoned through the trocar into the subcutaneous tissue of the inguinal and femoral regions. It can be done more rapidly than the intravenous method. The reported results were satisfactory.

Another method which has attracted little attention, but which has given striking results, is that of arterial infusion. This has recently been perfected by Dawbarn,[6] who records the resuscitation of several almost moribund patients. The solution at a temperature of, at least, 120° F. is syringed into the femoral artery through a Davidson syringe and a hypodermic needle.

NEURECTOMY IN SPASMODIC TORTICOLLIS.

Gardner and Giles,[7] in a paper on neurectomy in spasmodic torticollis and retrocollic spasm, report two cases, one of spasmodic torticollis, the other of retrocollic spasm without torticollis, which were treated by exposure and partial resection of both spinal accessory nerves and subsequent division of the posterior branches of the second and third cervical nerves. This treatment was completely successful in the first case, nearly five years having elapsed since the last operation; in the second case it was followed by ceasation of all bad symptoms, save some trifling spasmodic movements of the deep rotators of the left side, which it is anticipated will be completely cured by another operation. Gardner, who had charge of these cases, claims precedence over Keen with regard to section of portions of the posterior branches of the second and third cervical nerves, having performed this operation a few months before it had independently been thought out and practised by the latter surgeon. The following general considerations regarding the operation are deemed advisable to observe in the surgical treatment of these distressing cases:

(1) The operation on the spinal accessory nerve should precede, by a considerable interval, the difficult operation on the cervical nerves for two reasons: (*a*) because the milder operation has been known to be successful, even in cases in which spasmodic movements occurred in muscles not supplied by the spinal accessory nerve; (*b*) because the trapezius being completely paralyzed after neurectomy of the spinal accessory, time is also given for a more complete study of the muscles involved in the spasm, and in this way unnecessary operations with their risks and resulting scars may be avoided. (2) If the sterno-mastoid is involved in the spasm, the spinal accessory nerve should be exposed in front of this muscle, but if the trapezius alone is involved the nerve should be sought for by an incision along the posterior border. In neither case need the incision, if properly placed, exceed the length of two inches. (3) No injury to the patient will arise from the paralysis of muscle as to function. From an æsthetic point of view it is of advantage that the extent of the spasm should necessitate an operation on both sides, as thereby dissimilarity in the appearance of the right and left muscles is avoided. (4) The neuralgia which follows section of the nerves is especially felt in the shoulders, and appears to be of very fleeting character. (5) The spinal accessory nerves may be both cut down upon at the same operation, as the whole procedure can be performed with precision in about fifteen minutes. In the case of the posterior cervical nerves the two sides should never be attacked at the same stage, because the duration of the double operation might seriously increase the risk to the patient, or the onset of dangerous symptoms might necessitate the second operation being left unfinished.

A NEW AND SAFE METHOD OF CUTTING ŒSOPHAGEAL STRICTURES.

This is described by Dr. Robert Abbe,[8] and is claimed by him to have been successfully used, and to be superior to the "Billroth" method (external œsophagotomy and division of stricture by incision, for high strictures only), or internal œsophagotomy, an operation always "in the dark" and at times very dangerous. It is especially indicated in cases of dense fibrous strictures such as result from lesions due to caustics. For "impermeable" or very tight strictures, gastrostomy through the oblique incision, parallel to the costal arch is first performed. The œsophageal orifice is explored with the finger and a small conical (gum elastic) bougie guided into it with the finger. Dilate, if it can be done without force, by the gradual method. If unyielding, carry a heavy braided silk ligature by a small bougie up the œsophagus until it can be drawn out through the mouth. The largest bougie which the stricture will admit is now introduced so as to put it on the stretch. The string is now drawn upward by the fingers introduced well back in the mouth, and the bougie is felt to advance as the tense string wears away the tense stricture. The operator see-saws the string up and down, while his assistant presses the bougie gently through the stricture. Larger bougies are passed in the same way as the stricture yields. When the desired dilatation is attained, a rubber-tube of corresponding diameter is drawn up into the œsophagus till one end is above the seat of the stricture and the other remains outside the abdominal wound. A smaller tube is also introduced into the stomach for nourishment. The patient can thus swallow water to clean the mouth, or saliva, without injury to the wounded surface. The tube also keeps up dilatation. It is removed on the second or third day and the subsequent dilatation accomplished through the mouth by bougies. The gastric fistula is subsequently closed as soon as the condition of the patient will permit the operation, in one case eight weeks after the primary dilatation.

INTRA-ABDOMINAL ADHESIONS THE CAUSE OF SEVERE PERSISTENT COLIC.

Dr. Carl Lauenstein reports ten cases. The diagnosis was confirmed by operation.[9] The cases are reported in detail. In all the adherent surfaces were dissected apart. Bands and strands were extirpated. The results were nine permanent cures and one death. The statements of Lauenstein relating to diagnosis are as important as those describing the treatment. The diagnosis is difficult and is made only after a careful study of the case and exclusion of other causes. The noticeable facts thus obtained are the absence of febrile

[9] Arch. f. Klin. Chir., 1893, xlv, 121.

disturbance. The appearance of the patient as if a severe affection were present. The localization of pain at definite points in the abdomen. Unfortunately, however, there are cases in which a probable diagnosis is impossible and when an explorative laparotomy is the only solution of the problem.

ASEPSIS IN LAPAROTOMY.

Minnow, at the Gynecological Klinic of Professor Fritsch, of Breslau, has made an investigation to ascertain if a perfect method of asepsis was possible or practical.[10]

The operative work was done in rooms that were especially reserved for this class of cases. The same rule was carried out with reference to equipment, that is, tables, operating clothes, instruments, aprons, etc. Sterilization was by steam, at 100° C., for one hour immediately before operating. The water was boiled for one hour. Instruments were cleansed with a two-per-cent. carbolic solution. Hands (and patient) were subjected to mechanical cleaning in sublimate solution (1 to 1000) for five minutes, and then bathed in sterilized water. The silk ligatures were sterilized by steam for one hour. No antiseptic solution was used in the abdomen. The dressing was sterilized gauze and cotton.

The contents of the abdomen were tested bacteriologically, before and after the operation in each case. He thus investigated thirty-one cases where the abdomen was opened. Of twenty-eight cases examined at the end of an operation, micro-organisms were identified in twenty. The remaining eight showed no trace of bacteria. When the examination was made as soon as the peritoneum was opened, micro-organisms were demonstrated only thrice in twenty-three cases. The inference is that entrance of germs was during the operation from without and that the present aseptic method does not preserve the abdominal cavity from the entrance of germs in a bacteriological sense. But it was also found, that, although the above conditions were present, septic infection was seen only in one case, a patient septicæmic before the operation. In eleven of fifteen cases where bacteria were found, marked elevation of temperature was observed. Examination of the air in the vicinity of the open abdomen showed the same micro-organism as the cultures from the abdomen. Hence, although of a so-called non-pathogenic nature, these bacteria were apparently the cause of the temperature elevation, 38° C., which in some cases lasted several days. Most of the patients recovered without this febrile reaction where the abdominal exposure was of short duration. Other facts reported are that it is very difficult to furnish an operating-room with air free from bacteria. That the peritoneal cavity does not contain germs which can be cultivated by the gelatine and agar-agar method. That adherent Fallopian tubes or cysts in most cases, even when their contents are purulent, show no living micro-organisms. That the abdominal surgeon has to deal in a large number of cases with non-infected tissue and that asepsis, although not perfect, is enough for practical results. When septic infection exists in uterine cases an operation should be preceded by uterine irrigation followed by an iodoform gauze tampon. That infected tissues should be removed by Pacquelin cautery rather than with the scalpel or scissors.

[10] Centbl. f. Gynekologie, 1892.

THE ACCIDENTS WHICH MAY FOLLOW REMOVAL OF PORTIONS OF THE OMENTUM IN OPERATIONS FOR HERNIA.

W. T. Bull,[11] has recorded a number of interesting accidents under operations for hernia, and he states that in dealing with the omentum the following dangers are to be borne in mind:

"(1) Bleeding from inefficient ligature.

"(2) Damage to neighboring intestine from faulty application of the ligature.

"(3) Inflammation and abscess of the omental stump.

"These dangers should make the management of the omentum the subject of special care. Any threatened inflammation should be met with prompt incision so soon as symptoms are urgent."

THE RADICAL CURE OF HERNIA BY BONE PLATES.

Thiriar,[12] has operated upon twenty-five cases of hernia by interposing a decalcified bone plate somewhat larger than the internal ring between the peritoneum, which has been dissected up from the inner surface around the stump of the previously ligated hernial sac, and the abdominal parietes. This plate is secured in position by sutures so adjusted as to approximate the layers of the abdominal wall. He uses bones from a beef. The bones are denuded of periosteum and placed in a ten-per-cent. solution of hydrochloric acid. They are sufficiently soft when they are pliable under water. These pieces of bone are then placed in a 1–1000 bichloride solution, and finally preserved in an ethereal solution of iodoform, but before use they have to be dehydrated in ninety-five per cent. of alcohol.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

TENTH ANNUAL MEETING, NEW YORK, OCTOBER 9, 10, 11 AND 12, 1893.

INTRODUCTORY SESSION.

MONDAY EVENING, OCTOBER 9TH.

THE meeting was opened by an Address of Welcome by the Chairman of the Committee of Arrangements; following this came an address by the President, Dr. S. B. Wylie McLeod. He naturally took a retrospective glance at the work of the past ten years, and alluded to the growth of the Association and the variety of the scientific contributions. Although the Association was only organized on February 4, 1884, it now has a membership of eight hundred, and its library has increased to nine thousand volumes.

Dr. John Shrady also delivered an address in which he went over much the same ground, only more in detail. The address by Dr. Gouley on "The Nosology of Disease"; the one on "Pathology," by Dr. E. G. Janeway;" the paper by Dr. Van Zandt, on "Commercial Prescriptions;" the discussion on "The New Hypnotics;" the discussion on "Peritonitis;" and that on "Pneumonia," were mentioned as having been particularly interesting and profitable.

A special feature had been the "prepared" discus-

sions, a plan first devised and put in practice by the British Medical Association, and now very generally adopted by our more progressive medical societies. It had saved much time, and added greatly to the scientific work of the Association. The first discussion of this kind was on "Pneumonia," and was suggested by Dr. Flint. The speaker also referred to a contribution in which is given the history of what is claimed to be the first case of nitrous oxide anæsthesia. The date is fixed as November 25, 1821, and it is said that the subject was a young man who surreptitiously inhaled a large quantity of the gas from a tank placed in a room adjoining one in which an exhibition was being given of its peculiar properties.

Among the more recent papers, was a practical paper by Dr. James G. Porteous, of Dutchess County, entitled "Winter Cholera." It describes the prevalence of choleraic diarrhœa in Poughkeepsie, due, as the author very clearly shows, to contamination of the river water which is supplied to the town. With this paper the writer presented some very interesting researches on drinking water, made by the bacteriologist, Dr. E. K. Dunham, of New York.

FIRST DAY (TUESDAY). — MORNING SESSION.

Dr. James G. Porteous, of Dutchess County, read a paper on the

PREVENTION OF DISEASE,

in which he referred particularly to the many ways in which tuberculosis is spread broadcast over the land, and of the simple measures by which it could be very materially restricted. He showed a printed card which he gives to his consumptive patients, and which gives them directions how best to avoid carrying the infection to others, and at the same time, reminds their friends how they can best assist in this good work. For instance, it advises consumptives to avoid spitting on the floor or in public vehicles, to have separate table utensils and linen, to sleep in a separate bed and to abstain from kissing people. The well persons are informed that this disease is principally communicated by the swallowing of the germs, by inhaling them and by their introduction into wounds. They are cautioned not to eat or sleep with consumptives, or to use clothing belonging to such patients, and especially to be very careful not to put in their mouths such small articles as coins which have been handled by tuberculous patients. As a precautionary measure, they are advised not to kiss on the lips *any one* who has a cough.

Dr. E. D. Ferguson, of Rensselaer County, read

AN ADDITIONAL NOTE ON NEPHROTOMY AND NEPHRECTOMY,

in which he stated that many of these cases are not originally tubercular. He prefers a free incision and packing of the wound, to the use of a drainage-tube.

Dr. John Cronyn, of Erie County, in discussing the paper, illustrated the difficulties of diagnosis by relating the history of a lady who, for four years, had symptoms referable to disease of only one kidney, yet the post-mortem examination showed that both kidneys contained calculi. He expressed the hope that some of these difficulties would vanish under the more general and expert use of the cystoscope or some similar mode of examination.

Dr. Ferguson said that many of these cases of renal disease begin at the inferior portion of the genito-urinary tract and spread upwards. Although frequently not primarily tubercular, they are quite liable to become infected secondarily. He disapproved of the use of the cystoscope and of ureteral catheterization on account of their liability to aggravate the disease.

Dr. Gouley coincided in this view, and stated that not only was an exploratory operation comparatively safe, and much more satisfactory in its results, but it afforded an opportunity, in the event of the diagnosis being confirmed, to immediately perform nephrotomy. Nephrectomy should not be resorted to except as a subsequent measure.

Dr. Nelson J. North, of Kings County, in a paper on

THE TREATMENT OF EPITHELIOMA AND THE CHANCROID ULCERS BY TOPICAL APPLICATION,

described the favorable results he had attained by the local application of concentrated lactic acid to cases of epithelioma and uterine carcinoma. The treatment was particularly applicable to inoperable cases. This acid does not produce an eschar, but seems to destroy the vitality of the abnormal cells. It has little or no action on normal tissue. When applied to a carcinoma, the tumor becomes brownish, shrinks up and discharges after a short time a thin, brownish fluid.

AFTERNOON SESSION.

Dr. N. P. Dandridge, of Cincinnati, read a paper on

THE SURGICAL TREATMENT OF PULMONARY CAVITIES.

This treatment is applicable to cases of abscess of the lung, gangrene of the lung, hydatid cyst and to tubercular or bronchiectatic cavities. Of course, in most cases of bronchiectasis, the cavities are so numerous that surgical treatment cannot be employed, but when there is one cavity much larger than the rest, and the secretion is quite abundant, it is proper to look for a good result from surgical interference, if the cavity is sufficiently accessible. Tubercular cavities are usually still more favorable, as they are ordinarily more superficial. The following case was cited as an illustration of the type considered by the author most favorable for surgical treatment: The patient was a man, twenty-nine years of age, having a decided phthisical family history. He had a constant dry cough, a slight fever and severe pain in the right side of the thorax. The cavity having been located, it was exposed by incision and resection of three inches of the eighth and ninth ribs in the axillary line. The cavity was very superficial and its walls were rough, as is commonly seen in phthisical cavities. About half a pint of sanguineous fluid was removed, the cavity washed out with sterilized boric-acid solution and a drainage-tube inserted. This patient improved steadily and rapidly after this operation. An operation of this kind is not infrequently undertaken under the supposition that the case is one of localized empyema. The operation when performed in properly selected cases is easy and comparatively free from danger.

In gangrene, abscess and hydatids of the lung, modern opinion favors incision and drainage of the cavities, when these can be accurately located and easily reached. The cavities should be packed with iodoform gauze after incision.

It goes without saying that the danger of the operation is greatly augmented by the absence of protecting

adhesions between the pleura and thoracic wall. A large aspirating needle is used in locating the cavity, and it then serves as a guide for the knife. It should be remembered that the quantity of material expectorated bears no constant relation to the size of the cavity.

DISCUSSION ON LESIONS OF THE PLEURA.

This was one of the "prepared" discussions already alluded to. It was opened by DR. JOHN SHRADY, of New York County, who propounded the following questions:

Question 1. — What are the factors of pleurisy? Its forms and contributive conditions? What are the pathological changes in a case of progressive pleurisy ending in recovery?

Question 2. — What are the points of differential diagnosis in pleurisy and other affections of the chest?

Question 3. — What is the treatment of empyema, with relative value of aspiration, rib-resection and free opening with tube drainage?

Dr. Shrady looked upon cold and traumatism as the chief etiological factors, and he said that the fact that a given case was due to traumatism would be generally revealed by the withdrawal with the aspirator of bloody fluid. The key to the diagnosis of pleurisy with effusion is the shifting line of dulness obtained by percussion over the upper part of the thorax, the patient's position being changed from time to time during the examination. Tubercular pleurisy is commonly revealed by the presence of peritoneal or pericardial complications.

Adopting Osler's recommendations, the treatment of pleurisy with serous effusion may be said to be the adoption of measures calculated to limit the exudation at the beginning, allay pain, relax the bowels and reduce the fever; in the later stages, the treatment must be directed to promoting the absorption of the effusion. Aspiration should be resorted to, when there is sufficient fluid to cause intermittent orthopnœa, when it half fills the pleural cavity, when it shows no sign of being absorbed after a month and always when it becomes purulent. Aspiration is best performed, when circumstances permit of selection, in the sixth intercostal space, in the axillary line and close to the upper border of the seventh rib.

Empyema may be secondary to such diseases as pyæmia and puerperal septicæmia; in adults, however, it is most commonly associated with pulmonary tuberculosis. The fact that symptoms of suppuration are not evident until some of the pus has been absorbed, should lead one to be particularly alert to detect this change in the character of the pleuritic effusion. If a simple incision does not admit of free drainage, it is advisable to resect a portion of the lower rib, but it should be remembered that this does not necessarily mean that the entire width should be excised. A rubber drainage-tube, preferably without lateral openings, should be inserted and sutured to the skin. In conclusion, the writer said: "Bowditch, of Boston, after all did not leave us much to learn; he was first rational, then bold, then lucky."

DR. WILLIAM MCCOLLOM, of Kings County, read a paper in reply to the first question propounded. He is a firm believer in the theory that the streptococcus, staphyloccus and pneumococcus have an important etiological relation to pleurisy, and he explains the various discrepancies which have arisen in the various researches on this point, by supposing that the investigators have made their examinations for these organisms at different stages of the disease. Again, the pneumococcus is a short-lived micro-organism and hence it does not follow because it was not found in the exudate, that it had not been present at an earlier stage than at which the examination was made.

DR. J. BLAKE WHITE, of New York County, replied to the second question. He said that localized pain cannot be considered as characteristic of pleurisy, although many times its peculiar character may aid us in the diagnosis. The pain may be misleading by being referred by the patient to another part, as the abdomen. Nor can dyspnœa by itself be relied on as a characteristic of pleurisy. Where the pleurisy is of tubercular origin, there is usually, first, cough, then pain in the side, and lastly, dyspnœa, whereas in other pleurisies, there is usually first pain in the side, secondly, dyspnœa and then cough. The tendency to clear the throat frequently when there is no lesion in the throat is strongly indicative of pleuritic adhesions. A short cough points to these adhesions being high up in the chest, and a more prolonged cough, to adhesions lower down. The speaker asserted that no investigation yet made had proved conclusively that pleuritis is due to microbes. The presence of such microbes in pleuritic exudations by no means establishes their causal relation. Tuberculosis affords the strongest argument in favor of the microbic theory, and yet he is a poor diagnostician who waits for the microscope to make the disgnosis in these cases.

DR. J. G. TRUAX, of New York County, also discussed the second question. He said that the pleuritic friction râle is quite localized, frequently changes its position, is often heard within a few hours after the onset of the disease, and may be felt as well as heard. It may be mistaken by the tyro for bronchial crepitation.

DR. CHARLES A. LEALE, of New York County, answered the third question. As an illustration of what may be accomplished in cases of empyema, without resort to operation, if circumstances are favorable, he related the history of a boy, who, after treatment for two years, was practically well, and at the end of five years from the occurrence of the empyema, the lung and pleura were found in normal condition. He said that whenever he heard free incision into the chest advocated, he was reminded of an army officer who came under his observation with a large wound in the thorax. This man begged most piteously to have the opening closed that he might be relieved of his intense and constant suffering.

Incidentally, also the speaker referred to a case in which a robust farmer contracted tuberculosis from his wife, and developed an empyema. Fortunately his health was completely restored by a long residence in Egypt, and the patient was not then willing to believe that he had ever had pulmonary tuberculosis, yet the post-mortem examination showed only too plainly the evidence of his former consumption. Nature had been kind to this man, yet he thought if her beneficent process of repair had been interfered with by an operation on the empyema, it is hardly probable that there would have been the thick, protecting exudation which was found at the post-mortem and which had offered an effectual barrier to the progress of his consumption.

DR. THOMAS H. MANLEY, of New York County,

dropped a bomb into the camp of those who defend aspiration in serous pleurisy by boldly asserting that not one of his cases treated by aspiration had lived more than three years, and his experience with this treatment led him to fully endorse what had been stated by a distinguished French authority regarding the dangers of thoracentesis.

Dr. Cronyn expressed his regret at hearing this declaration from Dr. Manley, for he had long made early and free use of the aspirator in serous pleurisy, and, he was convinced, with the best results. He was not in favor of treating empyema by resecting the ribs, because this practice is totally unnecessary.

He said he had noticed that sometimes certain diseases appeared to be cured by metastasis, and in support of this view he cited a case — one of several similar ones — in which a patient under his care, with pulmonary tuberculosis, was suddenly cured of his tuberculosis by an attack of acute mania.

Dr. Donald McLean, of Detroit, said he had discarded the aspirator except in occasional instances as an aid to diagnosis. His objection to it was, that it was incapable of completely evacuating a cavity. Resection of the ribs is done in obedience to one of the most important and widely-recognized principles of surgery, namely, the establishment and maintenance of free drainage.

Dr. Dandridge also favored resection of the ribs. With regard to aspiration, he said it possessed one decided advantage over an opening into the chest, and that was it maintained a negative pressure in the pleural cavity, which was exceedingly useful in aiding the expansion of the lung. It is a useful method of treatment, therefore, even though it may be necessary subsequently, as it will probably, to resort to incision.

EVENING SESSION.

Dr. Austin Flint, of New York County, read a paper on

FERMENTATIVE DYSPEPSIA.

He said he had yet to see a case that had been benefited by the ordinary preparations and combinations of pepsin and so-called pancreatin, although he did not wish to include in this condemnation, the use of partially digested or peptonized foods. Digestion is one of the most complex of the physiological processes, and even now is but very imperfectly understood. It is well known that the combined, as well as the successive action of the digestive fluids is essential for normal digestion. The distress after eating, experienced by many dyspeptics, is not necessarily due to a deficiency of pepsin; it is rather brought on by the accumulation of gases in the stomach, as a result of the fermentation of the food. This fermentation he believed was due to the action of micro-organisms. For proper intestinal digestion, the so-called pancreatin, which is really a combination of several substances secreted by the pancreas, requires the assistance of the bile and of the intestinal juices which are of unknown composition. Fermentation usually begins in the stomach, and is continued in the intestine. When it originates in the intestine, there is usually a deficiency of bile, and there is apt to be more or less diarrhœa present. When the digestive discomfort begins two or three hours after taking food, and diarrhœa and flatus are present, it is probable that the fermentation is purely intestinal. It is very important to relax the bowels, or at least, to regulate them, and for this purpose he had found Villacabras water very useful. The dose must be carefully adjusted to the individual, and enough given to produce a free movement. It will then be found that the bowels will usually continue to move daily for several days, after which the dose may be repeated. After it has been used in this way for a time, it will often be found that the dose can be diminished rather than increased as is the case with many similar remedies.

The author said that in the treatment of fermentative dyspepsia, he had found his father's well-known practice of giving salicin in ten-grain doses before meals very useful, but in about twenty-five per cent. of the cases it failed. During the past ten months he had been prescribing the subgallate of bismuth in five-grain doses, either before or after meals, and he had only noted two cases during this time in which it had failed. Both of these were very chronic, and had previously resisted a great variety of remedies. He was led to employ the subgallate of bismuth from its reputed success as an intestinal antiseptic in the diarrhœa of children. The medicine is best given in capsules or in tablet form.

Dr. Cronyn thought that in the same class of cases in which Dr. Flint would give the subgallate of bismuth, equally good results would follow the administration of dilute hydrochloric acid, for he believed the condition was primarily due to a deficiency of this acid in the stomach. He called attention to the fact that dyspepsia is often kept up for a long time by a too prolonged adherence to some special diet.

Dr. Henry F. Risch, of King's County, said that it was essential to the successful treatment of fermentative dyspepsia to determine whether the fermentation was due to the hydrocarbons or the nitrogenized substances. If due to the decomposition of hydrocarbons, the product of the fermentation will be carbonic acid gas, but if to the latter, it may be detected by the foul odor imparted to the patient's breath. Having ascertained which class of food-stuffs is the offender, this must be excluded from the dietary. Until this is done, there is but little use in resorting to medicines in a haphazard way.

Dr. C. A. Leale said that lavage of the stomach and bowels had been extensively practiced on the infants brought during the last summer to St. John's Guild Hospital, suffering with diarrhœa. Having cleaned the alimentary canal in this way, the infants were given only sterilized milk, and, as might be expected, all the symptoms promptly improved. The tris-nitrate of bismuth and Fowler's solution had also been found useful in restoring the digestive tract to its normal state.

Dr. John A. Wyeth, of New York County, read a paper entitled

BLOODLESS AMPUTATION AT THE HIP-JOINT: REPORT OF CASES OPERATED ON BY THE AUTHOR'S METHOD.

This method was introduced by him to the profession in 1890. He presented brief histories of thirty-nine cases in which this method of amputation at the hip had been adopted, and the fact that this series included a great many operators of widely different degrees of experience and skill only served to enhance the value of these statistics. Sixteen of the amputations were done for sarcoma, with two deaths, or 12.5

per cent. mortality; eighteen were for inflammatory disease of bone, with three deaths, or 16.6 per cent. mortality; four cases were for severe injuries, with four deaths, or 100 per cent. mortality; and one case was for a nerve lesion; recovery. In other words, thirty-five cases were for disease, and of these, five died, or 14 per cent.; the four cases of injury all died.

(To be continued.)

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

F. W. DRAPER, M.D., SECRETARY.

REGULAR Meeting, October 4, 1893, the Vice-President, DR. S. W. ABBOTT, in the chair, and twenty members present.

PROF. WILLIAM T. COUNCILMAN read a paper on

THE PATHOLOGICAL CONDITIONS OF THE HEART WHICH RESULT IN SUDDEN DEATH.[1]

The reading of the paper was followed by a demonstration of anatomical specimens illustrating thrombosis, hypertrophy with dilatation, cardiac rupture and aneurism in the wall of the left ventricle.

DR. HARTWELL, of Ayer, said he desired to express his thanks to the writer of the paper for setting forth so clearly various points relative to cardiac emergencies which had been obscure. Physicians at a distance from populous centres had comparatively rare opportunities to study these cases and still rarer opportunities to observe the anatomical appearances. It was, therefore, very helpful to hear such a clear and instructive paper on a subject which was especially interesting to medical examiners. He mentioned two cases of rupture of the heart, both in old people and both involving the left ventricle.

DR. SWAN, of Cambridge, reported the case of a man, forty years old, who fell dead at his work-bench. The autopsy found the cause of death to be hæmorrhage into the pericardium through a rent in the wall of an aneurism of the aorta, just above the valves.

DR. HOUGH, of New Bedford, had seen a case of rupture of an aortic aneurism with death in less than a minute.

DR. SEYMOUR, of Northampton, presented a communication relative to a case of sudden death in which his right to make an inspection of the body which had been found dead in bed was disputed by a physician called in to the case, the reason for the objection being that he, the latter, was of the opinion that the death was caused, probably, by heart disease and not by violence. The county commissioners had supported this view of the case and had disallowed Dr. Seymour's account for his medical examiner service in investigating the circumstances of the death according to the requirements of the statutes. Dr. Seymour argued that it was only by "personal inquiry," and sometimes by "further examination," when personal inquiry failed to solve the doubt, that the element of violence could be excluded in such instances and insisted that the medical examiner was the proper one to make the investigation.

The CHAIRMAN spoke of the importance of the subject as a practical question and said that it was obvious that in a death under such circumstances the element of violence, or its absence, could not be determined accurately except by such methods as the law required in the statute relating to inquests.

[1] See page 457 of the Journal.

The matter was farther discussed by Drs. Hough, Dolan, Bronson and Presbrey, the prevailing sentiment favoring the view that the cases of persons "found dead" were proper cases for a medical examiner's investigation, although at the time of the finding a suspicion of violence was not yet entertained and had not been expressed.

DR. DOLAN, of Fall River, read a paper on the

RIGHTS AND DUTIES OF MEDICAL EXAMINERS IN THE INVESTIGATION OF CERTAIN CASES OF HOMICIDE.

He defined the methods which he believed should be taken to secure evidence, the medical examiner's control of premises where a homicide has occurred, the notes which he should take concerning the temperature of the dead body, its position, color and surroundings; its internal condition as shown by autopsy with especial attention to the contents of the stomach. The value of photography in delineating the attitude and external appearance of the body was mentioned. The reader justified the decapitation of the body and the preservation of the injured parts of the skull, if the case were important and the head were the part attacked in the killing. The correct demeanor of the medical examiner on the witness stand was outlined.

DR. PRESBREY, of Taunton, said he thought the use of the ordinary clinical thermometer for determining the temperature of dead bodies was of limited value, since these instruments register down to 94° only and are not available for temperatures below that.

DR. DOLAN replied that where two homicides, nearly coincident, are to be studied, accurate determination of the body-heat in the two cases is important in deciding the question of the priority of death.

SUFFOLK DISTRICT MEDICAL SOCIETY.

HENRY JACKSON, M.D., SECRETARY.

REPORT OF THE COMMITTEE APPOINTED TO SECURE FROM THE LEGISLATURE "IMPROVED SANITARY LEGISLATION."

AT a meeting of the Clinical Section held October 18th, Dr. Cheever, as chairman of the committee, made his report. This committee was appointed November 16, 1892, by Dr. F. C. Shattuck, chairman of the Section, in accordance with the recommendation of a previous committee to present Propositions 3 and and 4 of their report[1] in proper form to the Legislature. These propositions refer to sanitary legislation in the State of Massachusetts.

BOSTON, June, 1893.

The Committee appointed by the Section on Clinical Medicine of the Suffolk District Medical Society, "to secure from the Legislature improved Sanitary legislation," respectfully report, that they have failed to obtain the sanction of the General Court to two of the measures proposed, and ask to be discharged.

Your Committee, after numerous meetings, to which members of the State and City Boards of Health were invited, formulated three bills (here appended) which were kindly prepared by Mr. Ernst, as counsel.

No. 401,[2] provides for advisory medical inspection, throughout the State.

No. 402, provides for the registration of vital statistics under supervision of the State Board of Health.

[1] See Boston Medical and Surgical Journal, December 22, 1892, p. 610.

[2] Boston Medical and Surgical Journal, vol. cxxviii, page 528.

No. 403 makes obligatory a return of all contagious cases to the State Board of Health, by local boards of health.

No. 403, alone, was passed.

Your Committee received the support of the State and City Health Boards, and of the Mayor of Boston, also of Mr. Parkman in the Senate and Mr. George von L. Meyer in the House.

Your Committee had a hearing before the Joint Committee on Public Health of the Legislature. At this hearing, your Chairman made an extended argument for the bills, and was supported by the following gentlemen, who attended and spoke at length, in favor of the bills, at his invitation: Rev. Lyman Clark, Andover, N. H.; Gen. Francis H. Walker; President Dr. James C. White; Dr. C. F. Folsom; Dr. Harvey, of Westborough; Prof. D. R. Dewey, Institute of Technology; Rev. S. W. Dike, of Newton; Prof. W. T. Sedgwick, Institute of Technology.

The Joint Committee of the Legislature on Public Health reported favorably Bill No. 403, and allowed the rest to lapse by default. The subject being again called up in the Legislature by Senator Parkman and Representative Meyer, was recommitted to the Joint Committee on Health, to give another hearing. At this hearing, Drs. Walcott and Cheever addressed the Committee.

This Committee then reported *favorably*, and the Bill 401 was referred to the Committee on Finance. This Committee (Mr. Rideout, of Cambridge, Chairman) reported that the bill ought not to pass. The Bill (401) "for the appointment of advisory medical inspectors throughout the State," was rejected in the House, 85 to 36.

Thus was a final quietus given to a measure of the highest sanitary importance.

Respectfully,

DAVID W. CHEEVER,
JAMES C. WHITE,
CHARLES F. FOLSOM,
HAROLD C. ERNST,
HENRY J. BARNES,
} *Committee.*

Dr. Cheever's report was unanimously accepted.

On motion of Dr. Knight, a vote of thanks was passed to the members of the committee for their arduous and painstaking labor. Also to Mr. Geo. A. O. Ernst for his valuable and gratuitous services in drawing up the bills and to the various gentlemen who appeared before the Committee of the Legislature on Public Health to speak in favor of the bill.

Recent Literature.

A Contribution to the Pathology of the Vermiform Appendix. By T. N. KELYNACK, M.D., Pathologist to the Manchester Royal Infirmary, etc. London: H. K. Lewis.

This book is an extensive monograph on the appendix. The first chapter contains the early literature on the anatomy and the diseases of the appendix. This is followed by a description of the various differences in length, position and lumen, with an account of the various fossæ which are to be found in its vicinity. He distinguishes three fossæ in the vicinity of the appendix which are almost constant. (1) The ileo-colic fossa, a peritoneal pouch formed at the angle produced by the junction of the ileum and colon. (2) The ileo-cæcal fossa, situated behind the angle of junction of the ileum and cæcum, extending for a variable distance upward behind the ileo-colic junction and parallel to the ascending colon. This fossa may be divided into two parts by the meso-appendix. (3) The sub-cæcal fossa, situated immediately beneath the cæcum.

A description of the various pathological conditions, with their diagnosis and treatment, follows the anatomical description. In this the literature has been gone over very thoroughly, and a large number of statistics collected. The book is essentially a clinical study, and the pathological description of the conditions met with is poorly done. The description of the normal histology of the appendix is incomplete, and there is no description whatever of the histological characters of the lesions. No mention is made of the blood-vessels or lymphatics of the organ, their relative number, their course and distribution; and we might suppose that these were absent altogether.

The work contains nothing new; and the statistics he has collected add little to those in the exhaustive monograph of Fitz. What we want now is a more careful anatomical study of the lesions of the appendix, the character of the pathological processes, their course and their causes. None of these questions have been considered.

Leçons de Thérapeutique. Par GEORGES HAYEM, Professeur de Thérapeutique et de Matière Médicale à la Faculté de Médecine de Paris, etc. Les Médications. Quatrième et dernière série. Paris: G. Masson. 1893.

The greater part of this volume is devoted to the treatment of the various forms of disease which the author includes under the term dyspepsia; special stress is laid upon the careful methods of diagnosis which Professor Hayem and M. Winter have elaborated. These methods are in advance of those in general use in making a diagnosis of certain conditions of the stomach, and some of them demand a greater familiarity with chemistry than one finds in most practitioners; but the author is, of course, quite correct in considering an accurate diagnosis the first step in the proper treatment of the disease. The treatment of dyspepsia is fully and carefully considered. Diet, the influence of repose and exercise, the care of the skin, the use of purgatives and other medicines are discussed. In short, the diagnosis and treatment in their narrowest and widest sense are well given.

In the latter part of the volume the author considers the treatment of dyspnœa, cough, albuminuria, uræmia, etc., but brings forward nothing especially new. The style of the writer is easy but diffuse; the interest of the book lies chiefly in the field to which he has given much attention, namely, certain diseases of digestion.

A Manual for Boards of Health and Health Officers. By LEWIS BALCH, M.D., Ph.D., Secretary of State Board of Health of New York. Albany, N. Y.: Banks & Brothers. 1893.

Dr. Balch has performed a useful service in presenting in this Manual a digest of the various laws and duties which pertain to local boards of health. In the words of the author the book is "a practical manual for practical men, who desire to do their duty when serving their fellow townsmen as members of boards of health."

While the book has been specially prepared with reference to the duties of public officials acting under the provisions of the Health Code of the State of New York, it also contains much information relative to nuisances, the management of contagious diseases, vital statistics and other sanitary matters, which give it a more than local interest, and will make it generally useful as a hand-book for local health officials.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 9, 1893.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE WATER-SUPPLY OF LONDON.

IN last week's issue of the JOURNAL a brief notice of the water-supply of London was presented; but the increasing needs of this rapidly growing metropolis are now so prominent, and in some measure so closely resemble those of our own cities and of all other large centres of population with thickly settled surroundings, that we are induced to comment more fully upon the report of the Commissioners, now in our hands.

The Royal Commission appointed in March, 1892, to determine the adequacy of the present sources of water-supply of London, has made its report, dated September 8, 1893.

This Commission was required to ascertain "whether, taking into consideration the growth of the population of the metropolis, and the districts within the limits of the metropolitan water companies, and also the needs of the localities not supplied by any metropolitan company, but within the water-sheds of the Thames and the Lea, the present sources of supply of these companies are adequate in quantity and quality, and, if inadequate, whether such supply as may be required can be obtained within the water-sheds referred to, having due regard to the claims of the districts outside the metropolis, but within these water-sheds, as will have to be obtained outside the water-sheds of the Thames and the Lea."

The report gives a brief historical sketch of each of the eight water companies supplying London, with estimates of the population of the metropolis for fifty years to come, the probable quantity required for such population, and proposed methods of improving the present supply.

Different estimates of the future population of London are presented, according to the method of making the estimates — the highest estimate for 1931 being about twelve millions and the lowest eight and one-half millions. The present consumption of water amounts to 31.19 gallons per capita daily, of which quantity about twenty per cent. is used for trade and public purposes, leaving about twenty-five gallons per head as the domestic consumption, which is much less than the average in cities of the United States.

The water-supplies of these eight companies are at present filtered through large areas of sand and gravel, covering about one hundred and nine acres of surface. The average depth of the sand in these filter beds is about two and one-fourth feet, and the rate of filtration is about two gallons per square foot per hour.

The filter-beds of the Berlin water-works, which are more carefully and thoroughly prepared, are nearly five feet in depth, and the new filter now in successful operation for purifying the Lawrence water-supply, is also about five feet in depth.

In commenting upon the sanitary phase of the question, the Commission speaks as follows, p. 68:

"Doubtless, these bacteriological questions are not matters concerning which it would become us to make positive and dogmatic assertion, seeing that at present experts in the science of bacteriology are themselves avowedly holding their judgment in suspense. This much, however, we can state without hesitation, that, as regards the diseases in question, which are the only ones known to be disseminated by water, there is no evidence that the water supplied to the consumers in London by the companies is not perfectly wholesome. In coming to this conclusion, we are glad to find ourselves in full accord with the opinion expressed, with equal conviction, by the water commission presided over by the Duke of Richmond, in 1869.

"Before leaving this subject, however, it will be well for us to apply the test of experience to the suggestion mentioned in an earlier paragraph, that a few typhoid bacilli, or even a single one, might possibly pass through the filter-beds and, getting access to a domestic cistern, might there multiply to such an extent as to cause an outbreak of disease, limited to the household using that cistern.

"We shall, we believe, be well within the mark in estimating the number of household cisterns in such use in London to have averaged at least half a million during the past twenty years. Day by day, water for drinking purposes has been drawn from each of these cisterns, and a fresh supply admitted from the mains, so that it is no exaggeration to say, that there have been in the last twenty years thousands of millions of opportunities offered for the suggested catastrophe; and yet not a single instance can be adduced in which it has actually occurred. It may, of course, be said that such a thing may have happened without detection, and it is impossible to prove that such may not have been the case; but, seeing what innumerable opportunities there have been for the occurrence, the absence of a single demonstrated case forms so strong a presumption against its practical possibility that it may, in our opinion, be dismissed from consideration."

In order to preserve the wholesomeness of the water delivered to consumers, and to meet the natural sentiments against drinking water which, although rendered wholesome by purification, has been at some time polluted, the Commission recommends the greatest possi-

ble vigilance over the water-sheds of the Thames and the Lea, to insure thorough treatment of all sewage, before its effluent is admitted to the rivers, by the most efficacious methods that science and experience may dictate, and to enforce the adequate storage and filtration of such water as is abstracted at the in-takes.

The Commission made a careful investigation of all sources of pollution upon the tributaries of the Thames, and found such sources very numerous, and that the Rivers Pollution Prevention Act of 1878 had been a dead letter, so far as its practical enforcement was concerned.

The following are the conclusions of the Commission with reference to the quantity and quality of the water-supply of London:

"We are strongly of opinion that the water, as supplied to the consumer in London, is of a very high standard of excellence and of purity, and that it is suitable in quality for all household purposes. We are well aware that a certain prejudice exists against the use of drinking water derived from the Thames and the Lea, because these rivers are liable to pollution, however perfect the subsequent purification either by natural or artificial means may be; but having regard to the experience of London during the last thirty years, and to the evidence given to us on the subject, we do not believe that any danger exists of the spread of disease by the use of this water, provided that there is adequate storage, and that the water is efficiently filtered before delivery to the consumers.

"With respect to the quantity of water which can be obtained within the water-sheds of the Thames and the Lea, we are of opinion that, if the proposals we have recommended are adopted, a sufficient supply to meet the wants of the metropolis for a long time to come may be found without any prejudice to the claims, or material injury to the interests, of any districts outside the area of Greater London.

"We are of opinion that an average daily supply of forty millions of gallons can be obtained from wells and springs in the chalk of the Lea Valley without affecting any material interests; but that, if that quantity is exceeded, it is probable that the springs and wells in the parts of the valley immediately adjacent to the wells, and all the districts further down the valley may be injuriously affected.

"From wells in the chalk area on the south side of the Thames, in the district of the Kent Company, we are of opinion that a daily average supply of twenty-seven and one-half millions of gallons may be obtained.

"We think it of very great importance that distinct obligations should be laid upon any Company or local authority which is allowed to pump water from the chalk for purposes of public supply, to keep accurate observation of the effect of their operations on the level of the water in the wells from which they pump, and return the results to the water examiner under such regulations as may be framed. The great difficulty which we have had to encounter has been in getting accurate and reliable information as to the actual effect of the operations now carried on. The importance of procuring this will increase each year as the limit of what can be taken from any district with safety is gradually being reached.

"From the River Lea we are of opinion that, with adequate additions to the present system of storage, fifty-two and one-half millions of gallons may be taken daily

"We are of opinion that by the construction of storage reservoirs in the Thames Valley, at no great distance above the intakes of the companies, it will be possible to obtain an average daily supply of three hundred millions of gallons without taking in any objectionable part of the flood-water.

"To our minds one great advantage of such a scheme of storage reservoirs is that it can be carried out progressively to meet the increasing demands for water, and, should the population not grow so rapidly as we have thought it right to contemplate, the extensions may be from time to time deferred as successive decennial enumerations reveal that the ratio of increase is remaining stationary, or even falling.

"From the sources and by the methods we have mentioned a daily supply of 420,000,000 gallons can, in our opinion, be obtained. This is a sufficient quantity to supply thirty-five gallons a head to a population of 12,000,000 persons, which is about three-quarters of a million in excess of what the total population of Greater London together with the outlying parts of Water London will have become in 1931, even if the ratio of increase in the decennial period from 1881 to 1891 is fully maintained.

"We are further of opinion that a large supply of water might be obtained from the chalk area east of the Kent Company's district, in the basin of the Medway, and in the district further east without any risk whatever of damage to that area."

Recent investigations by the State Board of Health of Massachusetts would seem to indicate that the multiplication of typhoid bacilli in household water-cisterns is even less probable than the language of the Parliamentary Commission would appear to imply.

The following experiment[1] conducted by Mr. Mills, at Lawrence, is applicable, at least, so far as concerns cold-weather conditions.

"To prove whether typhoid-fever germs would survive in the Merrimack River water, when at the low temperature of the month of November, long enough to pass from the Lowell sewers to the service-pipes in Lawrence, a series of experiments was made by the Board by inoculating water from the service-pipes with typhoid-fever germs, and keeping the water in a bottle surrounded by ice, at as near freezing as practicable for a month, and each day taking out one cubic centimetre and determining the number of typhoid germs. The number continually decreased, but some survived twenty-four days.

On the first day there were	6,120 germs.
On the fifth day there were	3,100 "
On the tenth day there were	490 "
On the fifteenth day there were	100 "
On the twentieth day there were	17 "
On the twenty-fifth day there were	0 "

This experiment indicates that typhoid-fever germs from the sewers of Lowell may live in winter to enter the Lawrence reservoir in large numbers; that the numbers will decrease in the reservoir; but still a considerable fraction will live to enter the service-pipes, and that this fraction will decrease as the water proceeds in the pipes across the city."

With the results of modern investigation in view as to the natural filtration of water through sand or gravel,

[1] Twenty-second Annual Report of the State Board of Health of Massachusetts, p. 512. Article on Typhoid Fever in Relation to Water-Supplies.

and with the fact also in view that two of the largest cities in the world (London and Berlin) have, in consequence of the adoption of such methods of filtration, the lowest death-rate from typhoid fever enjoyed by any of the large cities of the world, it is difficult to see how a sanitary journal issued in London can publish such statements as the following, in commenting upon the merits of a patent filter:

"It is now established that water flowing through clean sand passes out precisely as it passes in — with the exception of visible substances — totally unaltered in every respect, sand, in itself, possessing no filtering property whatever."

The same paper, in proclaiming the virtues of a water-softening process, says: "The hardness of water being caused by the lime suspended in it, it is susceptible of softening by a *kind of vaccination* with lime. This is now extensively known; but there is a tendency to overdo the lime, just as some ill-advised medical practitioners overdo human vaccination, with the result in either case that more harm is effected than good."

Such metaphorical mixtures of chemistry and pathology are, undoubtedly, within the province of the advertizer, but are out of place in the pages of reputable journals.

BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA.

DR. HERMAN M. BIGGS has just made an interesting report to the Board of Health of the City of New York in regard to thirty-six cases reported as membranous croup in which he has made bacteriological investigations during the past four months. In all the cases examined, the pseudo-membranous deposit was confined almost exclusively to the larynx. In thirty cases the Klebs-Loeffler bacillus was abundantly present. These, therefore, were undoubtedly cases of laryngeal diphtheria. In the remaining six cases no diphtheritic bacilli could be detected, and these he regarded as cases of catarrhal pseudo-membranous inflammation analagous to similar non-diphtheritic inflammations in the pharynx. In five of the laryngeal cases in which the Klebs-Loeffler bacillus was found, cases of pharyngeal diphtheria both preceded and followed within a week in the immediate vicinity of the patient. In three other instances the cases were preceded, and in some instances followed, by cases of true diphtheria. In the remaining fifteen cases in which the diphtheritic bacillus was found pharyngeal diphtheria, so far as known, neither preceded nor followed in the immediate vicinity. None of the six cases in which no Klebs-Loeffler bacillus was met with was followed or preceded by cases of diphtheria. Dr. Biggs concludes his report by stating that during the last four months nearly 84 per cent. of all the cases of so-called membranous croup referred to the Health Department for bacteriological examination, have proved to be true diphtheria.

MEDICAL NOTES.

ILLNESS OF DR. ROSWELL PARK. — Dr. Roswell Park, of Buffalo, is ill at the Buffalo General Hospital, with diphtheria, which he contracted while in attendance upon a patient upon whom he was obliged to operate for diphtheria. It is one more example added to the many cases of physicians who daily expose their lives for the sake of their patients.

YELLOW FEVER. — The number of new cases of yellow fever each day at Brunswick, Ga., is slowly diminishing, and the people are beginning to return, although the Marine-Hospital Service authorities consider it a great mistake for them to do so yet while there is a chance of more warm weather. A few cases have occurred at Jesup, and one at the detention camp near Waynesville.

CHOLERA. — The cholera epidemic abroad has been steadily declining for some time. In Arabia, no cases have been reported from Jeddah for over a month. The quarantine station at El Tor received over 30,000 pilgrims, among whom there were but 132 cases of cholera and 99 deaths. In Russia, cases are still reported in St. Petersburg, Moscow, Tiflis and Baku, and through the provinces, with a slight increase during the last week. In Germany, there has been a small outbreak at Stettin, owing to a contamination of the water-supply at the filtering beds. In Galicia and the various Turkish provinces cases are still rather numerous. Palermo and Leghorn are still infected, and in France, Brest and Nantes are the most seriously affected cities. In Spain, the disease is thoroughly scattered throughout the country, a few cases only occurring in each place.

CONSUMPTION OFFICIALLY DECLARED A COMMUNICABLE DISEASE IN MICHIGAN. — At its meeting of September 30th, the Michigan State Board of Health unanimously decided that consumption is a dangerous, communicable disease, and must be reported by physicians and householders to the several health boards.

A LARGE ANATOMICAL MODEL. — Dr. Nardi, of San Francisco, who was General Grant's physician during his travels abroad, has recently finished one of the largest anatomical models ever made. It is a model of the human heart thirty-five times the actual size.

RECOVERY OF DAMAGES FOR MISCARRIAGE. — The Superior Court of New York City has ruled that when a married woman is so injured through the negligence of another person as to miscarry, her husband can recover damages for the loss of the child. In the case on trial the damage was assessed by the jury at $2,250.

ATTRACTIVE CIGARETTE MATERIAL. — The *Medical Press* says that it has been discovered that all the used cotton-wool and lint of the Lariboisière Hospital in Paris has for years been systematically sold by the servants, as their perquisite, to the makers of cigarette-papers. The practice has been put a stop to.

BOSTON AND NEW ENGLAND.

A Medal Awarded the Boston City Hospital. — A medal has been awarded to the Boston City Hospital for the completeness and excellence of its exhibit at the World's Fair.

Massachusetts Cremation Society. — The retort building of the Massachusetts Cremation Society is approaching its completion and will be ready for use the first of next January. The Society is in a flourishing condition and has recently voted an increase of the capital stock to $50,000 by the addition of 25,000 shares of $10 each.

Children in Factories. — During the last year an effort has been made by the State Police to lessen the number of children employed in factories, with the result that there are now but 253 children under fourteen years of age at work in factories in the whole State, as against 1,656 a year ago.

Tetanus from Frozen Feet. — From December, 1888, to March, 1893, the hospital records of the State Almshouse at Tewksbury, show three cases of tetanus. The disease has in each case been concurrent with frozen feet. Among the nine thousand patients treated in the hospital during this time, no other cases of tetanus have occurred from any cause whatsoever. In two of the cases referred to, the frost-bite was superficial and called for no active surgical interference. The tetanic spasm was treated in one case with chloral; in the other with chloral and hyoscyamus. Both cases proved fatal. In the third, amputation of the foot had been decided upon when the tetanus intervened. The amputation was, however, performed, but without apparent effect on the course or progress of the disease.

NEW YORK.

Mortality. — During the week ending October 28th, the number of deaths reported in the city was 646; which is 56 less than in the preceding week and 58 less than the average of the corresponding weeks for the past five years. This represents an annual death-rate of only 17.62 per thousand of the estimated population, and the number of births reported during the week exceeded the deaths by 355. On October 28th only the following cases of contagious diseases were under treatment at the Riverside Hospital on North Brother Island: — Small-pox, 21; scarlet-fever, 26; diphtheria, 21; measles, 3.

Typhoid Fever at Tarrytown. — An outbreak of typhoid fever having recently occurred at Tarrytown on the Hudson, the village authorities applied to President Wilson of the Board of Health to assist them in detecting its source. Accordingly, he instructed Dr. Biggs, Chief of the Bureau of Bacteriology, to make an expert examination of the water supply, and Dr. Biggs, in connection with the local Water Commissioners, made a thorough survey of the different sources of the water. The supply comes from three wells sunk in a marsh northeast of the village, and several small brooks empty into the marsh from the surrounding hills. On one of these brooks, something less than a quarter of a mile from the pumping station, it was found that a house was located in which one or more cases of typhoid occurred in the latter part of September. The privy was situated directly over the stream, and this afforded an ample explanation of the outbreak in the village. Samples of the water from both the brook and the supply wells gave evidences of contamination.

Miscellany.

LARGE DOSES OF STRYCHNINE IN PULMONARY AND CARDIAC DISEASES.

In a recent address before the Philadelphia County Medical Society, Dr. Thomas J. Mays advocated most strongly a more frequent use of strychnine in the treatment of pulmonary and cardiac disease. In his experience he has found better results from the use of this drug than from any other single remedy. In addition to the powerful stimulating influence over the nervous system, and its special influence on the nerve supply of the lungs and heart, it has been recently shown that strychnine also has the faculty of multiplying the corpuscular elements of the blood, and is therefore, like iron, a blood-builder. A combination of such valuable properties in a single agent makes it apparent on theoretic grounds alone why strychnine should possess such a beneficial therapeutic effect in the diseases here considered, since anæmia is one of their most common complications. It is his belief that many affections of the lungs and heart are fundamentally dependent on disorder of the nerves which supply these organs, and that the curative effects of an agent in these diseases rests largely on the power which it has of correcting this primary aberation.

He considers that the best effects have not, as a rule, been obtained heretofore owing to the administration of too small doses. The sixtieth or fiftieth of a grain he thinks comparatively worthless, and for some time he has been in the habit of beginning with at least a thirty-second of a grain. This dose he gradually increases to the limit of toleration. Contrary to the general belief, he has not found strychnine to have any especial cumulative effect, but that the long-continued use brings a degree of tolerance, so that the poison line recedes. It has been his custom "to incorporate one grain of strychnine with quinine, or some other remedy, and divide the whole into thirty-two capsules, and give one capsule four times a day. This lasts eight days, and then one-eighth of a grain more of strychnine is added to the whole quantity, which is thereafter increased one-quarter of a grain every eighth day until the limit of toleration is approached." This may be as high as one-tenth, one-seventh, or even one-sixth of a grain four times a day, for several months continuously, permanently or again increased after a time. The only untoward effect he has noticed has been, at times, a slight tendency to cause diarrhœa.

The modes of administration has some influence upon the effect produced.

In asthma, Dr. Mays obtains the best effect by "introducing about a twentieth of a grain under the skin, and administering about a thirtieth or a twenty-fifth of a grain by the mouth four times a day, and gradually

increasing this in the way above indicated. Hypodermically, it is given once a day or every other day, and, if possible, in the evening, until there is an approach to the production of the toxic effects of the drug. Suitable doses of phenacetin, quinine, capsicum and ammonium muriate will enhance its action."

In bronchitis, both acute and chronic, strychnine checks the cough, diminishes the expectoration, improves the appetite, and puts to one side the whole constitutional relaxation and feebleness frequently present, especially in the chronic form of this disease, but it must be given in ascendant doses.

In acute pneumonia, he gives a twentieth of a grain morning and night subcutaneously, with an additional twentieth of a grain by the mouth every three or four hours.

In cardiac disease, he has found in strychnine a most valuable adjuvant to digitalis. Each fulfils its own indications which are distinct: strychnine, in cases of disease from want of nutrition and proper innervation, as shown by irregular intermittent pulsation of a weak heart; while digitalis is preferable in cases where there is a want of compensatory power in the heart muscle, as in valvular incompetency.

"Bearing in mind this difference, strychnine should be prescribed when the nerve-supply of the heart is enfeebled through auto-intoxication such as is found in the post-paralysis of infectious diseases, and in poisoning from alcohol, lead, mercury, etc.

"Irregularity and intermittency of the heart's action are frequently benefited by the administration of large doses of strychnine, and more often than not do we find that digitalis is utterly useless in such cases. Sometimes the irregularity will remain even under the influence of strychnine, but the symptoms which are dependent on, or are a part of this condition — such as pain in the precordium, orthopnœa, oppression of the chest — will improve or disappear, especially if suitable evacuant remedies are used at the same time.

"Even in purely valvular disease there comes a time when digitalis fails to maintain relief. It has aided in restoring muscular power and nutrition, but when the nervous energy begins to flag, and the heart walls begin to relax, digitalis no longer possesses the requisite spurring properties.

"The pulmonary circulation becomes impaired, œdema and congestion of the lungs follow, and death is threatened by way of the pulmonary organs. It is at such a time, when digitalis fails to counteract these many incidental complications, that strychnine has its superior value as a tonic to the waning nerve energy of the heart and lungs."

TRI-STATE MEDICAL SOCIETY OF ALABAMA, GEORGIA AND TENNESSEE.

THE annual session of the Tri-State Medical Society was held at Chattanooga on October 17th, 18th and 19th. There was a large attendance and a very general discussion upon the various papers which were read.

The following officers were elected: President, J. B. S. Holmes, Atlanta, Ga. Vice Presidents, James A. Goggans, Alexander City, Ala.; Dan. H. Howell, Atlanta, Ga.; T. Hilliard Wood, Nashville, Tenn. Councillors, W. E. B. Davis, Ala.: G. W. Mills, Ga.; J. B. Murfree, Tenn. Secretary, Frank Trester Smith, Chattanooga, Tenn. Treasurer, W. C. Townes, Chattanooga, Tenn. Recorder, W. L. Gahagan, Chattanooga, Tenn.

The following resolutions were adopted:

"For five years annually the Tri-State Medical Society has enjoyed the hospitality of the medical fraternity of Chattanooga, a hospitality that is only bounded by their opportunity to share the liberality and magnificent hospitality which particularly characterizes the Chattanooga doctor. There must be something in the atmosphere or water, or more likely in the fact of this city being surrounded by these grand mountains which has the effect to draw out and develop the better qualities and higher instincts that belong normally to every man's heart, and these magnificent surroundings have succeeded in developing a body of medical men that are not only an honor to the profession, but have and are now giving to this beautiful city a reputation that has become national.

"The Tri-State Medical Society feels to-day as we have unloosed the cable and from this day forward we are afloat and will have our annual home in Georgia, and then Alabama, and that we fully appreciate the sensation of a child leaving its paternal home and going out into the world to try his fortune. We fully appreciate the importance of this step, and as we leave the home nest and wander in other lands our thoughts, our affectionate rememberances and our prayers will centre here, and our thanks and gratitude and heart-wishes for the medical fraternity of Chattanooga will ever grow brighter and brighter as the years go by. Be assured that in the heart of every member of the Tri-State Medical Society the memory of many kindnesses and splendid hospitality will ever remain a green spot, the memory a thing of beauty and a joy forever."

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

NEW YORK, November 1, 1893.

A MEETING of the Executive Committee of the Congress of American Physicians and Surgeons was recently held at the house of the Chairman, Dr. Landon Carter Gray, there being present Dr. A. L. Loomis, President of the Congress; Dr. H. P. Bowditch, representing the Physiological Association; Dr. F. H. Bosworth, representing the Laryngological Association; Dr. D. B. St. John Roosa, of the Ophthalmological Association; Dr. Abraham Jacobi, of the Pediatric Association; Dr. P. A. Morrow, of the Dermatological Association; Dr. James B. Walker, of the Climatological Association; Dr. R. W. Taylor, of the Genito-Urinary Association; Dr. W. T. Lusk, of the Gynecological Association; Dr. F. J. Shepherd, of the Association of American Anatomists; Dr. L. McLane Tiffany, of the American Surgical Association; Dr. Wm. H. Welch, of the Association of American Physicians; and Dr. Landon Carter Gray, of the American Neurological Association.

A Local Committee of Arrangements in Washington was appointed as follows:

Dr. S. S. Adams (Chairman), representing the Pediatric Association; Dr. John S. Billings, the Surgical Association; Dr. H. C. Beyer, the Physiological Association; Dr. S. O. Ritchie, the Otological Association; Dr. S. C. Busey, the Gynecological Association; Dr. W. W. Johnson, the Climatological Association; Dr. I. Atkinson (Baltimore), the Dermatological

Association; Dr. W. H. Welch (Baltimore), the Association of American Physicians; Dr. I. C. Rosse, the Neurological Association: Dr. Samuel Theobald, the Ophthalmological Association; Dr. T. Morris Murray, the Laryngological Association; Dr. D. W. Prentiss, the Genito-Urinary Association; Dr. Frank Baker, the Anatomical Association.

It was arranged that the following subjects should be discussed by the Congress at its next meeting in Washington, in the latter part of May, 1894:

The Climatological Association: "Sewer Gas."

Genito-Urinary Association: "The Surgical Kidney in its Clinical Aspects."

Dermatological Association: "Leprosy in the United States."

Laryngological Association: "Intra-Nasal Surgery."

Gynecological Association: "Conservative Treatment of the Female Pelvic Organs."

Neurological Association: "The Effects of Infectious Processes on the Nervous System."

One Association is yet to select a subject for discussion.

Dr. W. H. Carmalt, of New Haven, Conn., resigned from the sub-committee deputed to take charge of the organization of the Congress, and Dr. Wm. H. Welch, of Baltimore, was appointed in his place, so that the committee now consists of Dr. A. L. Loomis, President of the Congress; Dr. Landon Carter Gray, Chairman of the Executive Committee; Dr. Newton M. Schaffer, Secretary of the Executive Committee; and Dr. Wm. H. Welch.

LANDON CARTER GRAY, M.D., *Chairman of Exec. Com.*, No. 6 East 49th Street.

NEWTON M. SCHAFFER, M.D., *Secretary of Exec. Com.*, No. 28 East 38th Street.

Correspondence.

AN INTESTINAL ANOMALY.

HARVARD MEDICAL SCHOOL, BOSTON, Oct. 30, 1893.

MR. EDITOR: The following intestinal anomaly, in a male subject, was found in the dissecting room, and seems to me to be of considerable interest in connection with abdominal surgery.

The sigmoid flexure was found in the right iliac fossa, with its mesentery attached to the right iliac artery, and the lower part of the mesentery of the ilium adherent to the sigmoid flexure.

The cæcum, vermiform appendix, ascending and transverse colons, were in their normal positions.

Below the splenic flexure, the mesentery of the descending colon was partially adherent to the posterior abdominal wall, but the intestine itself was quite free and moveable.

On approaching the sigmoid flexure the mesentery of the descending colon shortened, but was not attached to the abdominal wall, except, of course, in the median line.

On the third lumbar vertebra it was not over an inch in length, and here the intestine crossed the aorta, to the right side of the body. Its mesentery then increased in length, was freely moveable, and seemed to be attached to the right iliac artery. A freely movable sigmoid flexure with a long mesentery was found in the right iliac fossa. The mesentery of the small intestine was normal in its attachment, but the lower six inches were adherent to the anterior surface of the sigmoid flexure.

Coils of small intestine were alone found in the left iliac fossa.

Truly yours,

FRANKLIN DEXTER, M.D., *Demonstrator.*

METEOROLOGICAL RECORD,

For the week ending October 28, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,299: under five years of age 823; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 391, acute lung diseases 256, consumption 256, diphtheria and croup 156, diarrhœal diseases 107, typhoid fever 56, scarlet fever 23, cerebro-spinal meningitis 16, malarial fever 12, whooping-cough 10, erysipelas 5, measles 4, small-pox 2.

From scarlet fever Philadelphia 9, New York 4, Brooklyn 3, Boston 2, Milwaukee, Lowell, Cambridge, Salem and Newburyport 1 each. From cerebro-spinal meningitis New York 4, Worcester 3, Washington 2, Brooklyn, Boston, Cleveland, Lynn, Somerville, New Bedford and Brockton 1 each. From malarial fever Brooklyn 5, New York and Charleston 3 each, Nashville 1. From whooping-cough Brooklyn 4, New York and Philadelphia 2 each, Boston and Haverhill 1 each. From erysipelas

New York, Brooklyn, Lynn, Somerville and Pittsfield 1 each. From measles New York 2, Springfield and New Bedford 1 each. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending October 21st, the death-rate was 18.4. Deaths reported 3,652: acute diseases of the respiratory organs (London) 277, diarrhœa 135, diphtheria 103, fever 82, scarlet fever 79, whooping-cough 65, measles 37, small-pox (Bradford 4, West Ham, Birmingham and Leeds 1 each) 7.

The death-rates ranged from 11.8 in Derby to 26.9 in Blackburn; Birmingham 17.8, Bolton 16.9, Bradford 14.8, Burnley 15.1, Croydon 12.9, Hull 20.5, Leeds 16.6, Leicester 17.0, Liverpool 24.7, London 18.8, Manchester 19.1, Newcastle-on-Tyne 18.3, Nottingham 14.2, Oldham 17.2, Portsmouth 14.6, Sheffield 15.8.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 27, 1893, TO NOVEMBER 3, 1893.

Leave of absence for one month with permission to apply for an extension of two months, is hereby granted to MAJOR CURTIS E. MUNN, surgeon, U. S. A.

CAPTAIN MARLBOROUGH C. WYETH, assistant surgeon, is relieved from duty at Fort Supply, Indian Territory, and ordered to Army and Navy General Hospital, Hot Springs, Ark., for duty.

CAPTAIN ROBERT B. BENHAM, assistant surgeon, having relinquished unexpired portion of sick leave, is ordered to Madison Barracks, New York, for duty.

FIRST-LIEUT. HARRY M. HALLOCK, assistant surgeon, is relieved from duty at Fort McPherson, Georgia, and ordered to Fort Bayard, New Mexico, for duty, relieving FIRST-LIEUT. PHILIP G. WALES, assistant surgeon.

FIRST-LIEUT. WALES, on being relieved by FIRST-LIEUT. HALLOCK, is ordered to Fort McPherson, Georgia, for duty.

The leave of absence granted CAPTAIN H. P. BIRMINGHAM, as istant surgeon, is extended twenty-three days.

FIRST-LIEUT. CHARLES LYNCH, assistant surgeon, is relieved from duty at Fort Omaha, Nebraska, and ordered to Fort Robinson, Nebraska, for duty at that station, relieving CAPTAIN EDWARD EVERTS, assistant surgeon.

CAPTAIN EVERTS, on being relieved by FIRST-LIEUT. LYNCH, is ordered to Whipple Barracks, Ariz., for duty, relieving MAJOR BENJAMIN F. POPE, surgeon.

MAJOR POPE, on being relieved by CAPTAIN EVERTS, is ordered to Angel Island, Cal., for duty, relieving CAPTAIN WILLIAM R. HALL, assistant surgeon.

CAPTAIN HALL, on being relieved by MAJOR POPE, will report for duty as attending surgeon, Hdqrs Department of California, and examiner of recruits at San Francisco, Cal.

LIEUT.-COL. HENRY R. TILTON, deputy surgeon-general, is relieved from duty at Fort Wayne, Michigan, and ordered to Fort Omaha, Nebraska, for duty at that post.

MAJOR LOUIS M. MAUS, surgeon, is relieved from duty at Whipple Barracks, Ariz., and ordered to Fort Sam Houston, Texas, for duty, relieving MAJOR CALVIN DEWITT, surgeon.

MAJOR DEWITT, on being relieved by MAJOR MAUS, ordered to Fort Leavenworth, Kansas, relieving MAJOR JOHN BROOKE, surgeon.

MAJOR BROOKE, on being relieved by MAJOR DEWITT, ordered to Philadelphia, Penn., to await orders.

The leave of absence granted LIEUT.-COL. JOHNSON V. D. MIDDLETON, deputy surgeon-general, U. S. A., is extended fifteen days.

MAJOR JOHN O. SKINNER, surgeon, U. S. A., having been found incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date October 26, 1893, under the provisions of Section 1251, Revised Statutes.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, November 13, 1893, at 8 o'clock, P. M.

Dr. G. W. Gay: "Some Cases of Strangulated Hernia." Discussion opened by Drs. D. W. Cheever (by invitation), J. Homans, C. B. Porter.

Dr. Abner Post: "A Case of Œsophagotomy." Discussion opened by Drs. M. H. Richardson and S. J. Mixter.

Dr. J. Homans will present before the Society a specimen showing "The Remarkable Effects of Divulsion of the Urethra."

Members are kindly requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., *Secretary.*

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, November 15th, at 8 P. M.

Paper: "The Prevention of Tuberculosis," Dr. H. F. Vickery. Drs. F. I. Knight, V. T. Bowditch, S. H. Durgin and others will take part in the discussion.

F. C. SHATTUCK, M.D., *Chairman.*
HENRY JACKSON, M.D., *Secretary.*

APPOINTMENT.

CHARLES P. PUTNAM, M.D., of Boston, has been appointed by the Mayor, a member of the newly-constituted Board of Visitors to the Public Institutions of the city.

RECENT DEATHS.

SIR ANDREW CLARK, Bart., M.D., F.R.S., LL.D., died in London, November 6th, aged sixty-seven years. He was born in Scotland and was educated at Aberdeen and Edinburgh. In the medical school he distinguished himself in all his work, gaining the first medals in anatomy, pathology, chemistry, botany, materia medica, surgery, pathology and practice of physics. For two years he assisted Dr. Hughes Bennett in the pathological department of the Royal Infirmary and was demonstrator of anatomy to Dr. Robert Knox. For four years Dr. Clark had charge of the pathological department of the Royal Hospital at Haslar. In 1854 after taking his degree of M.D. at the University of Aberdeen, he came to London and became a member of the Royal College of Physicians of London and was elected on the staff of the London Hospital. In 1858, Dr. Clark was made a Fellow of the Royal College of Physicians, in which he held the offices of lecturer, councillor, examiner in medicine and censor. He has been also Lettsomian lecturer and president of the Medical Society of London. He was consulting physician and lecturer on clinical medicine to the London Hospital; a F.R.S. and LL.D. of Cambridge, Edinburgh, Aberdeen (honoris causa), an honorary Fellow of the King and Queen's College of Physicians in Ireland, and consulting physician to the East London Hospital for Diseases of Children. He has held the offices of president of the metropolitan counties brauch of the British Medical Association and president of the Clinical Society. In 1888 he was elected president of the Royal College of Physicians, succeeding Sir William Jenner, and was re-elected in 1889 and 1890. In 1883 he was created a baronet. The following are some of his writings: "On the Anatomy of the Lungs," "On Tubercular Sputum," "Evidences of the Arrestment of Phthisis," "Fibroid Phthisis," "The Work of Fibrinous Pleurisies in the Evolution of Phthisis," "Renal Inadequacy," "The Theory of Asthma," "Neurasthenia," and "Anæmia."

CHAUNCY MUNSELL HULBERT, M.D., M.M.S.S., died at South Dennis, November 6th, aged seventy-five years. He graduated from the Vermont Medical College and has been for some years treasurer and librarian of the Barnstable District Medical Society.

STEPHEN CROSBY MARTIN, M.D., M.M.S.S., died in Brookline, November 5th, aged forty-three years.

BOOKS AND PAMPHLETS RECEIVED.

The Medical Students' Manual of Chemistry. By R. A. Witthaus, A.M., M.D., Professor of Chemistry and Physics in the University of the City of New York; Professor of Chemistry and Toxicology in the University of Vermont, etc. Fourth edition. New York: William Wood & Co. 1893.

A Practical Treatise on Diseases of the Skin; for the use of Students and Practitioners. By J. Nevins Hyde, A.M., M.D., Professor of Dermatology and Venereal Diseases in Rush Medical College, Chicago. New third edition. In octavo volume of 802 pages, with nine plates of which three are colored and 108 engravings. Philadelphia: Lea Brothers & Co. 1893.

The Blot upon the Brain; Studies in History and Psychology. By William W. Ireland, M.D., Edin., formerly of H. M. Indian Army; Corresponding Member of the Psychiatric Society of St. Petersburg, and of the New York Medico-Legal Society, Member of the Medico-Psychological Society. Second edition. New York: G. P. Putnam's Sons. Edinburgh: Bell and Bradfute. 1893.

Asiastic Cholera: Its Genesis, Etiological Factors, Clinical History, Pathology and Treatment. By John A. Benson, Professor of Physiology and Associate Chief of the Department of Clinical Medicine, College of Physicians and Surgeons of Chicago, Ill.; Member of American Anthropometric Society, of American Medico-Psychological Society, of the Chicago Pathological Society. Chicago: The J. Harrison White Co. 1893.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XIX.

SURGICAL DISEASES OF THE BLOOD-VESSELS.

The simplest form, of which we will speak first, is the ordinary

NÆVUS OR BIRTH-MARK,

that is, an enlargement of the capillary blood-vessels due to some unknown cause before birth, and generally developing and growing larger after birth. The face is the favorite seat for it; though occasionally it is found in the hairy scalp, or the back; it is usually about the eyelids, nose and lips. It usually appears on the infant as a small, flat, slightly-raised red patch, perhaps as large as the finger-nail; does not pulsate, but is spongy and erectile. If you compress it firmly with the thumb, the blood will be pressed out, and slowly return. When it happens to be near the mucous membrane, as of the eyelid, or nose, or lip, it increases because the tissue is loose, and it has a chance to grow and distend. In other locations, as the cartilage of the nose or forehead, it increases very slowly. This is the simplest form of enlarged vessels, being confined to the capillary circulation, which, of course, is dilated far beyond its normal size; but the disease apparently originates in it.

It is painless and innocent, except for the deformity which it causes. The ordinary nævus sometimes goes away of itself. If it is small, and in a place where it does not grow easily, after the excitement of the first dentition is over, it frequently sinks away and disappears. If, on the other hand, it is where it has a chance to distend, or if it is a great deformity, an operation can be done to relieve it.

Very small ones can be cured by the application of simple caustics, which leave only a small puckered scar. Caustics like nitric acid may be used. A small one can be burnt out by the electric wire, with which it can be touched. This must be distinguished, in your minds, from the treatment of any varicose, or enlarged vessels, or aneurisms, by throwing a current of electricity through them, electrolysis. That acts by coagulating the blood and does not destroy the tissues of the sac. The electric cautery, or galvanic cautery, merely burns off the whole affair, and shrivels it up and makes an ordinary scar, just as nitric acid does. In places where the nævus is not conspicuous, as on the back or arm, it can be very well cured by vaccination. That sometimes may be worth thinking of in simple cases, where the nævus is small. In larger cases there are several ways of operating to get rid of them. The ligature may be used. This makes a bad scar always; can hardly fail to do so. The nævus may be surrounded by a thread and strangled in one or two directions, and allowed to slough out; and the wound heals by granulation. A neater way is to cut them out. If the tissues are loose so that you can cut around them in sound skin, you can make a very neat result. The whole thing can be dissected out and the skin brought together as you do in taking out a small, fatty tumor, or wen.

Injecting the nævus with styptics like perchloride of iron is frequently successful, but not free from danger, inasmuch as the thrombi which are formed in the vessels are sometimes taken up and carried on in the circulation; and instances have occurred in which the injection of nævi upon the scalp of young infants has been fatal in a few moments. Of course that is a very distressing event, and we have to reflect, after such an affair as that, that we could have done it by a safer way. The larger the vessels, the more chance of absorption of clot, and some destructive consequence.

Small ones can be burnt out; larger ones can be strangled or excised. Some will go away of themselves.

The next form, which is more serious, is the venous form of

VARIX,

which is erectile tissue, composed of large veins; does not pulsate; and comes preferably about the mucous membranes. A common site is inside the mouth; inside the buccinator muscle, about or over the lips, in which case it frequently produces a great deformity. The lip enlarges and everts; and this large spongy mass of bluish color, not pulsating, hangs out upon the face. Inside the cheek they grow rapidly, and are rather difficult to extirpate. They somewhat resemble the venous condition we find in hæmorrhoids. They form occasionally in the vulva, and about the nymphæ. This form is distinguished by the fact that the tissue is frequently cavernous or erectile; and is composed of large blood cavities, and does not pulsate; but the blood can be pressed out of it like a sponge; and then it slowly fills again so as to be as large as before.

This can be cured best by the ligature. It would be especially dangerous to use the electric current. A very neat result can be got by passing curved needles on a handle, with threads, through and under, and about them, in various directions; securing the whole mass, and allowing it to slough out.

The other form, which is more intractable, though not more dangerous, I think, is that composed of enlarged arteries, and now called

ARTERIAL VARIX.

This is made up of large, tortuous, intercommunicating arteries, originally formed by the small arteries, before they reach the veins. These dilate and form other anastomosing branches, until finally you have a considerable mass forming a tumor, which is pulsating to the touch, and which possesses some of the destructive power of an aneurism. If in the temporal region, it may absorb the temporal fascia, the muscle and the temporal bone, and finally lead to fatal meningitis. This form of varix is fed by numerous arteries around its margin, of considerable size; and the final supply of the whole current comes through the nearest main artery, which feeds the parts with blood. In the temporal region the supply is from the external carotid.

Such growths as that, if they are let alone, sometimes do not become dangerous. If they are not extending they may be let alone. If, however, they are extending, and obviously absorbing the neighboring tissues, or if they cause pain, then it is better to try to cure them; and to cure them is difficult by operation because they possess a great vitality, due to the

[1] These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

numerous arteries involved. In large cases, the best way, if it can be done, is to secure the main trunk first; for an aneurism of the temporal region, to tie the external carotid. If this is tied with an antiseptic ligature and closed up, it will obstruct the vessel and check the flow through the carotid, without cutting through the trunk of the vessel, and without the danger of secondary hæmorrhage. Frequently this can be neatly done, so that the wound closes promptly; after a week, or so, the carotid is entirely cut off.

The result of this upon the arterial varix above will be to starve it to a very considerable degree, but not cure it. It will begin to take its supply from anastomoses of the neighboring system, which supplies the head. But after the patient has passed through the first operation, then while the arterial varix is very much reduced in size and has not had an opportunity to fill up again to any great degree, it may be safely attacked by tying the vessels round about, which feed it in other directions; and finally tying the mass; strangling it completely; and forcing it to slough out. In this way they are cured without danger.

On the whole, simple vascular growths may be destroyed with safety by the cautery; larger ones more safely with the ligature. Resulting scar is inevitable, except in the case where we can cut it out and bring the parts together.

The next enlargement of vessels that I will speak of, because it comes next in order, is

VARICOSITY OF THE VEINS.

Varicosity of the Veins of the Left Spermatic Region. — Varicocele, occurring almost always on the left side, is frequently a great mental trouble to the patient, and sometimes it is the seat of pain. When the varicocele becomes large and heavy, the veins dilate the deep layer round the spermatic cord; subsequently the superficial veins dilate, so that finally the two sets dilate; the deeper ones around the vas deferens and artery, and the superficial ones scattered on the scrotum going back on the perineum, and going up on the groin. The result of this heavy load of blood is to dilate the walls of the scrotum, and distend it very much, so that the whole of that side of the scrotum becomes larger than the right side, and eventually produces pain, by dragging on the spermatic nerve; in this case the pain is of a dull, aching character, and extends up the cord, until it extends to the back and loins, along the course of the ureter, up to the kidney. This pain is annoying to the patient if he is working hard; and is always more troublesome in summer than in winter owing to relaxation.

Palliation may be afforded by a suspensory bandage. This has a tendency to prevent the disease from extending and increasing, and holds it in check. The unfortunate complication sometimes arises in which the patient is the victim of hernia on the same side with the varicocele. In that case the pressure of the truss on the external abdominal ring is liable to press on the recurrent veins, and lead to aggravation of the varicocele. The blood is pumped in by the arteries, the veins are already dilated, and are further obstructed by the pad of the truss. In such a case as this it may be necessary to operate to relieve the patient of the veins on account of the pressure of the truss on the site of the hernia. The truss devised by Mr. John Wood is very useful in this class of cases. It is made in the form of a horse-shoe. The two arms rest on the pillars of the ring; the flat part of the pad presses over the internal abdominal ring. The result is that the exit of the vessels is left without compression; and it is very comfortable to wear in this class of cases; a little point worth remembering in treating a case of hernia and varicocele together.

Patients with varicocele are much more anxious to be operated on usually than the surgeon is to undertake it. The results of the operation are not always brilliant. Although it may relieve the veins which are tied, it is liable to have some effect on the nutrition of the testicle; but whether that effect is more than the effect of leaving a large varicocele alone and allowing the testicle to be distended with venous blood, I am considerably in doubt. It is fair to say that when a large varicocele is tied the testicle almost always shrinks, and in that way probably loses some of its function. All this should be explained to the patient; and if he wishes to take the chances, and is sure the varicocele is painful enough to warrant it, the operation may be done.

Morning and night showering of the part thoroughly with cold salt and water; taking of cold baths; great care to relieve any tendency to constipation; avoidance of wearing any tight bandages about the waist to compress the recurrent circulation are useful. If the operation is done, it is usually done by ligaturing the veins, either by the open method of cutting down upon them and dressing the wound antiseptically, or the old method of operating subcutaneously.

This operation is followed by pain, swelling of the testicle and scrotum; requires the patient to be confined to bed some little time; leaves him afterwards for several months with a lump on that side of the cord, so that he is quite sure he is not cured; although you may feel that the larger that lump is the more certain is the cure.

There is a little danger in this operation. Phlebitis occasionally extends up to the abdominal cavity; and sometimes has been fatal. This should be taken into account before you undertake the operation. The danger is not great. It is something, however.

Varicose Veins. — The ordinary place for these is about the calf of the leg, and around the tibia. The cause is usually largely hereditary; persons of a certain type who have a large venous system, large veins at any rate; and also position, standing and walking, constantly on the feet. The first thing which takes place is that the column of blood not being thrown back promptly through these veins, they dilate. After they have dilated to a certain degree the muscular coat of the vein loses its tonicity, and thinning of the vein takes place. Then the dilatation presently causes a forcing open of the valves, one after another, so that, finally, in a bad case, if it is laid open, you may find all the valves, for quite a distance, laid back against the wall, and incapable of closing. The result of this is a struggle of nature to carry the blood back through other veins; hence, dilatation of other veins; rapid enlargement of all the anastomosing veins occurs, and eventually the diseased condition extends up to the groin, and involves sometimes the long saphenous vein in its entire length. In the short saphenous vein it extends up to the popliteal pouch. A pouch at the saphenous opening, and another marked venous pouch at the popliteal orifice, is very characteristic of the varicose vein. In addition to that, coagula form, numerous ones; and little hard lumps form throughout

the vein at different points, chiefly near the valves, which form a partial obstruction to the current. Occasionally, also, calcareous salts, and deposits of what are called stones in the veins, phlebolites, are also found, of various sizes. That is the condition and that the history. Once begun, it is sure to progress, unless means are used for its relief. Moving about in walking compresses the veins where they penetrate the muscles, and adds to the obstruction in long-standing cases; also the giving out of more and more valves, and thus a greater weight of the column of blood. Soon after this has taken place œdema of the feet and ankles begins, and serum is forced out from these dilated vessels into the surrounding tissues. Finally, as a last stage, the venous dilatation extends even to the capillary system; and we find in such patients the feet mottled with innumerable small blood-vessels, scattered about in groups where the capillaries have been distended. The feet and ankles in this condition are always swollen. The capillary veins are so dilated, and so many of them have been plugged by little coagula, that they do not go down and get relieved when the patients lie down at night; and a condition of chronic œdema of the feet results.

The best treatment is compression; and it is the most satisfactory. It may be done by a flannel bandage, if carefully applied; or by the elastic stocking; or in more marked and severe instances by the use of an India-rubber bandage, which will compress the veins very perfectly. The flannel bandage, in the mild cases, is the most comfortable that can be used. It must be put on every day and taken off every night. It does a good deal of good to bathe the legs frequently in cold water, and lie down and rest as often as the patient can. If the patient happens to be in easy circumstances he can get along perfectly well with a flannel bandage and cold baths and the rest he can take; and thereby prevent the disease from increasing very much. Not so with the patient who is forced to labor. In that class of patients the elastic stocking is invaluable; and frequently suffices without anything further being done.

In former times, surgeons seeing the varicose vein lying upon the skin with its dilated pouches, the thrombi and the useless valves, and its tortuous course, concluded that that was the whole disease, and that if that vein should be obliterated and destroyed, the disease could be cured; hence the older method of treatment was to destroy the vein by one of two methods. A favorite method was by caustic. This was done by a caustic of moderate strength, called the Vienna paste, made of caustic potash and some other ingredients, fastened over the vein, tied on and forced to slowly burn its way. It was painful, but it was a very effectual cure. As it went on in this destructive process it set up periphlebitis, caused coagulation, destroyed skin, cellular tissue, and even made a deep scar, shrinking everything up, so that no vein could ever exist in that spot again. It was customary, where there was a long varicose vein like the long saphenous, to put half a dozen of these pledgets of Vienna paste up and down the limb; and allow this process to be done a number of times, until the vein was obliterated. This was quite safe. Thrombosis and diffused phlebitis rarely occurred, for the simple reason, I suppose, that it was gradual. Anything to which the body is subjected, if it is a gradual influence, nature accommodates itself to; so that it was a safe operation, although painful; and it accomplished what it set out to accomplish; but it did not cure, by any means, the disease. The other method which was used was the ligature, and this was more dangerous because its application was instantaneous. The current was cut off at once. Adhesive phlebitis and thrombosis was excited in the course of a few minutes or hours, and the travelling of clots and production of embolism was not a very rare consequence in this mode of operating. In addition to this, in old times, suppuration occasionally took place; and a diffused erysipelatous inflammation of the leg, already the seat of poor circulation, was apt to occur. However, in a very bad case, where they may be expected to do any good, either of these methods are justifiable; but as curative agents they are failures; and the reason is that although you destroy the vein, you have no control over the condition of the anastomosing veins which penetrate the muscles, and connect the superficial with the deep veins; so that you merely convert a superficial varicosity into a deep one, if you destroy the superficial veins.

Philosophically speaking, the only treatment of varicose veins is compression and care. An operation may be done for a case where an ulcer is overlaid by a vein so that it will not heal until that vessel is destroyed, or something of that kind; but an attempt to cure a varicosity of a limb by these operative procedures is not successful, and is a matter of some risk.

PHLEBITIS,

or inflammation of the veins, is sometimes idiopathic; and sometimes the result of injury. It may come on of itself. If it comes on of itself it may be acute, or chronic.

It is supposed to be rather an inflammation around the vein than in the vein itself. The cellular tissue around the wall of the vein inflames, and the process continues through the vein; results in coagulation of the blood; plugging up of the current and continued building up of clots; so that sometimes an obstruction which begins down in the calf, may extend up in the pelvis before the disease has run its entire course.

Certain diseases, apparently, bring on this condition, especially diseases of the erysipelatous type, and different forms of diffused cellulitis.

The appearance of phlebitis, when it occurs in the acute stage, is very marked. In the first place, pain comes on. Then it will be noticed that the limb becomes marbled with dark lines, which are the veins becoming obstructed. If these are pressed upon, it will be found that the current is flowing in them, but it returns with great slowness, and does not flow promptly, as in the healthy vein. The current is slow; the vein becomes conspicuous and swollen and darker colored, so that it shows plainly under the skin. It is painful. The neighboring tissues are swollen. The cellular tissue is infiltrated and the limb becomes big and hard. Very soon it will be found that one of these veins is completely obliterated, and that there is no current in it, and that it can be distinguished very distinctly under the skin as a hard cord pursuing its course up the leg. It is impervious; filled with coagula; and these coagula are going to extend upward. Whether or not they will do any harm depends upon the cause of the disease. If the cause of the disease happens to be septic, the coagula appear to be imperfectly formed; soften readily; become themselves occasionally the seat of septic decay, and the factors,

so to speak, in producing the different stages of pyæmia, and absorption of pus, as it used to be called, from the vessels, in distant parts of the system. But if the phlebitis happens to be caused by a blow or wound, which is doing well in a healthy individual, or comes on in a person of feeble circulation, who is old and feeble, and who has a slight coagulum form in the vein from the slowing of the current, then, in either of these cases, the course of the disease is not rapid: is not very acute, and it is not very dangerous. It is very annoying, very tedious, but does not usually result in septic infection, or the travelling of large embolic clots. Phlebitis as an accessory, as a condition of a septic state already existing, is one of the most dangerous signs that we can see; and we may almost despair of arresting its progress and its tendency to produce pyæmia, if we see it occurring in connection with a foul wound, or a bad state of the limb in which it happens to be; on the other hand, phlebitis of a more moderate and subacute kind is not essentially dangerous.

Treatment. — The treatment of the milder and chronic kind is the more successful, of course. The first requisite is entire rest in the horizontal position; and the next requisite is that, as regards any manipulation, the vein must be left entirely alone. Hot applications are frequently very grateful, and some of them of a good deal of influence in quieting down a moderate state of subacute periphlebitis. The limb should be in an easy and relaxed position; the patient confined to bed; and the parts heavily covered in large poultices. To these frequently may be added with benefit, laudanum, and outside of it India-rubber cloth, or oiled silk, so that the leg may be steadily steamed and fomented in the poultice. This gives comfort, and seems to assist in resolving the trouble. Patients who have had one of these troubles instantly recognize what is taking place. They are seized with a stabbing pain, and find a little knot developing, which is hard and painful. Then a minute red line, marking the course of the vein, may be seen. Patients who have this tendency, and are subject to many attacks, if they know how to treat it at once, frequently can, by a week's confinement at first, prevent months of confinement afterwards.

In the septic variety, accompanied as it always is by suppuration and cellulitis, deep and free incisions; removal of all causes of irritation; antiseptic irrigations and washes; sustaining the strength of the patient with strong tonics and alcoholic stimulants, etc., may do something to assist in arresting the diseased process.

VENOUS HÆMORRHAGES.

When a vein is wounded it bleeds largely, but only in expiration. When the patient draws the breath in, the blood is drawn in towards the heart, and when the patient expires, blood flows with a great gush from the vein. This is the case in veins of ordinary size.

The most common cause of venous hæmorrhage, except from wounds, is the rupture of a varicose vein. This frequently occurs, and they bleed to a large extent; sometimes fatally, but not often. A venous hæmorrhage can be easily checked by pressure; and, if that is not sufficient, the vein can be exposed and tied exactly as an artery is tied. The old prejudice which used to exist against tying veins no longer exists; and whatever danger there may be in tying veins — the danger of setting up periphlebitis — is infinitely diminished by the fact that we use antiseptic ligatures, and dress them in an antiseptic way.

AIR EMBOLISM.

One of the most distressing and rapidly fatal accidents that can occur in the venous wound is the entrance of air. It must be a large vein to do it. It is sucked in in inspiration. That is the case in the larger veins about the neck which do not have valves; and is especially the case when the mouth of the vein happens to be held open, after it is cut, by its being attached to a fascia, as about the neck, in the popliteal space, in the groin, etc.; but especially the neck. When, for example, the surgeon is engaged dissecting out a tumor in the subclavian triangle, everything is done easier if the parts are on the stretch. The tumor is lifted to dissect it out; the parts beneath are on the stretch. They are out of sight, very likely displaced by the growth of the tumor. The vessels may be enlarged as well as displaced by the long-continued pressure of the tumor. It is then easy to understand how it frequently happens that the surgeon, in dissecting out the tumor, cuts through the fascia and the wall of the vein; the patient, making an inspiration, draws air into the vein, and the immediate consequence is what is sometimes called air embolism; that is, the air rushes down into the right cavity of the heart; appears in some way to obstruct immediately the action of the valves, either by displacing the blood and causing a froth, or by churning up of the blood; at any rate, the immediate effect on the heart is terrible and disastrous. The patient gasps; paleness and lividity come on; and death takes place in a very short space of time.

The best treatment, of course, is the preventive treatment; and there are two ways that must be used: either an assistant must be ready to thumb any vein that may be opened, and keep his thumb right about the subclavian region while the operation is going on; or another expedient may be used, which is to keep the bottom of the wound which is being dissected thoroughly wet in a puddle of some antiseptic fluid. Either of these measures are safe ones.

When the accident occurs it is generally fatal. One or two bubbles of air occasionally go in and do not make enough trouble to destroy life, although there is temporarily faintness and palpitation. The sound of the entering air is usually quite distinct. It is sucked in with a distinct gurgle; the surgeon at once becomes conscious of the fact; compresses the vein; injects ammonia or brandy; promotes artificial respiration; and, in the slight case, succeeds in saving life, but not in the severe ones.

ATHEROMA.

The next subject we will speak of is that condition of the arteries which leads to the formation of aneurisms. It is called atheroma. It is a fatty degeneration of the inner coat of the vessel followed by ulcerations and the deposition of calcareous salts, brittleness and stretching of the wall of the vessels and the formation of a sac.

An aneurism means a sac, or bag, which contains blood. It is usually what is called true or false. If it is a true aneurism, it is a dilatation of all the walls of the artery. If it is a false aneurism, it is a dilatation only of a portion of these walls.

The mode of its formation is always consequent

upon this atheromatous change in the arteries themselves. The arteries are very smooth elastic tubes. They twist and yield with every pulsation of the heart. They shrink and open. They are governed by a set of nerves which control the muscular movements of the walls. They enlarge or diminish in consequence of the needs of the part to be supplied with blood. When the part or limb is in violent exercise and the person running rapidly, an additional blood-supply is sent. The arteries enlarge; they beat more rapidly and expand also; therefore it is essential to the life of a part that the artery should be compressible, elastic, distensible. When the condition, or change, which is called atheroma takes place, the artery becomes diminished as to its calibre and stiffened as to its walls; loses its elasticity; cannot carry any more blood at one time than at another time. The consequence is, in elderly people, when the atheromatous condition is well pronounced, that the blood-supply to the feet and distant parts is not only insufficient, but is incapable of being increased. Let such a part be exposed to cold and the blood cannot come. The result is, frequently, in the elderly, the gradual occurrence of senile mortification of the foot in consequence of a slight bruise, or a little lameness, or ingrowing nail; exposure for a few hours in riding; anything of that kind will gradually bring on stoppage of the circulation; starvation of the part and mortification; senile gangrene of the limb. That is one of the consequences of atheroma.

Another is that it not only stiffens the walls of the vessels, but leads to ulcerations, deposits of calcareous salts and thinning of their walls and formation of aneurisms. Without going into detail we can make plain in a few words how this takes place. Given a very smooth elastic tube which has got to carry a certain amount of blood, and is constantly in motion by the pumping of the blood through it, the first thing that takes place usually is the loss of brilliancy and smoothness of the innermost coat. Now the innermost coat of the artery is nourished mainly by imbibition of the blood which runs through. One stage of the degeneration which results when the coat is not perfectly nourished is the formation of fat. Fat cells form. It loses its smoothness, becomes slightly roughened and softened. What takes place when in ordinary cases a current of blood that is being pumped through a smooth tube meets with an obstruction? What takes place when we cut an artery, or vein, and allow the blood to flow upon some surface? Immediate deposition of fibrin, and the blood separates into its clot and serum and fibrin. The result of this slight roughness inside of the vessels is that slow deposition of fibrin takes place; more obstruction ensues; the current of blood beats with irregularity upon the wall of the vessel, and the inner coat, being deprived more and more of its nutrition, finally gives way. The result is a slight ulceration. The result of the ulceration is a pocket of greater or less size in the wall of the vessel. In this pocket gradually become deposited the lime salts in the form of plates.

Given a point in the vessel where there happens to be a meeting and crossing of two or three currents, where the circulation is not so perfect, having to cross, as it would in a single tube, here let an atheromatous change take place with a little ulceration and you can see how readily that pocket will deepen, that ulceration will increase, and the coat of the artery will be stretched more and more, and finally we have a sac or pouch formed in which the blood must go round and round, and be delayed in its progress. This is the way the ordinary true aneurism is formed.

The moment the sac is formed, blood delayed in it and the circulation impeded, nature goes on to another process, which tends to cure it; and that is by the formation of large coagula in the sac, which shall resist the impulse of the blood; be buffers as it were against the danger, and lead almost to a state of repair. The layers of fibrin which are deposited from the coagula on the inside of the sac become pressed down thinner and thinner, and those which lie next to the wall of the sac become very white, thin and firm; the next less so, and the next less so; so that you can see, in cutting into a fresh aneurism, a long series of concentric layers like the layers of the bark of a tree; those nearest the sac white and hard, next a little darker, and the central ones more and more soft. Nature makes an aneurism by ulceration of the inner coat. She tries to cure this aneurism by the coagulation of the blood inside the sac itself. As these coagula form more and more, the current of blood must go more and more slowly and imperfectly through the sac. Finally the blood, instead of being forced through, trickles through, and the aneurism may be almost cured. This is nature's process. Now it seems to me that this process indicates precisely the course we should endeavor to pursue in curing an aneurism; that is, to imitate nature as nearly as we can; to slow the current, and encourage the deposition of coagula by gradual compression and by rest.

AN INVESTIGATION OF AN EPIDEMIC OF TYPHOID FEVER IN THE CITY OF SPRINGFIELD, MASSACHUSETTS, DUE TO INFECTED MILK.[1]

BY W. T. SEDGWICK, PH.D.,
Biologist of the Massachusetts State Board of Health,

AND WALTER H. CHAPIN, M.D.,
City Physician and Member of the Board of Health of Springfield.

About the first of August, 1892, it was noticed that typhoid fever was unusually abundant in a particular district of the city of Springfield. This city (of about 47,000 inhabitants) covers a large area extending north and south along the Connecticut River, and upon somewhat higher land to the eastward. Its soil is chiefly sandy or gravelly, and the situation is regarded as salubrious. The particular district in which typhoid fever began to appear in such abundance as to excite comment, and at length alarm, is known as the "McKnight district," and lies upon a gravelly plateau of wide extent, such as often characterizes the terraces of the Connecticut valley. It is included between State Street and St. James Avenue. The district has been comparatively recently "developed" by enterprising real-estate activity, and may fairly be described as having a refined and attractive suburban character; the houses, mostly of wood, standing somewhat back from the street, are provided with grassy yards or lawns and sometimes with gardens. The sanitary arrangements are in keeping with the exteriors; in brief, the district forms an inviting, whole-

[1] From the forthcoming Report of the State Board of Health of Massachusetts, for 1892.

some and excellent suburban community. There are other parts of the city, similarly situated, some as good, some better, than this; but most of the city is far less favorably situated, less inviting, less clean, and in parts, especially along the river, crowded with tenement-houses; still other portions consist chiefly of shops or stores or offices, amongst which dwellers of a lower grade are crowded. But in none of these except the McKnight district did typhoid fever make its appearance in July, 1892.

The perplexity of the people, therefore, was great, and, as is usual in such cases, various theories were advanced to account for the epidemic. Some of these were manifestly untenable; others, although resting only upon vague conjecture, were soberly propounded and seriously discussed among the citizens and in the newspapers. Even physicians and the local sanitary authorities were deeply perplexed. Attention was first drawn to well-water as a possible cause of the disease, some of the people in the McKnight district having resorted largely to well-water in preference to the city water during the hot months. But it was naturally urged as a sufficient objection to this hypothesis that many, indeed most, of the victims had used only the public water-supply for drinking purposes. A similar hypothesis was advanced in respect to certain spring-waters widely sold in the district, but the same objection was effectively raised in this case. Some turned to the drainage and some to the sewerage of the district as the probable source of the trouble. But it was immediately pointed out that the houses affected were mostly new and the plumbing was generally in good condition. With respect to the sewers, a stench from the man-holes in the neighborhood of Yale Street was said to be noticeable at times, and we found that this was a fact; but the superintendent of sewers showed that this was an incident of the hot season; that the smell was no worse this year than in previous years when there had been no fevers; that the fall of the sewers was usually good, and the system of flushing them excellent. Moreover, many of the houses nearest to the man-holes had no typhoid fever cases; so that the sewer-gas theory, also, proved to be inadequate to account for the outbreak.

The officers of the local Board of Health began work upon the impure-water theory, and in conjunction with a local chemist proceeded to examine, chemically, the numerous wells of the district. They found several wells containing large amounts of chlorine, and many which gave evidence of more or less remote sewage contamination. But in spite of their results it remained an insuperable objection to the theory of well-water contamination as the cause of the trouble that some of the cases had had no access to well-water.

Still new cases of fever continued to appear, and the local perplexity increased. It was observed by some of the citizens and made known, that many of the families affected were served with milk by the same milkman. The city physician, therefore, communicated with the latter, and on August 8th, by which time there were known to be twenty or more cases of fever in the district, visited, under the guidance of the milkman himself, the several farms from which he derived the milk furnished to his patrons in different portions of the city. All of the farms were thus visited by the city physician except one, which, he was informed, had already been visited by a well-known and competent physician of Springfield, and found to be in good condition. He was further informed by the milkman that all of the milk distributed to the McKnight district, had come invariably from two farms in Agawam, a town adjoining Springfield, and these he found to be excellent farms in good condition, with no history of any typhoid fever upon either of them. It was learned, also, that the milkman's cans were washed and steamed only at the Springfield Co-operative Milk Association's headquarters, and that there was no reason to suspect that the origin of the fever was in any way connected with the water thus used; for the same water, under the same system, at the same place, was used for many other dairymen's cans, and no typhoid fever had appeared upon their routes. The conclusions drawn from the results of investigation of the milk-supply was, therefore, as stated in a local newspaper on August 9th, that the milk-infection theory was "entirely set aside."

In the mean time it had been suggested that the comparative proximity of a neighboring cemetery might be the hidden cause of the epidemic, and a cemetery theory was fully discussed in all its bearings. This received a severe blow when it was found that a well in the cemetery itself contained less ammonia than the wells in the McKnight district, but it continued for some time to hold a place among the favorite theories, in spite of the fact that there was not a particle of evidence in its favor, and every reason to reject it. It was hard pressed by the sewer-gas theory, especially on those streets with odoriferous man-holes; but both soon after lost some adherents, who went over to the infected-vegetable theory, namely, the theory that green foods, such as lettuce, tomatoes, celery, having been splashed by liquid manure previously infected, had been eaten uncooked, possibly in salads, and had thus produced the disease. This theory, however, like most of the theories advanced, failed to explain why the people in this district only were affected, or why, among all the families in this district, the particular families affected had been smitten. Last in the series, the theory of ice infection was brought forward as the probable cause of the outbreak; but inasmuch as the ice-supply of this district was in no respect different from that of the rest of the city, and the affected families had been served by the same carts as many families totally unaffected, this hypothesis also seemed to be untenable.

It is interesting to bring together, as more or less typical of the vague and often wholly unsupported speculations as to the cause of particular epidemics of typhoid fever, those which were propounded in the present case and were deemed worthy of mention in the public prints. They were as follows: (1) impure well-water; (2) impure "city" water; (3) defective drainage or plumbing; (4) defective sewerage, or sewer-gas; (5) infected milk; (6) influence of a cemetery, probably upon the well-water supply; (7) infected vegetables; (8) impure ice. These were not all of the theories advanced, but they suffice to show the usual condition of public opinion in the presence of an outbreak of typhoid fever.

All of these theories, if such they may be called, were propounded and discussed at much length, both in private and in the public prints, within the first week after attention had been drawn to the epidemic. During the second week the local debate was actively continued, but no new theories were advanced, the State Board of Health was not notified, no thorough

investigation was made, and no just conclusion was reached. The anxiety and alarm of the citizens remained undiminished. Finally, in the third week of the debate, the State Board of Health was appealed to, and one of us (W. T. S.) was sent to the aid of the local Board of Health, arriving in Springfield on August 14th.

On August 15th, the authors began a joint investigation of the cases affected, using for the purpose the blank already described in connection with the epidemic in Lowell. After nineteen houses in the infected district had been visited and forty-six cases, examined, it became clear that all theories hitherto advanced were untenable except the milk theory. No other common bond of connection whatsoever could be found, but *all of these families except one had been taking milk from the same milkman*, as had already been alleged but not proved. This milkman (F. D. K.) was by no means the only milkman who sold milk in the McKnight district, but we soon discovered that he was the only one upon whose service there was any typhoid fever. In the exceptional case mentioned above, we afterwards found that the family got milk regularly from another dealer (upon whose route there was no other case of typhoid fever), but that almost as regularly this family bought milk from a grocery supplied by F. D. K. We therefore concluded provisionally that the epidemic was probably due to infected milk; but inasmuch as it seemed to be plain that one of us (W. H. C.) had hitherto been misled, we did not immediately announce our conclusions, although we straightway acted upon them, and proceeded to interview and cross-examine more closely F. D. K., the milkman who had served the infected houses with milk.

By him we were informed that all of the milk which had been supplied to the infected houses had come from the two farms in Agawam already referred to above. Upon this point he was positive and explicit. On the next day, therefore, we visited Agawam, in the hope of finding the source of the infection. As has been said above, these farms had already been visited by one of us (W. H. C.) on August 8th, in company with F. D. K. himself, and found to be in good condition; but to our surprise we now discovered on one of them, on the 16th, a well-marked case of typhoid fever, which had apparently developed since the visit on the 8th just referred to. The most careful cross-examination of the family (which was that of a well-to-do farmer) gave no indication of any previous case of typhoid fever on the farm, and this one appeared to have contracted the disease in Springfield, thus sharing, rather than explaining as a cause, the outbreak there. It was possible, however, that the local well which, as is usual in such cases, was not far from the privy, had somehow got infected, had conveyed the disease to the milk, through washing of the pails or otherwise, and had thus infected in turn not only those in the McKnight district served with the milk, but also the farmer's son, who might have got the disease either in this way or directly from drinking the water of the well, his parents, who were beyond the most susceptible age, having escaped. Much perplexed, we therefore took samples from the farmer's well for chemical and bacteriological examination in the laboratories of the State Board of Health in Boston. Bacteriologically the water proved to be unobjectionable, and chemically showed an excellent purification.

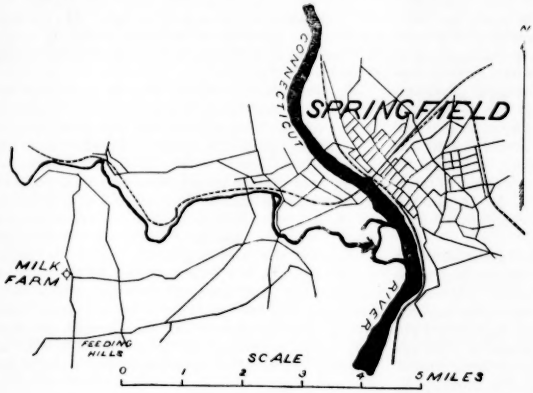
The inquiry was interrupted by the enforced absence of one of us, but was resumed on August 19th.

The samples from the farmer's well in Agawam having shown no evidence whatever of infection, the problem seemed as puzzling as ever, when we were suddenly put upon what proved to be the right track by information showing that we had been grossly deceived by the milkman, and that in truth the Agawam milk was not the milk regularly served to the infected houses in the McKnight district.

It has been stated above that the milkman took one of us (W. H. C.) to all of the farms from which the milk that he sold "on the hill" came, *except one*. We have since discovered that the milkman, probably in pursuit of a well-formed plan, took pains to drive the city physician first to the farms remotest from the one really to blame, and then to others in succession, until the latter grew weary of the apparently fruitless visitation of excellent farms. At last the milkman remarked to him that there was still one farm lying far to the westward and much out of the way homewards, from which he got some milk; but that "Dr. H. had been out there, and everything was all right." In the belief that this was true, the milk theory, which up to that time had had no better basis than any other, was abandoned by W. H. C.

We now learned, however, that the latter had been deceived, and that the milkman, before the public had become very seriously alarmed, had told Dr. H., who was his family physician, that the milk which he was serving to the infected houses in the McKnight district was coming from the one farm to which he did not take the city physician on his round of inspection; and thus we had positive proof both of his duplicity and of the true source of the infected milk. We therefore immediately proceeded to the farm in question, which was located in Feeding Hills, and were rewarded by the discovery that upon this farm there had been one, and probably more than one, case of typhoid fever several weeks earlier. The location of this farm, which we have every reason to believe was the source of the disease in Springfield, is shown upon the accompanying figure (see next page).

The farm was owned by a well-to-do farmer, who raised, among other things, tobacco, and kept a dairy. By inquiry we found that the farmer's daughter had had in the spring a case of "bilious typhoid fever." There was also a history of others upon the place "obliged to go to bed with slow fever," and it only remained to trace some possible connection between these cases and the infected milk. This we did not succeed in doing to our entire satisfaction, but we did find two possible avenues of contamination.



Most producers of milk for sale in cities cool the milk by allowing the cans freshly filled to stand in "coolers," surrounded by ice or iced water. In the present case the farmer had no ice, and therefore was in the habit of lowering the cans by means of ropes into a well adjoining the cow-yard. But unlike some of his neighbors, who hung cans in their wells just above the water level, this farmer *submerged* his cans, and allowed them to rest upon the bottom of the well, so that they were covered by from two to four feet of water. Here the morning's milk stood all day and into the evening, the evening's milk remaining if at all only a very short time before all was "collected" and carted off to arrive in Springfield, some six miles away, about midnight or a little later, being distributed at

dawn, by the milkman referred to above (F. D. K.), to the consumers in the McKnight district.

At the time of our first visit to the farm we discovered the cans of morning's milk quietly reposing entirely out of sight on the bottom of the well. This was in most respects an ordinary dug well, but of unusually large diameter. It was covered with a platform of old and badly worn planks loosely laid on, and with rounded edges bordering on wide cracks. To allow the cans to be sunk and lifted, the planks were loose and separate. The cans were lifted by worn ropes, each of which ran through a hole in a plank and ended above in a large knot. On one side of the well was a chain pump, the spout of which overhung the platform, so that careless pumping easily washed matters on the planks near by through the wide cracks into the well. On the planks lay lumps of manure evidently left there by the dirty boots of the men. A little pumping proved that these were easily washed into the well; and, indeed, ordinary stepping about upon the planks to handle the milk cans or to pump must have cleaned the boots of the men at the expense of the water in the well.

On lifting the cans, on one of our visits, we found, by drawing them up and inverting them, that out of nine four leaked milk around the wooden stoppers with which they seemed securely plugged. Moreover, not one of them was *completely* full. On shaking the cans, the splashing of the milk inside was plainly heard. It was clear that if milk would leak out when the cans were inverted in the air, water would leak in when the same cans were submerged under water. Thus by submersion the milk was not only cooled in temperature but to some extent augmented in volume. The well water was plainly dirty, and bacterial analysis showed it to contain *B. coli communis* in abundance, a form which testifies to the presence of fæcal contamination, at least of animal origin. There was no question in this case of pails or cans washed in infected water, for the former were washed in the house in mountain tap water, and the latter were steamed in Springfield.

This well, however, was at some distance from the house, and not used there for drinking. It was easy to see how, if the well were contaminated, the milk sunk in it might have become so. But how could the well have been connected with the cases in the house? A plausible hypothesis was the following: the excreta of the patients went into the privy, and there is reason to believe that they were not disinfected. The contents of the privy, shortly before the infection reached Springfield, were spread upon the tobacco field. From this field the workmen frequently passed to the well to get water and to work about the milk. It is not difficult to believe that in doing so they may have carried upon their boots masses of fæces, originally from the privy, from the field to the well into which pieces fell through the cracks while the men trod upon the irregular planking. Whether or not this theory is true we shall probably never learn. An alternative hypothesis, moreover, remains. Upon most farms of this sort the "help" is constantly changing. Hired men only a few grades better than tramps come and go. There was a history of much of this kind in the present case, and it may easily have been that some such person acting for the time being as milkman was suffering from incipient or "walking" typhoid fever. In such a case a self-infection of the fingers, such as can only too easily happen, may have led to a heavy infection of the warm milk, such as must have existed in the milk which was served by F. D. K. to the McKnight district in Springfield.

The milkman (F. D. K) for a time maintained with bold assurance that the milk from this particular farm had never gone to the infected houses; and therefore, in order to have independent evidence, we undertook a minute and systematic study of the somewhat intricate system of milk-supply in Springfield. The problem was complicated by the fact that this particular milkman delivered from two separate wagons, and loaded these with milk from several dairies at two distinct points. But after many vexatious researches, including a visit by one of us (W. H. C.) to all of the dairies selling him milk, for the sake of obtaining documentary and statistical evidence of the dates and amounts of milk supplied by the several farms, delivered by the carriers and loaded upon each of his wagons, with the time of starting and the route of each, as well as the actual purchases of his wholesale customers, to whom he now affirmed that all of the Feeding Hills milk had always gone (thus contradicting flatly his original statement to Dr. H.); after interviewing his assistant, or "striker," who had delivered the milk; after having had the aid, also, of the able inspector of the Board, Mr. McCaffrey, — we at last obtained positive evidence from wholly independent data that the milk which went to the infected houses must have come, beyond a peradventure, from the farm in Feeding Hills. In all of this we were very greatly aided by the officers of the Springfield Co-operative Milk Association, who courteously gave us access to their books, and in many ways afforded us invaluable assistance.

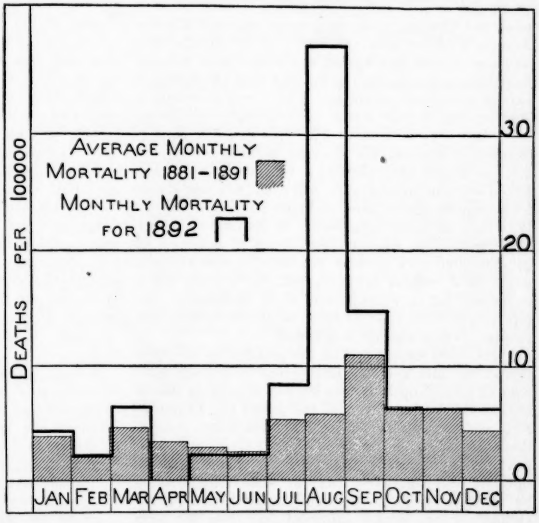
It now remains to describe somewhat more fully the

epidemic itself. It must not be forgotten that many other milkmen besides the one concerned served other houses in this district, which is thickly settled, but in none of these was there any fever. The correspondence of the cases of typhoid fever with their milk-supply is plain, although, as would be expected, some houses served by this milkman had no fever. There is good reason to believe that the infected milk was not the only kind that he carried, and that a different milk was sometimes delivered, for example, in the Ingersoll Grove district.

It will be observed that there were a few cases of typhoid fever in other parts of the city. A very few of these were imported. Of the others, those on Tenth and Essex Streets deserve special comment. After the milkman became alarmed, he is known to have refused, for a time, to take milk from the dairy in question. We have positive evidence that milk from this dairy afterwards went to Essex Street; and that here, also, the fever appeared, is one of the strongest links in our chain of intrinsic evidence. Similarly, seven cases of typhoid fever suddenly appeared about August 20th, in an hotel in the heart of the city; and while no positive evidence was found that milk from the infected dairy went to this hotel, we did discover that, at the time when this milk was under a cloud and was held by the Association, one can of reserved milk (ten quarts) was sold by them to that hotel, that this was an unusual occurrence, and at the very time required to have conveyed the disease to the hotel. As for the rest of the city, it was throughout the epidemic period almost wholly free from typhoid fever. The annual autumnal wave had not yet begun to rise.

The whole number of cases discovered and investigated was one hundred and fifty, and the whole number of deaths belonging to the epidemic was twenty-five. The intensity of the epidemic may be seen upon the accompanying diagram of monthly mortality from typhoid fever, which shows well also the limits of the epidemic period. A study of the death-rate from typhoid fever in Springfield, by months for the twelve years, 1881–92, shows a marked improvement since 1883, and an enormous excess in August, 1892, at the height of the epidemic. The death-rate from typhoid fever during this month was by far the highest during any month of the entire twelve-year period.

Out of the whole number of cases, one hundred and fifty, one hundred and one had milk sold by the same milkman (F. D. K.), while one hundred and thirty-five may have had access to the same milk.



For aid in the preparation of the map and diagram, we are indebted to Mr. R. D. Chase.

A LONDON surgeon recently completing a laparotomy, gave his needle a flourish that took out the lens from the eye of an unfortunate assistant.

AN INVESTIGATION OF AN EPIDEMIC OF TYPHOID FEVER IN SOMERVILLE, MASSACHUSETTS, DUE TO INFECTED MILK.[1]

BY WILLIAM T. SEDGWICK, PH.D.,
Biologist of the State Board of Health of Massachusetts.

TOWARDS the end of August, 1892, the attention of the Somerville Board of Health was drawn to a sudden and nearly simultaneous appearance of a number of cases of typhoid fever. The physicians reported the cases with commendable promptness, ten having been reported on August 23d alone, and an inquiry set on foot by the local Board of Health immediately revealed the fact that most, if not all, of the cases were served by one and the same milkman. Thereupon the Somerville Board reported the outbreak to the State Board of Health, and I was instructed to make an investigation. In view of recent experience in the Springfield epidemic, described in a previous paper, which I was still studying, I was able to work rapidly, and began by verifying the data already in hand. It afterwards appeared that during the three weeks, August 20th to September 10th there were in the entire city of Somerville thirty-five (35) cases of typhoid fever. Of these one was imported, one was plainly a secondary case, a third was a very old case tardily reported. Thirty-two (32) cases were apparently primary and indigenous and remained to be accounted for. Thirty (30) of these had been served with, or had had access to, milk supplied by one and the same milkman. Of the other two cases, one was an old case of which the diagnosis was uncertain, though there was also a possibility that it was itself secondary to an earlier one; the other was synchronous with the epidemic period, and was that of a young woman who was in the habit of buying milk at

[1] From the forthcoming Report of the State Board of Health of Massachusetts, for 1892.

a certain bakery. A bakery next door to the one from which she was in the habit of buying milk was supplied with milk by this particular milkman, and the keeper of this bakery and her daughter were among the persons who suffered from typhoid fever. I could not get the young woman or her mother to admit that they had ever been in the nearer bakery which had the suspected milk; but as they had to pass it to get to their regular bakery, I cannot keep feeling that on some unusual occasion some member of the family had perhaps stepped into the nearer bakery and got some milk. This case coincided in time with the rest; but in view of the evidence I have considered it an unexplained case.

The usual theories of water infection, sewer emanations, etc., were advanced by some to account for the outbreak, but were all easily disproved. The city of Somerville uses the "Mystic" water-supply of the city of Boston, and this supply is not altogether unobjectionable but, inasmuch as the same supply served the whole city as well as the neighboring cities of Charlestown and Chelsea, while the present outbreak was confined to a limited area, the theory of wholesale water infection was easily disposed of. The region most affected was a fine portion of the city with the houses in excellent sanitary condition. There was no reason to suppose that the air, water, ice or sewers were worse here than anywhere else. The only common bond of connection between the infected families which was not also shared by thousands of others who were uninfected was the milk-supply; and even this was shared by a large number of families in one portion of the city in which no fever appeared. It became necessary, therefore, before adopting the theory of infection by contaminated milk to show not only (1) how the milk might have become contaminated, but also (2) how it happened that only one portion of the milkman's route was affected with typhoid fever, while another and important portion was not so affected.

I addressed myself first to the problem of the infection of the milk, and after having interviewed the milkman at great length for the sake of mastering the details of his business, visited the farms (in Littleton) from which the milk was said to have come. All of these proved to be free from typhoid fever, and to be examples of unusually decent dairies. From Littleton the milk was sent once a day to Somerville, arriving by train early in the forenoon at the Union Square station. I was further informed that from this point it was carried in a wagon, still in the cans used for shipment, holding eight and one-half quarts each, to a kind of barn called the "milk house" near the residence of the milkman. I was also told that in the milk house the milk was "mixed" by being poured from the large cans into the mixer, a capacious upright metal tank provided at the bottom with a faucet. After mixing (to produce an even grade) the milk was drawn off into the small cans supplied to consumers, these being next stoppered with wooden plugs and finally set away in the ice box, where they were "iced" and stored until early the next morning. At daybreak or earlier these small cans were delivered to the consumers by means of two wagons, each having a special route and a special series of customers. Inquiry showed that in proportion to the number of takers the cases were about equally distributed upon the two routes, which indicated that the infection must have existed in the mixer or in the cans, or possibly in both. The milkman-in-chief had two sons, one of whom was lying dead of typhoid fever when I first arrived on the spot. The date of the report of his case, however, agreed closely with that of the other sufferers from the disease, and he was also said to have been a great drinker of milk, so that he appeared to be simply a sharer in the common calamity. This son (W. B.), I was told, drove one of the wagons and worked in the milk house, but never handled the milk. It was his duty merely to wash the cans, while his brother, who drove the other wagon, "handled" the milk. This brother was not attacked by the disease.

Thus far it appeared that the milk had unquestionably arrived in the city uninfected, and had been carried in the unopened cans directly to the milk house, still uninfected; but when it left the milk house in other cans, some of it, at least, must have been infected. There was but one logical conclusion, namely, that it had somehow got infected in the milk house. I therefore investigated more closely the case of the son (W. B.) who had just died of typhoid fever, and was rewarded by the discovery that, although his case had indeed been promptly reported by his attending physician, and thus apparently belonged with the rest, it was in reality much older than the others, and dated from a time early enough to allow him to have contaminated the milk, and thus to have been the unfortunate cause of the whole trouble. This young man had first consulted another physician, who had failed to inform him of the true character of his disease, and, instead of putting him to bed, had allowed him to keep on with his work until finally the fever affected him so seriously that he could hardly keep his seat on his wagon, and at last, in desperation, consulted a competent physician. Then, and not before, his case was recognized and reported, and he was sent to bed; but so far was the disease advanced that the next day he had one intestinal hæmorrhage, followed before long by others of great severity; and very soon after he died.

It is plain that this young man worked in the milk house about, if not at and over, the milk, until he was in an advanced stage of the disease. It was denied by his father and brother that he ever "handled," or, as the phrase is, "set up," the milk, that is, transferred it from the large cans to the "mixer" and then to the little (consumer's) cans. It was alleged that his office in the milk house was simply to wash the cans, never to set up the milk. This point was urged upon me with eagerness and persistence, as fatal to my theory; but without discrediting the honesty of the affirmation, I cannot readily believe from what I have seen and learned of the milk trade, milkmen, milk houses, etc., that a division of labor really existed in this case so complete as would be required to exclude all possibility of infection of the milk by a sick man working within a few feet of the "setting-up" process, and doubtless ready and willing to lend a hand. I do not believe that, when two men are working day after day over milk in one room, one man always and without exception washes cans, while the other always and without exception puts milk into cans.

As to the precise way in which such a person might contaminate the milk there is no difficulty, even if he were only a washer of the cans. If such a person, in the early stages of the disease, affected with diarrhœa, should merely fail to wash his hands on returning from the privy and should then proceed to wash cans or to

help in emptying the cans into the "mixer," particles upon his fingers might drop or be brushed or washed off into the milk. That many people do habitually omit to wash their hands under similar circumstances is a fact.

In spite of these important discoveries, there still remained for some time a very serious objection to the theory that the milk had really been contaminated at the milk house. In the vicinity of Union Square and also to the east and west of this region the same set of milkmen delivered a considerable quantity of milk and served a large number of customers. Here, however, there had been no typhoid fever. I was myself much puzzled by these facts from the start and the milkman-in-chief lost no opportunity of urging them upon my attention as an insuperable objection to the milk-infection theory. At last, however, in the over-eagerness of his affirmations, he himself afforded the clew which enabled me to solve the whole difficulty. In reiterating the importance of the absence of cases upon that portion of the route near Union Square, and saying that more of the milk went thereabouts than on the hill (where the cases had occurred), he added that he knew this because he "always waited around after the train came and gave the boys several cans off the wagon" which they sold directly to the uninfected districts. Immediately everything became plain. These districts had evidently not been infected, *because they had not usually had milk from the milk house*, but had been served with fresh milk just in from Littleton. Probably only enough was taken from the train each day to serve these customers and those upon the hill who would not wait for the train to arrive next day. No more would be carried over than was necessary, because if the supply ran low more could be got in time for use, next day; and milk in August does not keep well. This milkman's route extended over the line into Cambridge, in which city he served three families. I was interested to find in one of these, a case of typhoid fever synchronous with those in Somerville. There was no other case in Cambridge anywhere near this point at that time.

One of the most interesting features of the epidemic was the indication which it afforded that in the very early, and possibly even in the early prodromal, period of typhoid fever the patient must have been discharging the germs of the disease. His case was believed by two thoroughly competent physicians who saw him, to have been well on "in the third week," on August 28th. His first hæmorrhage, so far as is known, was on the 29th, and he died September 6th. The cases first began to appear on the 16th, on which day physicians were called to five cases in Somerville; and seventeen out of the whole number of cases had their first visit from the physician on this day or one of the four following. Previous to this there had been only one case in Somerville since August 5th. It would appear from a consideration of the epidemic itself, that the milk must have been most heavily infected between the 1st and the 10th of August; and we have every reason to believe that at this time one of the milkmen was in the early stages of the disease. This is the more interesting because the great epidemics in Lowell and Lawrence in 1890–91 were apparently due to excreta thrown off in the early stage of the disease, before the patients took to their beds. The same thing was true of the epidemic in 1892 in Chicopee Falls, and also of the important epidemic in Red Hill and Caterham (Eng.) in 1879. In the present case I was told by his father that the young man had not been able to do anything at the milk house "for a week or so" before he ceased to deliver milk and went to bed; that is, not after about August 20th. The last case had its first visit from the physician on September 3d, or exactly two weeks afterwards. In other words, after this young man no longer visited the milk house the epidemic ceased. Later in September there were one or two more cases of typhoid fever in Somerville, but they proved on investigation to have been imported, having obviously contracted the disease elsewhere.

My thanks are due to several of the physicians of Somerville for their valuable assistance, especially to Medical Examiner Dr. T. M. Durell and Dr. William A. Bell.

Clinical Department.

SOME ABDOMINAL OPERATIONS.[1]

BY MAURICE H. RICHARDSON, M.D.

TUBERCULOUS STRICTURE OF THE INTESTINE.

I REMOVED a few days ago from a girl of twenty-two, at the New England Hospital for Women and Children, an unusual and interesting specimen of tuberculous stricture of the intestine. As one of the consulting surgeons, I was asked by Dr. Keller to see this patient, and, if thought advisable, to operate. The chief symptom was abdominal pain coming in violent paroxysms without apparent cause, accompanied by loud gurgling. There was great emaciation and weakness. Obstruction was not complete. Although I have seen cancer of the intestine at this early age, I eliminated malignant stricture in the differential diagnosis because of the strong tuberculous taint in the immediate family of the girl. I was prepared to resect the gut under favorable conditions, but expected to be limited to inguinal colostomy, postponing the more radical treatment until she could regain her strength. The local conditions were so favorable, however, that I performed immediate excision. The stricture was in the lower portion of the ileum, and was situated between the umbilicus and the anterior superior iliac spine. One or two enlarged mesenteric glands near the seat of disease were not removed.

Resection was rapidly performed. The joint by the interrupted Lembert silk stitch was unusually satisfactory. The line of suture was protected by gauze packing. The patient died in three days, without any evidence of peritonitis. Abundant evacuations followed almost immediately upon the operation.

I think it would have been better to relieve by colostomy the obstruction, and to wait till the increased strength of the patient should justify resection.

The specimen shows a great thickening of the intestinal walls, with dilatation, above the constriction; below, the bowel is collapsed and its walls are comparatively thin. The lumen at the point of constriction is hardly large enough to admit a probe. The bowel above was much distended by thin, yeasty fæces, which were being constantly churned up by the intestinal paroxysms. The only difficulty in suturing was caused by the great difference in the diameters of the cut ends.

[1] Remarks made before the Boston Society for Medical Improvement at its regular meeting Monday, May 22, 1892.

This is a serious disadvantage in the immediate operation; nevertheless, with care, a very satisfactory joint can be made.

GANGRENOUS AND PERFORATED VERMIFORM APPENDIX.

At the last meeting of this Society I showed a gangrenous vermiform appendix nearly as large as the small intestine. The patient has made a good recovery. I have operated since that meeting in three other cases, with one death. In the fatal case, the abdomen was opened as a forlorn hope in a general peritonitis. Death took place in twelve hours. In this case, after the first attack, a year ago, the question of operation was considered. Almost before the patient's condition could be realized, in the second attack, a general septic peritonitis had developed, with vomiting and hiccough. Had I not seen at least one such case recover, I should have declined to operate. At such times operations offer so little hope that the question arises whether a surgeon does not owe something to his art and to his own reputation; and whether his duty requires him to interfere under conditions practically hopeless. After a long and varied experience in these frightful emergencies, I believe that the recoveries which occasionally result from operations undertaken in desperate cases justify the attempt in all where death is not absolutely certain; that interference is demanded in the strongest terms, and that the effect of the probable result upon the surgeon's reputation and upon the art of surgery is unworthy of serious consideration. The brilliant recoveries, though very rare, outweigh the harm, especially in a disease like appendicitis, which the lay mind looks upon as necessarily fatal if left to itself.

In another case a gangrenous and perforated vermiform appendix was situated behind the cæcum in a sac of healthy peritoneum, not shut off by old adhesions. The appendix was shelled out by passing the finger from the brim of the pelvis underneath the cæcum towards the kidney. The perforation was found at the tip, and under the gangrenous patch was the usual fæcal concretion. In this case pus could escape only by perforating the cæcum or by breaking into the peritoneal cavity. There was a possible route towards the right flank. Drainage in these cases seems to me always exceedingly dangerous — an opinion borne out by not infrequent fatal results, whether the case be treated surgically or left to itself.

I have taken the time of the Society to show this specimen and to comment upon the case because I do not agree with the views recently expressed by several writers, that the surgery of appendicitis is being carried too far. As one of those who see the most of this formidable disease, while not as yet accepting any fixed rules of procedure — certainly not that of always operating — I cannot but be sorry to see the let-alone treatment encouraged, especially as this method is the one most agreeable to general practitioners. An enormous amount of good has been done in the past eight years by the agitation of this subject. Any relaxation of our efforts in this direction, particularly that sanctioned by high authority, is in my opinion to be regretted.

EMERGENCY HOSPITAL AT WORLD'S FAIR.—There were treated at this hospital 18,500 cases, and there were 23 deaths at the institution.

FURTHER EXPERIENCE IN THE USE OF CHLORALOSE.

BY F. GORDON MORRILL, M.D.,
Visiting Physician, Boston Children's Hospital.

A CONSIDERABLE experience has convinced me that in "chloralose" we possess an hypnotic of great value. I have prescribed it in twenty cases of insomnia, with good results in almost every instance — exceptions to be noted a little further on. Properly used in cases *uncomplicated by hysteria or alcoholism* (I have had no experience with the drug in locomotor ataxia, sonambulism or pulmonary phthisis, the presence of either of which conditions is considered unfavorable to its action), it has appeared to me to justify the claims of its discoverers: that it is safe, produces no "habit," does not require a progressive increase of dose, and is reliable in its action, that is, produces refreshing sleep attended by no disagreeable after-effects. In simple insomnia it certainly acts "like a charm," and is destined, I think, to replace chloralamid, than which drug it is more reliable.

A case which particularly impressed me was that of an old man with organic heart-trouble, whose nights were rendered wretched by dyspnœa, palpitation and fear of sudden death. A fairly large dose gave complete relief every night during the six weeks which he survived after my first visit.

In the case of an elderly lady with whom other hypnotics had failed, and who, in her desperation, had formed the habit of obtaining sleep by taking a tumblerful of whiskey at bedtime, chloralose gave quiet and refreshing nights, and eventually enabled her to conquer a most obstinate insomnia of long standing. In this instance it was necessary to abandon the whiskey and pass several sleepless nights before taking the remedy, as alcohol is distinctly unfavorable to the action of chloralose.

A young married woman, whose inability to sleep was due to her anxiety concerning the health of her only child, took chloralose in a fairly large dose (six grains), and after a good night's sleep suffered from marked inco-ordination of motion for an hour after rising. The same effects followed a repetition of the dose, and the medicine was discontinued. A distinctly hysterical attack which occurred a day or two later furnished an explanation of the disagreeable after-symptoms.

In somewhat the same category may be placed the case of an old gentleman with an enormous prostate and a very irritable bladder, whose complaints of suffering always increased to a marked degree in the presence of a certain member of his family. Here six grains of the drug produced a very peculiar effect, for after three hours of quiet sleep he awoke delirious, and tried hard to get out of bed. Being restrained from this, he crawled about the bed for an hour, and then went quietly to sleep, expressing great satisfaction next morning for so quiet and restful a night — evidently having no recollection of the alarm he had caused his attendants. The chloralose was afterwards resumed in divided dose (the second cachet of three grains being given when the effects of the first had passed), and the result was far more satisfactory than that obtained by full doses of chloralamid, which had been given as a substitute in the interval.

A fuller appreciation of mental characteristics would have led, in the lady's case, to refraining altogether

from exhibiting chloralose, and in the last-mentioned instance the divided dose only should have been given.

A brief analysis of Goldenberg's thesis (Paris, 1893) shows sixty-four cases in which the drug was used. Of the fourteen failures, eleven were cases of women. Five of them were hysterical subjects; two were alcoholics; one suffered from severe gouty pains; one was a consumptive: and one had pulmonary emphysema and a secondary heart. The cause of failure in the eleventh case is not mentioned. Three were male cases, with locomotor ataxia, paralysis agitans and nocturnal syphilitic pains respectively.

The best method of administration appears to be to give a cachet containing three grains (those made here are more convenient to swallow than the imported) an hour before sleeping-time, and repeat promptly when the time is up if no effects are obtained. In case insufficient sleep follows the first dose, it is repeated when the patient awakes. The largest dose I have given in a single night was twelve grains. As a rule, it may be assumed that three grains (repeated as above in some cases) will insure from five to nine hours of refreshing sleep in any case of insomnia which cannot be readily classed among the exceptions which resist the action of the drug. The results which I have thus far obtained certainly encourage me to persevere in giving this new hypnotic a more thorough trial. It is as certain in its action as chloral, and far safer; as harmless as chloralamid, and far surer, so far as I have been able to observe.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Concluded from No. 19, page 468.)

SUTURE AFTER LAPAROTOMY.

HOWITZ,[13] of Copenhagen, at the recent Surgical Congress held at Gothenburg, discussed the comparative value of the methods and kinds of sutures which are used after laparotomy. According to him the abdominal hernia which occasionally occur after operation are dependent upon the manner in which the sutures are applied. Three factors determine the strength of the cicatrix: (1) The nature of the uniting surfaces; (2) the manner in which they are held together, and (3) the kind of suture used. As regards (1) the incision in the linea alba is not advantageous, since the conditions required for the formation of a sound scar are not present. In order to form a strong cicatrix the opposing surfaces of the incision must be fairly extensive and smooth, they should contain only a small amount of fat, and should be in apposition without much tension. In order to secure this condition of affairs the author advises that the incision should be made about two-thirds of an inch from the middle line, passing through the substance of the rectus muscle. As regards the method of suturing, he recommends the twisted suture, such as is used for harelip. In applying the suture a slightly curved needle is used, and only a small amount of peritoneum included in the suture. The sutures are made from silkworm gut. After the operation the patient is kept in bed for three or four weeks, so as to allow the scar to become firm.

[13] Sem. Med., July 12, 1893; British Medical Journal, August 12, 1893, p. 25.

THE INDICATIONS FOR LAPAROTOMY IN ACUTE INTESTINAL OBSTRUCTION.

Schlange[14] has successfully removed by primary resection 135 cm. of intestine. The laparotomy and resection was done to relieve intestinal obstruction. In discussing the indications for operation he divides these cases into three classes: (1) When there is abdominal distention and peristaltic motion exists (hence no general peritonitis since this paralyzes the intestine) with sudden onset, or symptoms quite persistent, the case is probably one due to local trouble and one should operate. (2) With marked tympanites and no peristalsis (paralysis, general peritonitis) operation only hastens death. The most one is justified in doing is to rapidly make an artificial anus. (3) When a limited portion of the intestine is affected while the rest is normal, this section becomes greatly distended, is paralyzed. The symptoms are always violent. The patient's strength decreases rapidly. There is not diffuse peritonitis. Here laparotomy performed early is the only chance for the patient's life.

FAT EMBOLISM FROM FORCIBLE CORRECTION OF JOINT DEFORMITIES.

Fritz Colley,[15] of Marburg, has reported a case where death followed fourteen hours after a forcible straightening of both knees, with symptoms of pulmonary œdema. The patient was twenty-six years of age. The clinical diagnosis was death from fat embolism. The autopsy confirmed this. The case differs from the usual cases of fat embolism in that without any bony lesion, the rupture of the cicatricial attachment to the femur of a fatty degenerated muscle allowed enough fat to enter the circulation to cause death. Also, that as a result of the filling of the heart capillaries with fat caused such an impediment to its proper nutrition that within fourteen hours acute fatty changes were produced. These conditions would suggest that *brisement forcé* is not free from danger as it has formerly been considered. That it becomes a serious operation when a muscle which has become atrophied and fatty degenerated from disease, is torn or a bone showing conditions of fatty osteoporosis is fractured.

DIAGNOSTIC AND THERAPEUTIC VALUE OF PUNCTURE OF THE SPINAL CANAL.

Pritchard[16] has published an interesting abstract of V. Ziemssen's article on this subject. The method of Quincke, of Kiel, which was first used for the purpose of decreasing the pressure in hydrocephalus, was used by Ziemssen in several cases of tuberculous cerebro-spinal meningitis, brain tumors, etc. The spine is flexed to increase the interspace between the vertebral arches. The patient is anæsthetized. The fluid escapes with a rapidity proportionate to the pressure. The cerebral pressure was diminished by the operation. A case of tubercular meningitis was improved under this treatment. Quincke after operating twenty-two times found that the fluid reaccumulated rapidly. He found that hydrocephalic fluid contained less than 1% of albumen. Above 1% indicates that an inflammatory process is probable. Above 2% is sometimes found in tubercular exudations. He thinks puncture

[14] Berlin. Klin. Woch., 1892, No. 47.
[15] Deutsche. Zeitschr. f. Chir. 1893, xxxvi, p. 322.
[16] Annals of Surgery, 1893, vol. xviii, 235.

is indicated in acute exudations of tuberculous or serous nature. To prevent a reaccumulation of fluid he slits the dura so as to permit continual drainage into the surrounding tissues. Ewald, of Berlin, found puncture caused only temporary improvement.

THE CLINICAL COURSE, DIAGNOSIS AND STRUCTURE OF DUCT CANCERS OR VILLOUS CARCINOMAS OF THE BREAST.

Anthony Bowlby [17] has contributed a valuable paper upon this subject, and his conclusions are as follows:

"(1) In a considerable proportion of the cases there is at some time a discharge of fluid from the nipple, and this discharge may precede the development of any tumor perceptible to the patient for a period of even several years. The growths are, however, not associated with so-called eczema of the nipple, or Paget's disease.

"(2) The patients are mostly over middle-age.

"(3) The axillary glands are not usually affected.

"(4) The tumors are not of very rapid growth.

"(5) Neither the nipple nor the skin is usually retracted, but the growths are commonly situated near to the nipple.

"(6) The tumors are occasionally multiple in the same breast, and are firm and elastic, or else shotty and knotted to the touch rather than hard and nodular like a scirrhous carcinoma.

"(7) On section, the growths are seen to be encysted, and are generally darkly blood-stained, soft and friable. Sometimes they are of a lighter color, and grayish and granular on the surface. Some of the cysts are almost filled with solid growths, others contain little but blood-clot and serum. It can often be plainly seen with the naked eye that some of the cysts are formed by dilated ducts, and the solid growth can often be seen springing from the lining membrane of the latter. The cysts and the growth may be situated either in the gland or in the surrounding fat. Occasionally, the tumor may protrude through one of the dilated ducts on the summit of the nipple.

"(8) The tumors are liable to recur locally, but are not nearly so prone to affect the lymphatic glands or to disseminate as are the spheroidal-celled scirrhous carcinomas. If attention be paid to these points, I think no difficulty will be found in diagnosing these tumors from scirrhous carcinomas. Sometimes there is difficulty in separating them clinically from the cystic sarcomas.

"With regard to this the following points are worthy of attention: Duct cancers occur frequently in old women, in whom the growth of cystic sarcoma is relatively uncommon; they do not attain so large a size, nor do they grow so rapidly as do the cystic sarcomas; the cysts they form are usually much smaller than are the cysts in the latter class of growth; the discharge from the nipple is usually much more blood-stained."

THE PREVENTION OF SHORTENING AND OTHER FORMS OF MAL-UNION AFTER FRACTURE.

Keetley [18] has contributed an interesting paper upon this subject. He uses steel pins to secure the ends of the fragments of a divided bone, and the details of the method he has used are as follows:

"The instruments required are: (1) two L-shaped pins of hardened steel thickly plated with silver; (2) the patella instruments described by me in the *Lancet* for December 10, 1892, or at least the long-bladed brad-awl; (3) a pointed tenotomy knife; and (4) a flat sand-pillow. Each L-shaped pin consists of course of two arms, one cylindrical, the other flattened in a plane at right angle to the rounded arm. The cylindrical arm is seven millimetres in circumference, and has a rounded blunt point. The length is three and a half inches, that is, nearly nine centimetres. The flattened arm of one pin is three inches long, that of other being five inches. Both are one-fourth of an inch wide, about one-tenth of an inch thick, and there are notches at the edges at intervals of one-fourth of an inch. The patella brad-awl has, it may be mentioned, a blade three and one-half inches long, and both its blade and its handle are of one smooth piece of nickelled steel, the handle being made hollow for lightness.

"*Operation.* — Stringent antiseptic precautions must be used, and they are particularly easy in an operation like this, where the open wound is a puncture and nothing enters it except two or three straight and smooth pieces of plated steel. This easiness is no excuse for carelessness — it only makes neglect inexcusable. The following are the details of the operation:

"(1) Reduce the fracture under ether, breaking it down again if union has taken place recently in a bad position.

"(2) While two assistants make extension and counter-extension, adjust the fractured ends and try to ascertain the precise seat and place of fracture. Select a point in each fragment likely to be clear of the fracture, and in such a position that a straight line from it transversely perforating the bone would keep well clear of important vessels and nerves, synovial membranes, etc. In both my two cases I have been surprised to find how far it was necessary to go from the fracture in order to find a firm place in the lower fragment. The two points selected should lie as nearly as possible above one another, and not in a spiral line circling the limb.

"(3) Puncture the skin, push the brad-awl through the puncture down to the bone, use it very gently as a probe to define the position of the bone, and then bore steadily through. Take care not to break the long blade and not to perforate obliquely.

"(4) Slip the director along the awl. If the handle of the latter is in the way bend the former a little and have the skin pressed down on the bone.

"(5) Withdraw the awl, twisting and not jerking it out; keep the director carefully in position.

"(6) Pass in one of the pins through the bone and withdraw the director. Repeat 3, 4, 5 and 6 in the case of the upper fragment. Take care to bore both fragments in the same longitudinal plane.

"(7) The two pins being now in the bone, turn them into such a position that the flat arm of one lies upon, and touches the flat arm of the other. If the arms are to remain less than five inches apart the long-armed pin must lie over the other. The advantage of making the flat arms of different lengths will now be seen. The pins can be thereby fixed at any distance from two to six inches apart.

"(8) Full extension being made, and the limit demonstrated by measurement to be of proper length, lash the flat arms of the pins together with silver wire pulled taut and twisted home at the ends. See that

[17] Lancet, June 10, 1892, p. 1369.
[18] Lancet, June 10, 1893, p. 1377.

there is full tension on the pins before fixingt hem, for they have a slight elasticity. If this point is not attended to a quarter of an inch or more may be lost.

Dressings. — Iodoform gauze wrung out in sublimate solution (1 to 2000) should be placed beneath and above the external arms of the pins; the gauze should be flat and not lumpy. Over the gauze a well-rolled wood-wool pad should be placed, and all round the limb at and near the fracture there should be a sheet of absorbent wool. The whole should be bandaged firmly and evenly, firmly enough to prevent any internal extravasation. Lastly, external appliances suitable to the case should be put on. If, as in my first case, the superior fragments tend to ride forward, I use a double splint with transverse iron lips or brackets, and in all cases I should use extension."

He has used them in two cases. In one a boy of thirteen, the use of the pins prevented the slightest shortening. In the other case there was some rusting of the pins, which occasioned superficial suppuration. They were removed on the forty-third day following the operation, and the fifty-third day after the fracture. Firm union resulted without the slightest shortening.

A NEW METHOD OF DIRECT FIXATION OF THE FRAGMENTS IN COMPOUND AND UNUNITED FRACTURES.

After a careful review of all the methods which have been proposed for the direct fixation of fragments, Senn [19] brings forward a method he has devised, which consists of a bone ferrule which is applied in compound fractures. The method of preparation of the bone ferrules is as follows:

"The ferrules are made of different sizes from fresh bone obtained from the slaughter-house or butcher-shop. For the humerus and femur of the adult the femur of an ox should be selected; for children, the same bone of a smaller animal will answer the purpose. For the tibia, the corresponding bone of the animal is chosen. With a sharp saw the shaft of the bone is cut transversely, the length of the sections corresponding with the desired width of the ferrule, which will vary from a quarter of an inch to an inch. With a round file the medullar canal is enlarged until the thickness of the bone does not exceed one-sixth of an inch; in some instances a much thinner ring will furnish the necessary lateral support. If the ferrule is longer than an inch it should be perforated at a number of points in order to furnish so many avenues through which the products of tissue proliferation and the new blood-vessels can reach the tissues outside of the ferrule, and *vice versa*, and also with the intention of facilitating the absorption of bone after the fracture has become consolidated. Ferrules made of the tibia should retain the shape of the bone in order to adapt their lumen to the treatment of fractures of the tibia. Sterilization is effected by boiling for an hour or more, after which the rings are kept immersed in sublimate alcohol (1 to 1000) ready for use. Future experience may show that partial decalcification of the bone ferrule is an advantage. Should further clinical experience show that the bone is not sufficiently absorbable, such ferrule could be made of chromicized catgut."

The ferrules are applied in the following manner:

"In the treatment of compound fractures the observance of the strictest antiseptic precautions, and in the operative treatment of ununited fractures by this method, rigid aseptic measures must precede and accompany the direct treatment of the fracture. The seat of fracture must be exposed in such a way that both fragments are readily accessible. The ferrule must be large enough so that it can be slipped over the fragments without danger of breaking it. In the majority of cases the use of an anæsthetic is indispensable for the purpose of securing complete muscular relaxation and the necessary immobility of the limb not only until reduction is effected and the ferrule is in place, but until the whole dressing is applied and complete immobility at the seat of fracture has been assured. After the seat of fracture has been freely exposed, the most accessible fragment is isolated from the surrounding tissues with as little disturbance of the periosteum as possible, when the ferrule is slipped over the fragment and is pushed away from the line of fracture far enough to clear the other fragment. After reduction has been accomplished, the second fragment is engaged in the ring, which is then pushed back sufficiently far to grasp both fragments securely.

"A reliable assistant should hold the limb in proper position, as bending at the seat of fracture might break the ring. Hæmorrhage is to be carefully arrested, and if the wound is aseptic the different tissues are separately united by buried sutures. In case of infected fractures, and in fractures accompanied by troublesome oozing, free drainage must be established. Bending at the seat of fracture is prevented and absolute immobilization secured by a circular plaster-of-Paris splint, which can be fenestrated at a point opposite to the wound if the wound has been drained. Harmful pressure is avoided by interposing between the surface of the limb and splint a layer of antiseptic hygroscopic cotton at least an inch in thickness, and localized decubitus is prevented by protecting all bony subcutaneous prominences with special care.

"With a view of securing perfect immobility of the fragments as early as possible, small splints of wood or metal are incorporated in the plaster-of-Paris dressing in such a way as to form an unyielding bridge across the line of fracture, an important matter during the time required for the setting of the plaster. The limb, especially if it is in the lower extremity, should be kept suspended in an elevated position for a number of days, in order to prevent as far as possible the occurrence of œdema at and below the seat of fracture. If the wound has not been drained, and no indications for a change of dressing present themselves, the first dressing should not be disturbed until union between the fragments is sufficiently firm to prevent displacement during the second dressing. In wounds that require drainage, the dressing is changed after two to five days without interrupting the fixation splint. Should suppuration set in, the bone ferrule should not be removed until direct fixation has become unnecessary, when the sinus is enlarged, the ring cut on one side with bone forceps, and fractured on the opposite side by bending, when each half can be extracted separately. Loose fragments of bone are removed at the same time."

He draws the following conclusions:

"(1) Direct fixation of the fragments is indicated in all compound fractures in which perfect retention cannot be secured by simpler measures, and in the treatment of ununited fractures requiring operative interference.

"(2) This method is also justifiable in the treatment of certain forms of subcutaneous fractures, in

[19] Annals of Surgery, August, 1892, p. 125.

which reduction and retention cannot be accomplished without it.

"(3) Free exposure of the fragments in compound fractures secures the most favorable condition for thorough disinfection.

"(4) Perfect reduction and direct fixation of the fragments are the most reliable prophylactic measures against delayed non-union and deformity.

"(5) A compound fracture should be regarded in the same light as an injury of the soft tissues, and should be treated upon the same principles; namely, accurate coaptation of the different anatomical structures, and perfect retention by direct means of fixation, aided by an efficient external support.

"(6) Bone suture, metallic, bone and ivory nails do not furnish the necessary degree of support and immobilization in the direct treatment of fractures characterized by a strong tendency to displacement.

"(7) The solid intra-osseous splint of ivory or bone as advised by Heine, Langenbeck and Bilcher is objectionable because it interferes with the ideal production of the intermediate callus, and its spontaneous removal is beyond the absorptive capacity of the tissues.

"(8) The hollow, perforated ivory or bone cylinder devised by the author, answers the same mechanical purpose without the objections which have been charged against the solid cylinder.

"(9) The safest and most efficient means of direct fixation of oblique fractures is by a bone ferrule, which must be applied in such a manner that it surrounds both fragments.

"(10) Such a circular absorbable direct splint prevents to perfection lateral and longitudinal displacement.

"(11) Rotation of the limb below, and angularity at the seat of fracture, must be prevented by a carefully-applied circular plaster-of-Paris splint.

"(12) For fractures not requiring drainage the entire wound should be closed by buried and superficial sutures, as the bone ferrule is removed by absorption.

"(13) In suppurating wounds the bone ferrule should not be removed until direct fixation has become superfluous by the formation of a sufficiently firm union between the fragments.

"(14) The external splint should be applied in such a manner that it does not require a change throughout the entire treatment, permitting at the same time access to the wound should this become necessary.

"(15) Direct fixation of a fracture combined with perfect immobilization brings the different anatomical structures of the broken bone permanently into their former normal relations, preparing the way for the early initiation and speedy consummation of an ideal process of repair and the realization of a perfect functional result.

"(16) Should future experience demonstrate that bone is not sufficiently absorbable, the same kind of ferrules can be made of partially decalcified bone or chromicized catgut."

OLD DISLOCATION OF THE HUMERUS TREATED BY OPERATION.

Dr. A. M. Phelps[20] reports a satisfactory result, obtained by this method. The patient was an old man with a dislocation of the left humerus of several months' standing, with firm, bony adhesions. The head of the bone was exposed by an incision, removed and replaced in the glenoid cavity after this had been cleaned of the new-formed material. The patient recovered with fair motion. Dr. Phelps, in view of his experience in this case, considers that this method will give better results than the common practice of forcibly rupturing the adhesions by manipulation, followed by the attempt to reduce as in fresh dislocations.

A MEDICAL STUDENTS' PARADE. — The medical and dental students of Philadelphia had a torchlight parade last week, in which some fifteen hundred men took part.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

TENTH ANNUAL MEETING, NEW YORK, OCTOBER 9, 10, 11 AND 12, 1893.

(Concluded from No. 19, page 472.)

SECOND DAY (WEDNESDAY). — MORNING SESSION.

DR. WILLIAM H. ROBB, of Montgomery County, read a paper entitled,

TREATMENT OFTEN INDICATED AFTER TRACHELORRHAPHY.

The hygienic treatment he considered very important, and mercury and iodide of potassium he had found very useful in unloading the portal circulation and improving the nutrition of the uterus. Chronic endometritis is the most common affection met with, and it is best treated by dilatation, curettage and packing the uterus with iodoform gauze. Imperfect union of the torn surfaces after trachelorrhaphy sometimes results in a chronic enlargement of the uterus.

DR. W. D. GRANGER, of Westchester County, sent a communication on

VOLUNTARY COMMITMENT OF THE INSANE TO ASYLUMS.

He said that the modern idea was to make asylums hospitals in which the treatment might be individualized as much as possible. The law of New York State now permits insane persons to voluntarily commit themselves to family asylums, provided that their mental condition is such that they appreciate what they are doing. They are at liberty to leave the asylum at any time.

DR. GUSTAVUS ELIOT, of New Haven, Conn., read a paper on

THE TREATMENT OF ENTERIC FEVER.

He considered absolute rest of so much importance to the safety of the typhoid fever patient that he advised the physician to withhold his permission for a patient to leave his bed with any fever if there was the slightest doubt as to the diagnosis. The patient with enteric fever should be kept perfectly quiet, both in body and mind, not only during the whole course of the febrile stage, but for at least one week after the morning and evening temperature had reached 99°. The treatment he believed to be the most efficacious was at the beginning to administer seven to ten grains of calomel on alternate days for four doses, and then follow this by giving carbolic acid or iodine in very weak solution. This treatment improves all the symptoms and actually shortens the disease.

DR. GEORGE DOUGLAS, of Chenango, favored the calomel treatment at the outset, but would not give more than two or three doses. He did not approve of the free use of alcoholic stimulants in this disease.

DR. WILLIAM FINDER, of Rensselaer County, said he had unbounded faith in sulpho-carbolate of zinc as an antiseptic and astringent.

DR. JOHN H. MARTIN, of Otsego County, employed very much the same treatment as that described in the paper. He fed his patients well, however, from the outset, and was entirely opposed to the administration of alcohol in typhoid fever.

DR. E. R. SQUIBB explained that the probable benefit derived from the calomel lay in the fact that, when taken into the stomach, calomel is changed into an albuminate, and afterwards slowly converted into the bichloride, which is so well known as an antiseptic. On this account, the calomel should be given dry on the tongue, and on an empty stomach, for, if much diluted, it is not so promptly and thoroughly converted into the albuminate.

AFTERNOON SESSION.

SIR JAMES A. GRANT, of Ottawa, Canada, read a paper entitled

RARE FORMS OF GOUT AND RHEUMATISM,

in which he narrated the history of several cases, among others, one of a young girl who had all the usual symptoms of perityphlitis, until one day the joints of the upper extremities were attacked with acute articular rheumatism, when the abdominal symptoms rapidly subsided. This he was inclined to look upon as a case of rheumatism affecting the intestinal walls. Haig, of London, had reported such cases.

DR. DONALD MCLEAN, of Detroit, in a paper entitled

SURGICAL AND PATHOLOGICAL MEMORANDA,

spoke, among other things, of ununited fractures, and said that an extensive experience with such cases had led him to believe that in a large proportion of cases the cause of the non-union was to be found in excessive violence at the time of the fracture. He showed the aortic compressor which he uses to control hæmorrhage when amputating at the hip-joint, and expressed himself as most decidedly in favor of this method, which he considered even superior to Wyeth's.

DISCUSSION ON THE TREATMENT OF APPENDICITIS.

DR. FREDERIC S. DENNIS, of New York County, opened the discussion, propounding the following questions:

Question 1. — What proportion of cases of appendicitis end in resolution?

Question 2. — What class of cases require immediate operation?

Question 3. — What class of cases do not require immediate operation?

Dr. Dennis said there were several different varieties of inflammation occurring in the region of the cæcum, and it is now generally accepted as a fact that about fifty per cent. of all such cases go on to resolution, and only about eleven per cent. show a tendency to relapse. He did not approve of operative interference in appendicitis except the symptoms are decidedly acute, and remain unabated for forty-eight hours. The operation should not be looked upon lightly; it is by no means easy; the length of the incision makes ventral hernia a very common sequela, and the fact that eminent practitioners frequently err in the diagnosis should make one slow to resort to operation without the best of reasons for so doing.

DR. J. W. S. GOULEY, of New York County, took the same position. He cited several illustrative cases taken from his own experience, to show that many cases presenting urgent symptoms, still recover without operation.

DR. MCLEAN spoke of the perplexing nature of the questions propounded, and the heavy responsibility which they carried with them. He also referred to a

number of cases showing how frequently these inflammations terminate in resolution, and also one as a lesson to those who were inclined to look upon the operation as one of but little gravity.

DR. JOSEPH D. BRYANT, of New York County, said if the fever, tenderness and tympanites continued after three days, and especially if there was rigidity of the rectus muscle, he would advise operation. He considered the presence of this muscular rigidity a more reliable guide than the temperature. He stated that seventy per cent. of all males have a foreign body in the vermiform appendix, while this condition is present in only about forty per cent. of females. As this is about the proportion in which appendicitis affects the two sexes, it would seem that the presence of a foreign body had much to do with the occurrence of the appendicitis. When perforation occurs, the symptoms are usually quite acute, and indicate the need of immediate operation. The "McBurney point" cannot be considered as characteristic of appendicitis, for it has been found in other conditions, and, moreover, no such fixed point can represent approximately the position of the *caput coli*, which is now known to be situated not infrequently down in the pelvis, or high up behind the colon.

DR. WYETH, of New York County, was in favor of an early resort to an exploratory operation, for all the disasters he had seen in this department of surgery had been due to delay. Again, in the early operations, there is less danger of ventral hernia.

THIRD DAY (THURSDAY). — MORNING SESSION.

DR. DOUGLAS AYRES, of Montgomery, read a paper entitled,

THE MALE CATHETER, WITH SOME OBSERVATIONS UPON THE PROPER MODE OF INTRODUCTION INTO THE BLADDER.

The silver catheter is his main reliance, because its exact position in the urethra is so much more easily determined. The patient should be recumbent, with the thighs drawn up and well separated, and the shoulders raised. The introduction is sometimes greatly aided by pressing down the soft parts over the pubes, thus relaxing the suspensory ligament.

DR. GOULEY exhibited a bronze model of the catheter found in the ruins of Pompeii. It had the sigmoid form generally thought to have been invented at a much later period; it is distinctly conical, and had a single eye near the vesical end.

Dr. Gouley also exhibited a number of catheters of American make, which he claimed had a finer finish than those of foreign manufacture.

DR. WILLIAM FINDER, of Rensselaer County, in a paper entitled

RESEARCHES ON THE EFFICIENCY OF VACCINIA AFTER TYPHOID FEVER,

said that from 1874 to 1880 small-pox was almost epidemic in Troy, and at this time he first noticed that persons that had recently been sick with typhoid fever could be vaccinated with the greatest ease, and comparing them with others who had also been previously protected in their childhood by vaccination, he found that typhoid fever seemed to possess the power of eliminating from the system the protection produced by vaccination. It is his practice now to vaccinate his patients after recovering from typhoid fever. He had hesitated to present this theory until he had made a great many observations, and could verify his position beyond a doubt; but opportunities of this kind are not very frequent, and finding that some observations made some years later were confirmatory of the first ones, he had decided to ask others in the profession to continue these observations, that the correctness of this theory might be determined.

DR. H. ERNST SCHMID then read an entertaining and very suggestive paper entitled

REFLECTIONS ON THE NEED OF CLOSE OBSERVATION OF DISEASE, AND UPON THE VALUE OF HYGIENIC THERAPEUTICS.

He showed that some of the seemingly miraculous diagnoses of quacks were easily explained by a habit of exceedingly minute and rapid observation.

DR. DARWIN COLVIN, of Wayne County, reported a case of

PUERPERAL BLINDNESS,

with a view to showing the action of venesection, both prophylactic and curative.

DR. T. J. MCGILLICUDDY, of New York, said he had had five cases of such blindness occurring with puerperal eclampsia, yet all had completely recovered without resort to bleeding.

Dr. McGillicuddy then read a paper entitled,

A PLEA FOR THE NON-OPERATIVE METHOD OF TREATING DYSMENORRHŒA, PELVIC INFLAMMATION AND PELVIC ABSCESS.

He thought much good could be accomplished by the free use of hot water, both by mouth and by rectum, thus stimulating the portal circulation and promoting the absorption of exudates.

A number of other papers were contributed, but most of them were read by title.

The following communication was ordered sent to the American Medical Association, in answer to its circular letter inquiring as to the advisability of amending the Code of Ethics:

"In reply to the notice that the American Medical Association had requested the State medical organizations in affiliation with that body to express their wishes in reference to any changes in the Code of Ethics, the New York State Medical Association has to state that it has made that code one of its foundation stones, and that it is entirely opposed to any alteration therein. This is the result of a full reconsideration of the subject, and after an experience of ten years of organization under the code."

Dr. Thomas D. Strong, of Chautauqua County (fourth district), was elected President for the ensuing year; and Dr. Isaac de Zouche, of the first district, Dr. John C. Benham, of the second district, Dr. Homer O. Jewett, of the third district, and Dr. John D. Rushmore, of the fifth district, were elected Vice-Presidents.

"THE MEDICAL PROFESSION" IN ENGLAND. — In the official census reports of the Registrar-General's office of England, the medical profession, which in legal language means only medical practitioners on the Register, is made to include dentists, dental-apparatus makers, medical students, assistants, midwives, nurses, and invalid attendants, "*as well as sundry other persons more or less directly connected with medicine.*"

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 16, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

THE LATE SIR ANDREW CLARK.

Dr. Andrew Clark was one of the indefatigable workers of this age. His private practice was large, his *clientèle* influential. His contributions to medical journals, though somewhat desultory, would fill a large volume, and most of these writings contain new facts and possess a permanent value. He was always a favorite writer. He was a master of good style. Among his contributions we may specify, as containing much original observation and investigation, his Lumleian lectures on Dry Pleurisies; his exhaustive studies on Fibroid Phthisis; papers on Neuræsthenia, on the Hemoptysis of Aged Persons, on Tuberculous Sputa, on the Anæmia and Chlorosis of Girls, on Disease of the Valves of the Heart, etc. In 1891, he began a course of clinical lectures on Common and Functional Diseases, completed last year, which attracted wide attention and has been of service to the cause of medical education. These lectures were of great use in showing students his own methods of seeing patients, and his own way of eliciting the truth as to their case and wants.

Dr. Clark was an eminently practical man, and his almost intuitive faculty of getting at the basic facts of a case and analyzing them on common-sense principles, made him much sought after as a consultant. It was always his aim, if possible, to meet causal indications, but, failing in this, to bring to every case an adequate understanding of the physiological principles applicable to the removal of the conditions imperiling life. He insisted especially on attention to all the minutiæ of the hygiene of patients — food, drink, sleep, exercise, etc.

Dr. Clark was associated with the London Hospital from 1854, about which time he came to London for the sole purpose of studying pathological histology (and with no intention of engaging in the practice of medicine), and helped create the great medical school now attached to the hospital. For his services in connection with this medical school he was honored by an ovation and a presentation July 15, 1889.

Dr. Clark labored to bring up the medical societies of London, and especially the Clinical Society of which he was a favorite member, to the highest standard of efficiency, through diversity of inquiry, community of work, unity of purpose and severity of procedure. Not soon will be forgotten by those who were present the golden words of his presidential address delivered at the Clinical Society of London, January 26, 1883, a portion of which may be appropriately quoted here:

"In the work of the younger members of our profession I see, or at least I think that I see, greater care, patience and accuracy in observation, a more rigorous fidelity in the record of therapeutical experiments, wiser caution in speculation, graver deliberation in judgment, a growing frankness in the confession of oversights and errors, increasing severity in the siftings and testings of their own conclusions, a readier effacement of the personality in the work, less unseemly eagerness for mere priority of publication, a deepened sense of the responsibilities of premature speech and writing, a rapidly abating bitterness in the conflicts of opposing views, a more robust and manlier spirit of scientific life, and less reluctance in making admission that there is no unconditional truth in the results of our inquiries — no finality in our finished work, no creed in medicine. But the Society has done more than train good workers; it has repressed bad workers. For one competent and conscientious worker there are ten who are incompetent and unconscientious, and who in divers ways hinder our progress and spoil our present possessions. Intolerant of the patient and painful toil of the true worker, acute in power of superficial observation, gifted with a certain showy versatility, quick at catching hold of new ideas, ingenuous in guessing, crude in experiment, loose in therapeutic trials, hasty in speculation, strong in dogmatic assertions, accomplished in the transfiguration and use of other men's work, finding what they want wherever they seek it, unhindered by difficulties, facile in speech, ready in writing, thirsty for notice, such men, now, alas, not uncommon in medicine, beget papers so quickly that they can have no necessary relation to time, observation or thought, and flood our literature with their unworthy if not unveracious lucubrations. The favorite hunting-ground for such men is therapeutics, and their favorite sport is the catching of remedies, the putting of them to new uses, and the setting forth of their successful results. These men discern no difficulties and have no failures; they can illustrate their successes by scores of cases, and explain them by the most ingenious theories. There is scarcely any limit to the extent and variety of their achievements, and as they flaunt along in the fulness of self-satisfaction, they look down with pitying condescension upon those in the straight and narrow way who conscientiously toil with small success in seeking after truth, but who, nevertheless, missing the praise of men, find strength and solace in their favored search."

His introduction to the discussion on "Cases of Valvular Disease of the Heart, known to have Existed for over Five Years without Causing Serious Symptoms" — a discussion which took place in the Section of Medicine at the annual meeting of the British Medical Association in 1886 — will be recalled as an important and valuable contribution to practical medicine.

As President of the Royal College of Physicians,

and thus the official representative of the profession in England, Sir Andrew was most kind and hospitable to medical men from other countries visiting London, and to none more so than to our countrymen. Any one who had the privilege of knowing him in his own home could not fail to be impressed by the amount of systematic work which he accomplished in the twenty-four hours.

At the funeral, which recently took place in Westminster Abbey, Mr. Gladstone was the chief pall-bearer. The occasion was an impressive one. The wise and eager physician borne to his last resting-place at the age of sixty-seven by the distinguished and eager statesman at the age of eighty-four, whom as friend and physician, he, the younger man, had so often and so long shielded from the consequences of his own restless impetuosity. It would have been a distinct gain for the profession had some one been able to do for the physician what he himself had done for so many other well-known men. For Sir Andrew, at the age of sixty-seven, was still, as years count in England, a young man.

VERTICAL HANDWRITING.

THE relation between one's penmanship and spine does not at first appear to be very close; but the direct and important hygienic effect of the position of the body required in one or another style of penmanship is well brought out by the statement and illustration of Mr. Witherbee in a recent paper. In his "Argument for Vertical Handwriting"[1] he adds to the plea for the more legible vertical style of writing, a forcible statement of the important effect upon the child's health and figure which a more rational handwriting entails.

The Vienna Commission to investigate the cause of the increase of spinal curvative and ocular trouble among school children reported that the chief factor was sloping handwriting and the faulty positions necessitated by it.

The vertical script is easier to read, easier and quicker to write, as it requires a shorter distance for the pen to travel in making each letter; for the mathematical reason that the perpendicular of a right angled triangle is shorter than the hypothenuse. There is less strain upon the eyes as the position of the body faced squarely to the desk brings both eyes at an equal distance from the paper. With the lateral position taught in most of our schools the pupil most either twist the head to one side, adding to the spinal bend, or strain the accommodation of the eyes to unequal foci.

The specimens of writing and photographs which are reproduced are most telling arguments for the justice of the plea, and aside from the arguments as to ease of teaching or reading or the elegance of appearance, the simple fact that vertical writing puts the pupil in a correct position as regards the spine and the eyes is sufficient grounds for its adoption in our school systems.

[1] Popular Science Monthly, November, 1893.

MEDICAL NOTES.

BEQUEST FOR A NEW HOSPITAL FOR NEW YORK. — The will of the late Mrs. Mary March, after giving $10,000 each to Bellevue Hospital and the Louise Home of Washington, leaves the remainder of the estate, which is valued at nearly a million dollars, to Grace Church, in New York, for the erection of a hospital, to be known as the John Payne March Memorial Hospital, for the relief of the sick, aged and indigent in Grace Church parish.

DEATH OF DR. MONCRIEFF. — The report of the probable death of Dr. David Scott Moncrieff, which was received during the summer, has been confirmed by the United States Minister to Japan, who reports that the body of Dr. Moncrieff has been found at a place called Vingov, on the Saghalian coast of Siberia, whence it was sent to Alexandrovski. He was sent to Siberia, to study anthropology, by the Peabody Museum of Harvard University, and was drowned when out sailing.

THE ABOLITION OF THE OFFICE OF CORONER. — At a meeting of the Medico-Legal Society held on November 8th, Clark Bell, of New York, Judge Abram H. Dailey, of Brooklyn, Theodore H. Tyndal, of Boston, Wyatt Johnson, M.D., of Montreal, Judge S. G. Garrison, of Camden, N. J., H. W. Mitchell, M.D., of New York, Morris Ellinger, Esq., of New York, were appointed a committee of seven to prepare a memorial to be presented to the Legislature of the State and to the approaching Constitutional Convention, favoring: (1) The abolition of the office of coroner in the State of New York; (2) the adoption of appropriate legislation and changes in the Constitution of the State that would remedy the defects in the existing system; and (3) brief reference to the labors of this body during the past years for the attainment of this result, and the recent action of the New York *Herald* and other journals and the Grand Jury of New York County upon the subject.

ROYAL OBSTETRIC FEES. — Dr. Playfair, who recently attended the Princess Marie, of Roumania, in confinement, was presented by the king with a gold snuff-box and the insignia of a Grand Officer of the Order of the Crown of Roumania, in addition to his fee, which is said to have been £2,000.

A PHYSICIAN'S GIFT TO SAN FRANCISCO. — Dr. Levi C. Lane, of San Francisco, has presented to the city of San Francisco a large building with two wings, each two stories high, which he has had built for a fully equipped hospital, to be used as an annex to the Cooper Medical College of that city.

PHILADELPHIA MATERNITY STATISTICS. — The figures given in the report of the Philadelphia Maternity Hospital add another proof of the value of lying-in

hospitals and obstetrical cleanliness. During the last hospital year there were 132 cases treated, with two deaths, one from phthisis and one from chronic nephritis. Three children were still-born and of the 134 born only five died. In the last four years, with 565 deliveries, no patient has died from preventable causes.

Medical Students in Germany. — The total number of matriculated students in the universities of the German Empire in the summer semester of 1893 was 28,053, of whom 8,838 were students of medicine. The number in the corresponding part of the foregoing academic year was 8,414, showing an increase of 424 or 4.8 per cent. The number of foreign medical students was 474.

Women Physicians in Russia. — According to Dr. Heizenstein, of St. Petersburg, there are about seven hundred women physicians in Russia. Their position is steadily becoming better and already many of them hold important public appointments to hospitals and almshouses. A large majority of them are native Russians, about twenty-five per cent. are Jewesses and the remainder of various Slavonic races.

BOSTON AND NEW ENGLAND.

Small-Pox in Boston. — During the last fortnight five cases of small-pox have occurred in Boston among recent immigrants due to infection during the voyage from Liverpool on the Cunard Steamer *Catalonia*. A case of small-pox occurred during the voyage but as all the passengers had been vaccinated they were allowed to land. A few days later two cases of small-pox were reported, both patients having been steerage passengers. Further inquiry has shown that one of these men, at least, washed his arm immediately after being vaccinated thereby making his protection useless. No new cases occurred until November 12th when three patients were reported from South Boston. It seems that a young girl of thirteen years who was a steerage passenger on the *Catalonia* went at once to live with her sister in South Boston. She was taken ill the next day but was not attended by a physician. Later, when she was convalescent, three others of the family were taken ill with what proves to be small-pox. All the patients have been taken to the hospital and the well members of the family are quarantined in their house.

Diphtheria in Lynn. — An outbreak of diphtheria has occurred at the Children's Home of the Lynn Poor Department. For some time the Home has been overcrowded and without sufficient means of isolating sick children. Of the twenty-five inmates, seven are already ill and one has died. An unoccupied house has been secured for the use of the children not yet ill, and the City Government has voted the money needed to finish the improvements at the Home.

Bequests for Medical Purposes in Memory of Dr. Hunt. — By the will of the late Mrs. Mary C. Hunt, of Hartford, Conn., widow of Dr. Ebenezer K. Hunt, $25,000 is left for the sole use of the Medical School of Yale University. Provision is also made for erecting a building in Hartford for the use of the Hartford City Medical Society as a memorial to Dr. Hunt.

Maine General Hospital.—At the annual meeting of the trustees of the Maine General Hospital held last week, the report of the resident physician and superintendent showed a total of 1,069 patients treated during the past year, 221 of them being free patients. The income the past year was $3,915.22 less than the expenses. The total amount expended for the treatment and care of free patients was $18,327.08 against 13,791.78 last year.

Miscellany.

THE RESULTS OF TOO MANY MEDICAL SCHOOLS.

In his inaugural address at the opening of the four years' course of study in the Medical Department of the University of Pennsylvania, Dr. William Pepper reviewed the progress toward higher medical education in this country. He said:

"Much of the evil of a debased medical education standard in this country has come from the reckless distribution by State legislatures of charters and degrees conferring privileges to new and imperfectly equipped medical schools. . . . In 1877 there was an average of one medical school in the United States to every 477,392 inhabitants, while in Germany or Great Britain there was one to one and three-quarters of a million population. In the twelve years from 1878 to 1889 inclusive, there were sixty new medical schools established. Fortunately they are apt to be short lived. At present I have been able to demonstrate the existence of only 140 or one to 440,150. In every other country the ratio has increased in the opposite direction. It cannot be maintained that the sparsely settled state of our country justifies or explains this condition. In Brazil there is now but one medical school for every 7,001,167 inhabitants; and in Russia but one for every 14,403,317; while in New York State, with 6,000,000 population, there are fourteen medical schools, or one for every 428,418; in Missouri, with 2,679,184 population, there are thirteen, or one to every 206,091; and in that vigorous community of Ohio, numbering 3,672,316, there are, I believe, in actual existence, no less than nineteen medical schools, or one to every 193,279.

"The effect of these numerous small medical schools upon medical training and the medical profession at large can only be harmful. A more remote but no less important effect upon the community at large is very properly brought to notice. Medical education no longer does consist, and never should have consisted, in the reading by the professor of systematic courses of lectures to bodies of students which might number 2,000 as well as 200. A certain amount of such systematic instruction is retained, and we hold that it answers a useful purpose. But the broad basis of modern medical education is the careful training of the individual student at the bedside and in the laboratory.

"There are branches of study, like Greek or mathematics, which may be studied as well, granted a true teacher and the necessary books, in a small village as

in a metropolis. But no excellence on the part of the teacher can atone to the student of medicine for the want of the extensive and varied experience with all forms of disease and injury only to be acquired in the hospitals and dispensaries of a great city. Nor is it without importance, for both the public and the profession, that side by side with this obvious evil of excessively numerous medical schools comes the inseparable but more insidious danger of pauperizing the community by a superabundance of free medical service. Each medical school inevitably desires the most liberal use of hospital and dispensary facilities as attractions to draw students, and as a basis for practical instruction; and when, as is so common among us, these schools are in excess of the needs of the community, or are in towns too small for the purpose, the eager desire for ample clinical material is gratified at the expense of the local profession, and of the self-respect of a considerable portion of the community."

MECHANICAL VIOLENCE IN THE TREATMENT OF DIPHTHERIA.

At this time of renewed and enthusiastic study as to the nature of the infection of diphtheria, when diagnosis is aided by cultures taken directly from the patient's throat, and when the treatment is so apt to be made too purely local, it is well to consider the effect of mechanical violence upon the throat.

Dr. J. R. Culkin,[1] of Rochester, calls attention to this subject in a recent article, in a spirit of fairness and common-sense. After speaking of the various types of the disease, and the course of systemic infection, he says:

"The majority of the profession believe that diphtheria is a germ disease, and that the Klebs-Löffler bacillus is probably the cause of it. The experiments carried on by various bacteriologists confirm this belief, but they are not as yet numerous enough to enable us to say that it is so beyond doubt.

"In considering the local effects of mechanical violence to the throat, we will do well to have in mind the following facts:

"(1) That we probably have in the throat pathogenic germs ready to invade every area laid bare of epithelium.

"(2) The poisonous ptomaines are more readily absorbed by a raw and bleeding surface than by one covered by epithelium.

"(3) That a portion of the involved tissue is already necrotic, another portion nearly so, and the area surrounding those portions is acutely inflamed.

"(4) That it is impossible to render by any means known to us a diphtheritic throat antiseptic.

"The numerous crannies and folds in the mucous membrane of a swollen and diseased throat defy the searching of a swab which, though saturated with antiseptic or caustic solution, soon becomes covered with mucus or bits of the necrotic membrane.

"The advantage gained in most cases is more than balanced by the fatigue to the child, the irritation and unavoidable mechanical violence to the throat which opens out a new bleeding point for fresh absorption of ptomaines, a new entrance of bacilli. The injuries resulting from compression of the tensely swollen glands about the jaw in severe cases, when the mouth is held forcibly open are not to be disregarded. Empty lymph channels absorb poison and convey it more rapidly than full ones — and vomiting makes empty channels.

"Important as are the cleansing and disinfecting of the throat, the rational side of the question is often overshadowed by the desire to destroy a bit of membrane and a few germs. It should be always remembered that the condition of the patient with diphtheria is one of acute septicæmia, in which the maintenance of strength, absolute quiet and nourishment is of prime importance. Our first object should be to save the child, not to kill the germs."

[1] New York Medical Record, October 14th.

LONG SUSPENSION OF NORMAL RESPIRATION.

In the October number of the Virginia *Medical Monthly* Dr. R. K. Smith reports a most unusual case of prolonged artificial respiration.

The patient, a man of twenty-four, had been ill for three days with slight headache and febrile temperature. On the fourth day he complained of severe headache, and rapidly became unconscious, with loss of reflexes and slow stertorous respiration (five or eight times a minute). The respiration ceased one hour after the patient became unconscious. Artificial respiration was begun and stimulants given subcutaneously. The pulse (84) continued good, as did the capillary circulation, but there was no attempt at normal respiration.

The following day the patient was cold, the pulse very weak (76), the eyes sunken, with dilated pupils. The pulse gradually failed, but the artificial respiration was carried on till the heart ceased to beat, which was thirty-eight hours and a half after normal respiration ceased, during which time about 46,000 forced breathings were accomplished.

The autopsy showed a purulent lepto-meningitis, with effusion into the ventricles. "The special features of interest were the mild symptoms and noticeable absence of pain up to the time the patient became unconscious; the cessation of respiration while the cardiac functions remained comparatively unimpaired, and the length of time the heart continued to beat under artificial respiration. What started as a demonstration to a young medical student became an experiment and finally a duty."

Correspondence.

[From our Special Correspondent.]

PARIS LETTER.

PARIS, November 2, 1893.

MR. EDITOR:— *Vive la Russe!* Had I been born in St. Petersburg with many consonants to my name, I might now be an honorary member of any medical society in Paris; but as I was not given Gilbert's privilege of belonging to other nations, I can only send you an outsider's account of the present *entente cordiale*, as it affects the medical profession. Even science has felt the hot joy of affection the last two weeks. The medical press of Paris set on foot the banquet in honor of the five surgeons from the Russian squadron who were in Paris. But this was not enough; and the invitation was extended to all the Russian physi-

cians and scientists of any standing in Paris. The dinner was given at the Grand Hotel, and over two hundred physicians were present. The hall was lavishly decorated; but everything paled before the glowing tributes of the after-dinner speakers. Professor Cornil presided, while round him were some of the best known medical men of Paris. The Minister of War furnished a band of music and toasts were drunk to everything Russia in the Russian manner. The greatest enthusiasm was reached when Dr. Botkin, a young Russian physician and ensign, rose at the close of the banquet to thank the guests for having applauded his father's name, and in a voice trembling with emotion said, "I drink to the health of France — to the glad union of two sister nations — a union which no obstacle can prevent; for it would be annihilated with the same ease with which I break this fragile crystal glass." Suiting his action to his word, he called forth such emotion from all present that he was lifted from his chair and carried about the room on the shoulders of his friends.

Dr. Aristoff of the Russian squadron being present at a meeting of the Anthropological Society, the members rose in a body and made him a member by acclamation! And so it goes.

The Paris Surgical Society celebrated its fiftieth anniversary on October 25. M. D. Mayolin, one of the founders of the Society and its oldest member was the recipient of the medal struck for the occasion. Among the invited guests present were Spencer Wells, Thiriar, Boeckel and Reverdin. Telegrams and letters of congratulation were received from Billroth, Albert, and various medical societies of Europe. An excellent address upon the history of the Society was given by the Secretary, Dr. Charles Monod, in the large ampitheatre of the Medical Faculty. In the evening a very pleasant banquet closed the ceremonies.

Naturally much interest has been felt in the appointment of successors to Charcot in the various chairs he held. M. Brissaud has been delegated to take charge of the service at the Salpêtrière for a year until a permanent successor is appointed to the chair of diseases of the nervous system. At the Academy, M. Potain has already been appointed to the vacancy.

One of the recent meetings of the Academy was devoted to an interesting discussion of the regulation requiring notice of all cases of contagious disease be sent to the official boards. Each disease was voted upon separately and the list finally approved as filling all the requirements is as follows: Cholera and choleraic diarrhœa, yellow fever, plague, variola, varioloid scarlatina, miliary fever, diphtheria including croup and membranous angina, typhoid fever, typhus, dysentery, puerperal infection, ophthalmia neonatorum. Measles was rejected from the list by a vote which lacked but three of being unanimous against considering it sufficiently contagious to be admitted.

The death of Professor Leon Le Fort is another loss to the medical profession of Paris. He is the tenth member of the Academy to die this year. He died suddenly and quite unexpectedly the day after presiding as Vice-President at the Academy. His career though short had been brilliant. Interne in the Hospital at the age of twenty-four, he had risen rapidly and soon became full professor. Had he lived he would have been President of the Academy the coming year. He served with credit in the Italian campaign and always retained an interest in military surgery and was commissioned by the Government to study the military hospital system of Germany, Austria and England for the benefit of the French army. His work as prosector in the medical school was unusually brilliant. He was personally a man of attractive cordial manner, of a quiet but determined character.

Bicyling is now all the fashion; and the roads in the Bois are lined by cyclists in all the varied costumes which Parisian taste can suggest. Silk tights with short flounces about the hips are favorite and attractive costumes among the women who very sensibly discard long skirts for riding.

The health of Paris remains very good. A small outbreak of choleraic disease in the north of the city has been found due to wells contaminated by sewage. S. E.

METEOROLOGICAL RECORD,

For the week ending November 4, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 1,992: under five years of age 704; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 350, acute lung diseases 257, consumption 248, diphtheria and croup 148, diarrhœal diseases 87, typhoid fever 47, scarlet fever 21, cerebro-spinal meningitis 20, measles 10, whooping-cough 7, malarial fever 4, erysipelas 3, small-pox 3.

From scarlet fever Pittsburg 8, Brooklyn 4, New York and Baltimore 3 each, Lowell 2, Springfield 1. From cerebro-spinal meningitis New York 8, Brooklyn and Washington 3 each, Cleveland, Portland, Worcester, Lowell, Cambridge and Malden 1 each. From measles New York 8, Cleveland and Pittsburg 1 each. From whooping-cough New York 3, Brooklyn 2, Boston and Pittsburg 1 each. From malarial fever Charleston 2, New York and Cleveland 1 each. From small-pox Brooklyn 2, New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending October 28th, the death-rate was 18.3. Deaths reported 3,622: acute diseases of the respiratory organs (London) 271, diphtheria 110, diarrhœa 94, fever 71, whooping-cough 64, scarlet fever 58, measles 35, small-pox (Bradford 10, London and Birmingham 2 each, Bristol 1) 15.

The death-rates ranged from 10.5 in Croydon to 27.9 in Liverpool; Birmingham 21.2, Bolton 19.1, Bristol 15.5, Derby 14.5, Hull 15.5, Leeds 19.4, Leicester 16.4, London 18.0, Manchester 17.7, Newcastle-on-Tyne 25.1, Nottingham 13.9, Oldham 19.1, Portsmouth 14.3, Sheffield 19.4, West Ham 16.5, Wolverhampton 22.9.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 4, 1893, TO NOVEMBER 10, 1893.

By direction of the Secretary of War, leave of absence for four months is granted CAPTAIN WILLIAM STEPHENSON, assistant surgeon, U. S. A.

The station of MAJOR BLAIR D. TAYLOR, surgeon, is changed from the old post of Fort Bliss, Texas, to the new post of that name and he will report in person to the commanding officer of the latter named post for duty.

CAPTAIN FRANCIS J. IVES, assistant surgeon, is relieved from temporary duty with the Medical Section of the War Department Exhibit, World's Columbian Exposition, Chicago, Ill., and will return to his proper station, Fort Sheridan, Illinois.

FIRST-LIEUT. JOHN S. KULP, assistant surgeon, now on duty at Columbus Barracks, Ohio, will proceed to Jackson Park, Chicago, Ill., and report in person to the commanding officer, Camp Lamont, for temporary duty with the battalion of troops stationed there.

PROMOTIONS.

CAPTAIN EDWARD T. COMEGYS, assistant surgeon, to be surgeon, with the rank of Major, October 26, 1893.

FIRST-LIEUT. JAMES D. GLENNAN, assistant surgeon, to be assistant surgeon, with the rank of Captain, October 29, 1893.

FIRST-LIEUT. ALFRED E. BRADLEY, assistant surgeon, to be assistant surgeon, with the rank of Captain, October 29, 1893.

APPOINTMENTS.

By direction of the Secretary of War the appointments of WILLIAM W. QUINTON, THOMAS S. BRATTON, DEANE C. HOWARD, ALEXANDER S. PORTER and WILLIAM H. WILSON, to be assistant surgeons, with the rank of First-Lieutenants, to rank from October 26, 1893, are announced. They will report in person without delay, to the president of the Army Medical School in this city, for the course of instruction prescribed in General Orders No. 78, A. G. O. September 28, 1893.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 11, 1893.

WM. MARTIN, surgeon, ordered before Retiring Board.

N. J. BLACKBURN, passed assistant surgeon, from Navy Yard, New York, and to Norfolk Hospital.

T. C. CRAIG, passed assistant surgeon, ordered to Navy Yard, New York.

E. P. STONE, passed assistant surgeon, from Naval Hospital, Chelsea, and to Marine Rendezvous, Boston, Mass.

G. B. WILSON, passed assistant surgeon, from Marine Rendezvous, Boston, and to Naval Hospital, Chelsea, Mass.

B. H. KIDDER, medical inspector, promoted to grade of medical director.

JAMES E. GARDNER, passed assistant surgeon, promoted to grade of surgeon.

MILLARD H. CRANFORD, passed assistant surgeon, promoted to grade of surgeon.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday, November 22d, at 8 o'clock, P. M., by DR. M. H. RICHARDSON. Subject, "The Anatomy and Surgery of the Gall-Bladder." Physicians are cordially invited.

APPOINTMENTS.

DR. THOS. H. MCCARTHY has been appointed Pension Examining Surgeon for the Brockton, Mass., District.

WILLIAM L. RICHARDSON, M.D., has been appointed Dean of the Harvard Medical School, *vice* H. P. Bowditch, M.D., resigned.

W. TOWNSEND PORTER, M.D., of St. Louis, has been appointed Assistant Professor of Physiology in the Harvard Medical School.

F. A. DAVIS, M.D., has been appointed Instructor in Physiology.

RECENT DEATHS.

HENRY COLMAN, M.D., M.M.S.S., died at Lynn, November 12th, aged fifty-three years. During the war he served in the engineering corps of the Department of the Gulf, but afterwards completed his medical education and received his degree of M.D. from Yale. He was a member of the American Association for the Advancement of Science and a visiting surgeon to the Lynn Hospital.

HERMANN AUGUST HAGEN, M.D., Professor of Entomology at Harvard College, died in Cambridge, November 10th, aged seventy-six years. He was born in Konigsberg, Prussia, and received his degree of M.D. from the University of Konigsberg, in 1840. He devoted much time to the study of entomology, but began the practice of medicine and was for three years first assistant at the surgical hospital of his native town. In 1867 he was invited by Prof. Louis Agassiz to become his assistant in entomology at the Museum of Comparative Anatomy in Cambridge and in 1870 he was made professor of entomology in Harvard University.

CHARLES FREDERICK CREHORE, M.D., M.M.S.S., died at Newton Lower Falls, November 8th, aged sixty-five years. He graduated from the Troy Polytechnique School and received his degree of M.D. from the Harvard Medical School in 1854. In August, 1862, he entered the army in the rank of surgeon and was assigned to the Twentieth Massachusetts Regiment. For a time he was assigned to the ship *Cambridge*. The next year he was promoted to the rank of surgeon, and was attached to the Thirty-seventh Massachusetts Regiment, operating with the Sixth Army Corps in the Army of the Potomac. After the close of the war DR. Crehore resumed his medical practice in Newton Upper Falls for a short time, but soon gave up practice to attend to the large business interests left him by his father. He was a member of the Newton Water Board from 1880 to 1888.

BOOKS AND PAMPHLETS RECEIVED.

The "Perfected" Urethroscope. By William K. Otis, M.D. Reprint. 1892.

Tenth Annual Report of the Superintendent of Health of the City of Providence for the year ending December 31, 1892.

Thirty-eighth Annual Report upon the Births, Marriages and Deaths in the City of Providence for the year 1892. By Charles V. Chapin, M.D., City Registrar. 1893.

Transactions of the Fourth Annual Meeting of the Medical Society of the State of Washington, held at Tacoma, May 3, 4, 5, 1893. Spokane: Willcox Printing Co. 1893.

Polio-Myelitis. A Clinical Lecture on (1) Case of Polio-Myelitis; (2) Case of Chorea; (3) Case of Sacro-iliac Arthritis, etc. (probably rheumatic). By J. T. Eskridge, M.D., Denver, Col. Reprint. 1893.

A Practical Treatise on Materia Medica and Therapeutics. By Roberts Bartholow, M.A., M.D., LL.D., Professor of Materia Medica, General Therapeutics and Hygiene in the Jefferson Medical College of Philadelphia, etc. Eighth edition, revised and enlarged. New York: D. Appleton & Co. 1893.

The Principles and Practice of Surgery. By John Ashhurst, Jr., M.D., Barton Professor of Surgery and Clinical Surgery in the University of Pennsylvania; Surgeon to the Pennsylvania Hospital, Philadelphia. New sixth edition, enlarged and thoroughly revised. Philadelphia: Lea Brothers & Co. 1893.

The Cholera Epidemic of 1892 in the Russian Empire, with notes upon Treatment and Methods of Disinfection in Cholera, and a short account of the Conference on Cholera held in St. Petersburg in December, 1892. By Frank Clemon, M.D., Edin., Member of the Epidemiological Society of London. London: Longmans, Green & Co. 1893.

An Elementary Text-Book of Biology, Comprising Vegetable and Animal Morphology and Physiology. By J. R. Ainsworth Davis, B A., Trinity College, Cambridge; Professor of Biology and Geology in the University College of Wales, Aberystwyth. With numerous illustrations and glossary. Second edition, revised and enlarged. Two parts. London: Charles Griffin & Co. Limited. 1893.

A Text-Book of Physiological Chemistry. By Olaf Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized translation from the second Swedish edition and from the author's enlarged and revised German edition. By John A. Mandel, Assistant to the Chair of Chemistry, etc., in the Bellevue Hospital Medical College and in the College of the City of New York. First edition. New York: John Wiley & Sons. 1893.

Address.

THE GENERAL PRINCIPLES UNDERLYING ALL GOOD METHODS OF INFANT FEEDING.[1]

BY T. M. ROTCH, M.D.,
Professor of Diseases of Children, Harvard University.

JUST as the highest aim of the medical art should be directed to the province of preventive medicine, so the highest and most noble branch of preventive medicine should consist in the study of the best means and the most practical methods for starting young human beings on their life race; for preserving them from the perils which surround the early hours of existence; for giving them strength and vigor to resist the attacks which, greater and more dangerous in inverse proportion to their age, must inevitably be made on their vitality. The preventive medicine of early life is pre-eminently the intelligent management of the nutriment which enables young human beings to breathe and grow and live. In fact, it is a proper or an improper nutriment which makes or mars the perfection of the coming race.

Infant feeding, then, is the subject of all others which should interest and incite to research all who are working in the preventive medicine of early life.

The subject is a great one, and is worthy of the attention of the greatest minds of the age, worthy of the discussion of the leaders in medical thought of our Western Continent.

The responsibility of introducing such a serious question before such an assemblage of advanced medical thought is a grave one. It should be taken up carefully; it must be dealt with broadly.

We must acknowledge for the present, and in fact it is true, that in the status of infant feeding as it has existed up to the last few years, the average human breast-fed infant is more likely to live, the other factors of the life problem being equal, than the infant which is fed by any other method. But we must remember that the latest scientific work on this subject shows very clearly that it is not breast-milk, as a whole, which is pre-eminently good, but that there are definite known reasons inherent in the different elements of the breast-milk which make it the best known food. It is our province as scientific workers in this most important branch of practical medicine, to year by year elucidate and make use of these elements, once covered by a somewhat mysterious veil, but now rapidly becoming laid bare by the search-light of patient and laborious investigation. A great advance has been made in our knowledge as to what we are to copy from human breast-milk and what we must acheive in preparing a substitute.

The very essence of this practical information which we have gradually acquired, lies in the discovery that there is no one perfect nutriment for young human beings as a whole, but that it is the changes in the various elements of the breast-milk which satisfy the demands of the individual, and thus in time suits the many to such a degree that this protean food has erroneously come to be looked upon as one especial unchanging nutriment.

To thoroughly understand and successfully solve the feeding problem of the early months of life, a knowledge of the changes which take place in the mammary gland from many causes must be clearly kept in view. Again, the methods of modifying the milk in the human mammary gland, however limited in their scope they may be, should be practically investigated and carefully adapted to the individual, according to its age and size and general physical condition. The mammary gland in its perfected state, uninfluenced by disease or nervous disturbance or by the improper living of its owner, is a beautifully adapted piece of mechanism constructed for the elaboration and secretion of an animal food. When in equilibrium it represents the highest type of a living machine adapted for a special purpose, both mechanically, chemically, physiologically and economically. When from any cause this sensitive machinery is thrown out of equilibrium its product is at once changed, sometimes but slightly, but again to such an extent that the most disastrous consequences may follow when it is imbibed by the consumer.

To state, then, concisely what I have already referred to, we should, in studying the form of nutriment which shall be suitable for the early months of life, manifestly be guided by what nature has taught us throughout many ages. The researches of science are indeed, especially in the subject of infant feeding, wisely directed to learning to read the truths which nature presents to us. Great progress has been made in reading these truths. What we are at present endeavoring to do is to copy them.

The constituents of the nutriment which nature has provided for the offspring of all mammals are essentially animal and never vegetable. Human beings, in the first twelve months of life, are carnivora. It is, therefore, evident that an animal food entirely and always free from any vegetable constituents has been proved to be the nutriment on which the greatest number of human beings live and the least number die.

Where good breast-milk, or rather, one that is fairly adapted to the individual infant, cannot be obtained, or, if obtained, cannot be regulated by modification, it is desirable to combine the elements which good breast-milks represent. For perfecting this (which may best be called substitute feeding), we must have a material which, while as closely as possible approaching the analysis of good breast-milks, is also easily accessible. There is no mammal whose milk-production corresponds sufficiently to human milk to render a direct substitution safe or wise.

If, therefore, milk is used, the problem demands for its solution a modified milk. The mammal whose product, representing a carniverous food, has been proved from the earliest ages to best satisfy this demand is the cow. Certain breeds of cows are better adapted than others to produce milks which can be used for copying human milks.

For the use of this continent, these breeds are the Durham, Ayrshire, Holstein-Friesien, American grades and common natives.

The infant at the breast receives for its nutriment a fluid which is fresh, sterile, neutral or faintly alkaline, has a temperature of 98° to 100° F., and is furnished in an amount proportionate to its age and size. It is this fluid which we should copy in every possible detail when we undertake to prepare a substitute food. We should also consider as foreign matter, to be rigidly avoided, any element which we know is not to be found in the fluid which we are copying. Thus, and

[1] Address at the opening of the third session of the Section for Diseases of Children of the Pan-American Medical Congress, at Washington, D. C., September, 1893.

thus only, can we finally arrive at the proper solution of this intricate feeding problem.

It would seem hardly necessary to suggest that the proper authority for establishing rules for substitute feeding should emanate from the medical profession, and not from non-medical capitalists. Yet when we study the history of substitute feeding as it is represented all over the world, the part which the family physician plays, in comparison with the numberless patent and proprietary foods administered by the nurses, is a humiliating one, and one which should no longer be tolerated.

I would plead in the name of common humanity, as well as in that of the intelligence and scientific reputation of our profession, that this representative body of American physicians should, in its endeavor to advance the general subject of infant feeding, record itself as opposed to the use of patent or proprietary food of every description. If we are abreast of the times, and if we will but recognize and do justice to the work which has lately emanated from our own profession, we surely will not hesitate to boldly relegate to oblivion the statements of the food proprietors which on box and can, on bottle and on printed circular, attempt to stem the slow but inevitably progressing wave of scientific investigation.

It may be well to bear in mind that the attempts which in the past have been made to manufacture cheap foods have been markedly failures. We must first, regardless of expense, learn to produce by modification a perfected substitute food before we should endanger the success of our undertaking by allowing the mercantile side of the question to cripple us in the use of costly methods, which, however, we know to be the best. We should, in fact, remember that the nutriment which we are endeavoring to copy, far from being a cheap product, is, on the contrary, a very expensive one.

It is the knowledge of how to determine the best combinations of certain elements and the best methods of accomplishing these combinations which has in the last year or two especially claimed our attention, and in which we have met with signal success.

There is no doubt but that one of the most important questions connected with the preparation of a substitute food is the proper control of the primal milk-supply. What that control shall be, and how it shall absolutely be kept in the hands of those who by education and unselfish interest are most fitted to use their power wisely, is a matter worthy of your deepest thought. The State control, as represented in Denmark, is indeed a brilliant example of what can be accomplished in this direction. Whether a similar method would prove to be the best for us to adopt has not as yet by any means been proven. The political clouds which continually obscure the highest scientific aspirations on this continent make it probable that for the present, at least, the primal milk-supply can best be perfected by individual enterprise and enthusiasm.

Finally, I would call your attention and consideration to the great capacity of different infantile digestions for assimilating a variety of proportions of the same nutritive elements, and hence, when introducing new methods for preparing a substitute food, the necessity for providing for many prescription possibilities.

The latest researches on human breast-milk show that the albumen of the milk is not merely an exudation from the lymph vessels supplying the mammary gland, but that it is actually modified in the breast. We thus see that the mammary gland, besides being an elaborator and a storehouse for infant nutriment, is also a modifier.

Following, therefore, nature again closely, we learn that the precise modification of an absolutely pure and fresh primal milk-supply is the vital principle which should at present underlie our efforts to perfect substitute feeding; and I trust that those who will to-day take part in the discussion of this very important subject will especially enlighten us on two matters of extreme interest:

(1) What is the best method of obtaining a stable and perfect primal milk-supply?

(2) When this supply is obtained, how shall it best be modified?

Original Articles.

APPENDICITIS.[1]

BY A. WORCESTER, A.M., M.D.

ONE of the great disappointments of this age is the failure of the medical profession to make practical use of the brilliant discoveries of the pathologists. In some directions the general practitioner is not in the least responsible for this failure. Thus, in the matter of tubercular diseases, we can only stand with the laity anxiously awaiting the discovery of some method of treatment that will not dash our high hopes. But in other directions the general practitioner is responsible for not giving to his patients the benefits that logically belong to the recent discoveries in the natural history of certain diseases.

Nowhere else is this fault of the profession more glaring than it is in the treatment of appendicitis. In this paper I purpose to expose this fault and to urge the adoption of treatment based upon facts and reason.

The appendix cæci vermiformis, as its name signifies, is a blind tag-end of the large intestine. So far as is known, it is as useless as the nipples on a male breast. Very probably its proneness to decay is due in part to its uselessness, in obedience to natural law; but this liability to decay is also largely due to its exposed situation as regards bacterial infection. The alimentary canal teems with potential germs of disease which, although geometrically inside, are yet in reality as outside the body as if held in the closed fist. Indeed, our health and even our life depends upon the integrity of the gut in preventing the admission into the body of these deadly bacteria.

There is, however, a still stronger reason for the frequent inflammations of the appendix to be found in the study of its anatomical structure, which like that of the tonsil is largely lymphatic and absorptive. Its poor mucous lining cannot even lubricate itself against the accumulation in its cavity of foul material. This fæcal matter becoming inspissated naturally causes irritation and ulceration. If sharp-angled seeds or other foreign bodies are also present, and if the opening of the appendix into the cæcum is blockaded with hard fæces, such conditions would, of course, favor the ulcerative destruction of the mucous membrane.

What form of inflammation follows will then depend upon the kind of disease germs thus admitted into the

[1] Read by invitation before the Essex South District Medical Society, September 19, 1893.

structure of the appendix. A frequent result is an absolute interference with the blood-supply of that portion of the organ beyond the original seat of inflammation. Whether this interference be mechanical, from pressure, or whether from closure of the vessels by septic thrombi, the result is equally disastrous. There is then no escape for the outer portion of the appendix. Gangrene and sloughing must ensue. Often, however, the inflammation of the walls of the appendix is not completely annular, but more strictly localized, in which case a perforating ulcer may result without complete gangrene of the distal portion of the organ.

There also occurs more or less frequently a catarrhal inflammation, as it is called, which does not necessarily involve the destruction of any portion of the appendix. It is this variety which so often recurs, and so often precedes the destructive attack. But even this mild form is not so harmless as many would have us believe, for it is apt to cause a neighboring adhesive peritonitis which renders the proper surgical treatment much more difficult when later that becomes imperative. It is also the probable cause of the various deformities of the appendix, which are considered by some to be responsible for the occasional attacks of pain. However that may be, at any rate it is certain that the normal appendix is perfectly flaccid and may comfortably lie in any bent and crooked position. Only when the walls are thickened and stiffened by previous inflammation can any bend of the organ obstruct its lumen and thus cause appendicular colic.

These different varieties or stages of appendicitis may be distinguished by the eye, aided perhaps by the microscope, but not by abdominal palpation nor even by the rectal touch.

Were the appendix within easier reach, its various inflammations could, of course, be more accurately tabulated. It might then, perhaps, be possible for two or more authorities to agree upon the number of distinct varieties; and there might then be some foundation for those who pretend even now to diagnosticate the "mild catarrhal" from the "possibly fulminant" variety. But on the other hand, were the useless little organ within easy reach, whenever inflamed it would probably be snipped off and sent to the nearest pathological laboratory for culture-test examination, whereby alone may be obtained a certain diagnosis as to the character of the inflammation. For there can no longer be any doubt that the different forms of purulent inflammation are due to the presence in affected tissues and in serous cavities of the different species of pyogenic micrococci. Thus if the inflammation be caused by the staphylococcus pyogenes albus, it may be expected to be of a mild character. And even if the inflammation involves the outer wall, thus allowing a migration of the micrococci into the peritoneal cavity, there may still be spontaneous recovery from the peritonitis. But if, on the other hand, it is the streptococcus pyogenes that has invaded the walls, then there is no escape from a gangrenous appendix, which unless immediately removed will surely cause a fatal peritonitis.

Again, although the local ulcer that causes the perforation may itself be due to a comparatively harmless micrococcus, the cæcum and the appendix may nevertheless contain the most virulent species, which after the perforation may thus freely enter the abdominal cavity.

It is, therefore, most unfortunate for those who believe in temporizing that even the normal appendix is not within the field of easy observation. Indeed, owing to its obscure position it has only lately received even obituary consideration. Moreover, after it is inflamed, owing to the speedy yet consequent inflammation of the neighboring peritoneal surfaces, the appendix becomes more and more removed from the examiner's hands. Thus the difficulties of diagnosis increase with the progress of the disease.

Fortunately, in the early stages of its inflammation, it is not very difficult to discover the simple fact that it is inflamed. But that is all.

The disease itself would be of comparatively little consequence were it not for its after-effects. Indeed, it is usually recognized only by its frightful sequelæ, which nowadays with disgraceful inaccuracy are generally described as varieties of appendicitis.

The principal harm resulting from the disease is due to the perforation of the organ and the consequent passageway for the contents of the bowel into the abdominal cavity. This condition would invariably be followed by septic peritonitis, were it not for the facility with which the peritoneum, by adhesive inflammation previous to the perforation, blockades the threatened pathway. The possibility of this blockade depends largely upon the varying anatomical situation of the appendix as regards the walls of the abdomen and the neighboring coils of intestines. Sometimes quite a defence can be thus extemporized and there then results, instead of a general peritonitis, a perityphlitic abscess.

Either result admits of ready diagnosis.

There is no need of pursuing the subject of general septic peritonitis. Its terrors are only too well known. The only rational treatment is its prevention. That failing, the source of infection having been removed, the abdominal cavity must be given the freest possible drainage.

A perityphlitic, or, better named, a periappendicular abscess, is a somewhat less frightful result of a perforated appendix. A fatal issue is not so probable, and at any rate, is not so immediate. The medical attendant has more time to collect his wits and to arrange for the proper treatment, which is, of course, surgical, as it is in every other kind of abscess. There is never any justification for delay in evacuating foul pus. And the audacity of physicians who make a specialty of not using the knife in medically treating such cases, where the stench of the pus if evacuated renders the patient's house almost uninhabitable, is equalled only by that of the mind-cure practitioners who are said to continue giving "absent treatment" to their patients, if not informed of their death.

It is not, however, my present purpose to discuss at any length the treatment of the sequelæ of appendicitis. I mention the sad subject only to emphasize the importance of preventing disasters, which are liable to follow any attack. Such prevention is entirely feasible. It depends upon cutting short the appendicitis. And this can easily be done by cutting off the appendix.

Before considering the question of the treatment, it is proper first to consider the diagnosis of the disease. This necessitates the closest clinical study.

Appendicitis is by no means an insidious disease. To begin with, there is generally the help of a history of previous similar, but milder attacks. The disease always causes pain. At first, this pain is only a gen-

eral belly-ache, but more severe than, for instance, the pain caused by sharp cathartics. Nor is it apt to be so distinctly wave-like in character as that caused by over-active peristalsis. It has from the first a most discouraging come-to-stay feeling. This early pain is relieved somewhat by general pressure over the whole abdomen, just as the pain caused by an ulcerated tooth is relieved by pressure over the whole cheek; but, as is also the case with the toothache, it is increased by strictly localized pressure. A further most important characteristic of the pain is that it is made worse by removal of the pressure. The pain is also increased by motions involving the right psoas muscle, and by bending the trunk to the left.

Later, in the progress of the disease, the pain is increased and more localized in the right abdomen. From the frequent proximity of the appendix to the ureter, the pain caused by its inflammation is apt to shoot upwards and backwards into the loin, and still more often downwards and forwards into the penis and right testicle, or into the right labium. This often causes intense desire and yet ineffectual attempts to empty the bladder. An attack of renal colic is thus simulated.

Even if a laxative has not been taken by the patient before sending for the doctor, there is generally the story of some strainings for bowel evacuation in the hope of thus relieving the pain. But so far as the diagnosis is concerned no attention whatever need be paid to the condition of the bowels. Patients usually give a history of previous costiveness, whatever the nature of their complaint.

The pain of appendicitis, besides causing more or less futile attempts to empty the bowel and the bladder, is almost sure to cause nausea and vomiting. A severe attack of acute indigestion is thus simulated, and patients generally ascribe their trouble to some imprudence in diet. Prudence is an uncommon virtue. Often the pain is ascribed to some muscular strain or abdominal bruise, which, except for the coincident or sequent pain, would have passed unnoticed.

Finally, the pain usually becomes intolerable, which accounts for the customary deadly administration of opiates. Were it not for this terrible morphine-masking of the disease, more cases would be treated by timely surgery, and fewer physicians would be thus lulled into the lethal stupidity of inaction.

So much for the history and subjective symptoms, which indeed, even if taken alone, would strongly suggest appendicitis. The positive diagnosis can be made only upon the additional evidence that may be gained by physical examination.

The rate of the pulse and the height of the temperature at any one time are of absolutely no consequence; the variation between successive observations is, however, of exceeding importance. In the early stages of the disease, the pulse quickens and the temperature rises as the inflammation advances. The increase may be very slight, but it serves to eliminate all non-inflammatory affections. It is, however, to be remembered that the pulse and temperature are of absolutely no value as evidence after peritonitis subvenes.

By far the most important help in making the diagnosis, comes from palpation of the organ itself. If in normal condition, even through the thinnest and most conveniently lax abdominal walls, it is doubtful if the appendix can be felt. But if it is inflamed, it is larger and more rigid; it generally contains concretions; it is then exquisitely tender to pressure, and, as has already been mentioned, it aches more during the removal than during the application of pressure; and under these conditions it can generally be located by careful palpation, and the fact of its inflammation thus established.

There is usually noticeable some slight dulness on percussion immediately over the point of greatest tenderness; but, on account of the inflated intestine often adjoining, the absence of this sign counts for nothing.

Were the appendix to be found always in the same position, its certain palpation would be far more possible, and McBurney's famous point would be more deserving of its fame. But only the base of the appendix, at its origin from the cæcum, has any approach to a fixed location, which, by the way, is considerably lower than McBurney's line; and as the appendix may be from one inch to five inches long, and may lie in any direction from its base, and further, as only its tip may be inflamed and tender, it follows that the distinguishing resistance and tenderness pathognomonic of the disease may be many inches removed from the McBurney point. As a matter of fact this not seldom happens. If the appendix lies alongside the ascending colon, its tender tip may be found near the gall-bladder. If, on the other hand, it points downwards, its point of greatest inflammation, and consequently of greatest tenderness, may be attached to the ovary or to the rectum.

The only value in the McBurney point is in the attention that has been given by those who sought for it to the importance of a particular localization of tenderness and of resistance to pressure.

If it be remembered in how many different positions the appendix may lie, and that the point of tenderness may be in any part of its variable length, then it will be seen that thorough palpation of the whole right abdomen is necessary in order to exclude the presence of an inflamed appendix. Indeed, in one case which I saw in consultation this point of especial tenderness was low down and to the left of the median line. On abdominal section, the tip of the appendix was found attached to the rectum and directly under the point of especial tenderness.

But happily the usual position of the appendix is in the right iliac fossa where palpation is easiest. The smooth hollow of the false pelvis gives an even counter-pressure to the examining fingers, which should be laid almost flat on the belly wall and slowly pressed down until the even resistance of the ilium can be felt. Then by very slow and steady motion the fossa is to be explored by carrying the abdominal wall along backwards and forwards with the examining fingers. If no particular resistance or tenderness is encountered, then, after gradual release of the pressure, the fingers may be changed to another place on the surface, and so on over the whole right abdomen. If by such an examination no point of especial tenderness and of resistance is discovered, then there is no appendicitis. The converse, however, is by no means true. For when a definite resistance and an especial tenderness is localized even in the right iliac fossa, several other conditions must be considered and eliminated before making that diagnosis. Impacted fæces, movable kidney, malignant tumors, and in females enlargements of the uterine appendages also, must thus be considered. The two first named conditions, of impacted fæces and of movable kidney, ought not to escape definite diagnosis;

but only by abdominal section can a positive differential diagnosis be made as regards malignant tumors or enlargements of the uterine appendages. And, in fact, the combination of these last named diseases with appendicitis not seldom occurs.

Where there is good reason to suppose the existence of an inflamed appendix, and yet where, from unusual thickness or rigidity of the abdominal walls, its presence cannot be determined, some aid may be got from examining the belly under full anæsthesia. Still more help can be got by incising the muscular wall down to, but not through, the peritoneum. This procedure is commended to those who, not daring to open the abdominal cavity during the lifetime of their patients, retain for their own comfort the benefit of the doubt, instead of giving it, as they should do, to their patients.

In addition to these means of palpation we can employ the rectal touch, and in females the vaginal touch. Except in the rather rare instances where the appendix points directly downwards, little or no help is thus to be gained. In the diagnosis of perityphlitic abscess there is, of course, much more chance of gaining information by these routes. And indeed, after the abdominal walls are made rigid by a general peritonitis, that is often the only way of gaining information as to its cause. But let it be kept in mind that we are now considering the diagnosis of appendicitis, and not that of its sequelæ.

In order to emphasize the symptoms and signs by which this diagnosis can be made I offer the following summary.

Appendicitis begins with general pain in the abdomen, which afterwards becomes localized in the right side. This pain is constant; but is increased at times spontaneously, and always increased by palpation of the appendix and by motions of the body which disturb its relation with adjacent surfaces. It often shoots along the course of the ureter. It is generally intense. It is generally accompanied by tenesmus of the bladder and rectum and by nausea and vomiting.

There is always fever. This may be slight, but it steadily rises as the inflammation progresses until the complication of peritonitis subvenes. The inflamed appendix being larger and harder, and often full of concretions, at the beginning of the attack can be palpated. It is exquisitely tender to pressure. There is usually slight dulness on percussion directly over it.

Besides the diseases already mentioned, as simulated by appendicitis, in making the diagnosis there must also be excluded typhoid fever, perinephritic abscess, and all affections of the gall bladder and bile ducts.

It is within neither the scope of this paper nor the writer's power to set forth in full detail the processes of such eliminative diagnosis. But it cannot too forcibly be insisted that the diagnosis of appendicitis is not more difficult than that of any other local internal inflammation. This, indeed, would seem a superfluous assertion, while so many believe themselves able to diagnosticate even the particular varieties of the disease. Except by abdominal section there is no possible way of ascertaining the extent of the disease at any given time. Nor can the rate at which the inflammation travels ever be estimated with any sort of accuracy. Perforation may result in a few hours after the onset of the attack, or it may suddenly occur after many days of apparently mild inflammation. It is, therefore, puerile and ridiculous to lay down rules as to the proper day and hour for operating.

In perhaps half of the cases, perforation may not occur; but in half of these apparently recovered cases there will probably be a recurrence; and in half of these recurrences perforation is finally likely to happen. Of the cases where perforation does occur probably fifty per cent. die because of it. Such, however, would not be the sad fact if even then proper surgical treatment were generally employed.

The sum of it is that, under the present methods of treating appendicitis, in more than half of the cases consequent disasters are allowed to occur which are attended by a higher death-rate than that of pneumonia or even of diphtheria.

Were the appendix of any use, or were there danger in removing it at the very onset of its inflammation, there would be some excuse for this terrible mortality. Such, however, is not the case.

(To be continued.)

IS ACUTE POLIOMYELITIS UNUSUALLY PREVALENT THIS SEASON?

BY JAMES J. PUTNAM, M.D.,
AND EDWARD WYLLYS TAYLOR, M.D.

It was conclusively shown by Dr. Wharton Sinkler of Philadelphia, as long ago as 1875,[1] that poliomyelitis ("atrophic spinal paralysis," "infantile paralysis,") is pre-eminently a disease of the summer months of the year; and the statistics of foreign observers have proved that similar conditions prevail abroad.

An analysis of the cases observed at the Massachusetts General Hospital confirms Dr. Sinkler's conclusion, with the exception that, so far as the small aggregate numbers prove anything, they show that among us there is a greater prevalence of the dreaded affection in September than in August. The figures for 1888 to 1893, inclusive, are as follows:[2]

DATES OF ONSET BY MONTHS.

January	3 cases
February	0 cases
March	0 cases
April	4 cases
May	0 cases
June	4 cases
July	3 cases
August	6 cases
September	11 cases
October	6 cases
November	2 cases
December	0 cases

It would not have seemed worth while to report these few observations had it not been that the number of cases observed at the Massachusetts General Hospital in September and October of this year is decidedly larger than usual, and that the experience of the physicians at the Children's Hospital, and the Boston Dispensary, and the consultation practice of one of the writers, furnishes additional evidence that the disease is more than commonly prevalent this autumn, in spite of the persistence of what from the ordinary point of view would be called remarkably fine weather. If we put together these four sets of cases, and compare this year with 1892, as regards the Children's Hospital and the Dispensary, and with an average of the previous five years[3] as regards the

[1] American Journal of Medical Sciences for April, 1875.

[2] There is an error arising from the lack of statistics for November and December, 1893; but for present purposes this is unimportant. The figures would have been larger but for the fact that a number of cases were omitted on account of doubt as to the dates of onset.

[3] In 1892 there were no cases during August, September and Octo-

Massachusetts General Hospital, and add in three cases observed privately during October and November, 1893, we get the following figures:

August to November, inclusive, 1892	6 cases
August to November, inclusive, 1893	26 cases*

* In addition to the out-patient cases at the Children's Hospital, there are three acute cases in the wards which we did not count.

Of these twenty-six cases, eight had their onset in August, eleven in September, six in October, and one in November. Even if we leave out the three private cases, and admit that 1882 was an "off year" for poliomyelitis, as seems to have been the case, still it can hardly be doubted that the influences are unusually favorable for the development of the disease this year.

In 1891, similar conditions, perhaps, prevailed, since between August and November seven cases presented themselves at the Massachusetts General Hospital, the same number as this year. In 1888 there were six cases; but in 1889 only three; and in 1892, as stated, none at all. The attendance at the department during this period has been steadily increasing.

It is foreign to the purpose of this paper to attempt an analysis of the subtle meteorological influences which make the summer and early autumn months relatively so dangerous. Our main object is to lead other physicians to contribute their experiences to reinforce or counterbalance ours. It may, however, be of interest to indicate the lines of research which the facts so far gathered have marked out.

To what is the unfavorable influence of the summer due? It may be an affair of weather, as such, though obviously heat, pure and simple, is not the important factor; or the weather may act as favoring some other influence, perhaps bacterial in character. The reasonableness of this latter view is now conceded by many good observers; but it is certain that its advocates are still far from having made good their claim.

In favor of the doctrine is the fact that the outbreaks of the disease occasionally occur in distinct epidemics.[4] These so-called epidemics, however, have always happened in late summer and early autumn, and perhaps represent only exaggerated examples of the regular annual increase. It is also noteworthy that in some of these epidemics atypical and relatively virulent cases have been unusually common. Again, the occasional occurrence of acute poliomyelitis in conjunction with acute polyneuritis,[5] which is probably always of toxic, and often of infectious origin, bears out this view.

A striking case of this sort was published by one of us some years ago.[6] The evidence of the neuritis was, to be sure, only clinical in character, but the symptoms left little doubt on that score. The post-mortem examination of the patient, who died two months after being taken sick, showed the anterior gray matter to be threaded, on each side, throughout the length of the cord, with a line of inflammatory softening.

A patient, also an adult, whose case may be of similar character, is now at the Massachusetts General Hospital, under the care of Dr. F. C. Shattuck, who kindly gave one of the writers the opportunity of examining her. The atrophy affects all, or almost all, the forearm and hand muscles of both arms, but not the muscles of the legs. The onset was in August, and the symptoms seemed at first to point to a neuritis; but, later, the atrophy became so predominant, yet without being associated with any considerable nerve or muscle tenderness or impairment of cutaneous sensibility, that the diagnosis of poliomyelitis seemed probable. The case has not, however, been included in our summary.

One of the private cases above alluded to was also distinctly of neuro-myelitic character, and practically of the adult form, affecting, as it did, a young girl of twelve, who was living under the very best of hygienic conditions. This case is especially interesting from the fact that the onset was during the pleasant and cool weather of the current month.

Except for these two cases, and one case in a young child, where the initial pain was greater than usual, there has been nothing to mark the group of cases seen this year as belonging to any unusual type.

It is noteworthy, as against any strongly marked epidemic influence, that the patients did not come to any extent, from any one locality, but from different parts of the large area of the suburbs of Boston. The Charlestown and Chelsea district, however, furnished several cases. Very few of the patients came from Boston proper; and, as further evidence of the immunity of the city, it may be said that the records of the City Hospital yield but one case for this summer and autumn (onset in October), and none for last year.

In conclusion, the writers ask other physicians who have seen these interesting cases, or may see them in future, to send them brief records.

ber at the Massachusetts General Hospital, and only one case at the Children's Hospital.

Clinical Department.

A CASE OF ANGIOMA OF THE NASAL SEPTUM.[1]

BY FREDERIC C. COBB, M.D.,
Physician to Throat Department, Boston Dispensary; Assistant Physician Throat Department, Massachusetts General Hospital.

THE patient, Lizzie B., fifteen years of age, came to the Out-patient Throat Department of the Massachusetts General Hospital in October, 1892, complaining of obstruction of the right nostril and epistaxis from the same side. The duration of these symptoms was about six months. There had been no sneezing, and only occasionally a thick yellow discharge from that nostril. She was anæmic, always subject to headaches, and exhausted by the least exertion.

Her previous history, with the exception of an attack of scarlet fever, six years ago, was negative.

Examination of the anterior nares showed them to be normal on the left side. On the right side the nostril was wider, the turbinates slightly atrophic. Hanging from the septum by a thin pedicle inserted near the junction of the skin and mucous membrane

[1] Read before the Laryngological Section of the Pan-American Medical Congress, September 6, 1893.

above the end of the lower turbinated bone, was a small growth divided into two lobes by a constriction about its middle. It was soft to the probe, moved backwards and forwards on inspiration and expiration but was not seen to pulsate. At its lowest portion were a few small, black blood clots. The posterior nares, pharynx and larynx were normal.

With the aid of Hooper's snare and écraseur, the growth was removed, with very slight hæmorrhage. The base was not cauterized. The patient was given an alkaline wash, and returned two or three times until the site of the pedicle was completely healed, which occurred in about ten days.

She was examined in August, 1893, and has had no recurrence. The growth was submitted to Dr. Whitney, the pathologist to the hospital and the following report was received from him: "Growth with large vascular sinuses, with more or less round cells about — cavernous angioma."

In looking over the literature of nasal angiomata, one is struck by the lack of pathological accuracy shown by the reporters of cases. If we inquire what is the structure of angioma, we find, according to Bosworth, that it is composed almost entirely of blood-vessels held together by a slight network of connective tissue. Sutton, Ziegler, Birch-Hirchfeld and other pathologists agree with this definition. Now, if the reported cases of angiomata be judged by their pathological examinations, we shall find, I think, that a pure angioma of the nose is very rare.

The importance of pathological accuracy will be evident when we remember that the prognosis may depend upon it. Sarcomata and epitheliomata may contain small portions of nearly pure angiomatous tissue; and if such portions alone are removed for examination, they may lead to very erroneous conclusions.

The cases reported are those of Verneuil,[2] Wagner,[3] Steinbrügge,[4] Seiler,[5] Richet,[6] Roe,[7] Jarvis,[8] Vanderpoel,[8] Burckhardt,[9] Nèlaton,[10] Huguier,[11] Panas,[12] Guyon,[13] Dumenil,[14] Delavan,[15] Luc[16] and Bellows.[17]

There was no microscopical examination in seven cases, namely, those reported by Dumenil, Verneuil, Seiler, Panas, Guyon, Vanderpoel and Burckhardt. In five cases the growths contained mynomatous tissue, and are not, therefore, pure angiomata. Two of these cases are reported by Wagner, two by Luc, and one by Delavan. Three cases, those of Richet, Huguier, and one of Nèlaton's (reported by Boef), were probably fibromata rather than angiomata.

There remain only the cases of Richet (reported by Bazy), Roe, Jarvis, Bellows, Steinbrügge, and a second case reported by Nèlaton. The pathological descriptions of Richet's and Nèlaton's cases do not justify their classification as angiomata. Roe's case was undoubtedly a pure angioma, although it subsequently degenerated into an angio-sarcoma. No description of the growth removed by Jarvis is given, but only the diagnosis. The case reported by Bellows was clearly a pure angioma, and the pathological description is full and clear. Steinbrügge's case was as clearly an hypertrophy.

As a further proof of the rarity of this affection, I would say that, in an examination of 7,400 cases of nose and throat affections in the Massachusetts General Hospital records, I have found no other case.

With regard to symptoms, the only two of importance are hæmorrhage from, and occlusion of, one nostril. In all the cases reported, the most gentle examination with probe or finger caused extensive bleeding which was arrested with difficulty.

As regards prognosis, we must be cautious; since, although the danger of recurrence is not great, the tendency of such growths to malignant degeneration must be considered.

The diagnosis of pure angioma can only be made by careful microscopical examination but unusual hæmorrhage during palpation of any intra-nasal growth should lead one to suspect angioma.

In the treatment of these tumors we are met with less difficulty, since all recent authors seem to consider the snare, if slowly and carefully used, as the safest instrument. The length of time to be consumed in removal should depend upon the thickness of the pedicle. In Roe's case three hours were required for the bloodless removal of growth. Jarvis and Luc got no hæmorrhage with slow snaring, but considerable from more rapid use of the instrument. The former used his own snare and écraseur, the latter the galvano-cautery loop. In my own case I attribute the lack of hæmorrhage to the thinness of the pedicle.

Medical Progress.

RECENT PROGRESS IN OTOLOGY.

BY CLARENCE J. BLAKE, M.D.

The most striking advances in otology during the past year have been in the direction of aural surgery, and have been of two classes: those having for their purpose the radical treatment of suppurative disease of the middle ear and its complications and consequences, and those seeking to find a means for the better and more immediately satisfactory relief from impairment of hearing, annoying subjective noises, and so-called auditory vertigo.

The first class of cases, and the means to be employed for their treatment, appeal especially to the interest of the larger number of practitioners, because they include a surgical necessity which may at any time, under unfavorable conditions, become a surgical emergency, and because, in a large proportion of cases of long-continued suppurative inflammation of the middle ear, the ordinary treatment by means of syringing, dry cleansing and the application of astringents and antiseptic powders is inadequate to relief. Gradually the advance has been made from the treatment above mentioned to the use of intra-tympanic syringes and insufflators, to the use of curettes in the middle ear in a limited fashion, to the removal of the ossicles themselves when carious, and to the more thorough removal of carious portions of the tympanic walls, and

finally to the resort to the still more radical operation of reflecting the auricle forward and by chiselling away the posterior superior portion of the bony canal gaining access to the tympanic attic and the antrum.

This operation, first proposed at the Berlin Congress in 1890, by Stacke, and bearing his name, is both historically and clinically reviewed by Weismann[1] in a recently-published thesis. Following Toynbee the first carefully considered clinical report of suppuration of the attic of the tympanum, as it is now called, was published in the recent report of two cases by J. Orne Green,[2] who was followed by other observers. Bezold, in his paper on the treatment of cases of this class by means of boracic acid powder insufflation,[3] enumerates the three categories which most resist treatment as, (1) suppuration of the tympanum with osseous necrosis; (2) suppuration of the tympanum accompanying pulmonary phthisis, and (3) suppuration of the upper portion (the attic) of the tympanum. For the latter he recommends frequent lavage by means of the intra-tympanic canula or syringe, the only procedure commonly in use until Schwarze and Kessel defined the indications for, and described the method of removing the malleus and incus when themselves carious or when they obstructed drainage from the attic in cases of suppuration in that portion of the tympanum or impeded access to its diseased walls. The operation of Stacke consists in reflection of the auricle forward to such an extent as to permit access to the superior posterior portion of the osseous canal, this being removed by chiselling and the diseased cavity of the attic and antrum cleared and curetted, during which process the stapes is protected by an S-shaped hook introduced into the cavity from the front; a quadrangular flap is then formed, the soft tissues of canal tamponed into the opening made, and the auricle replaced.

Weismann offers the following conclusions to his thesis:

That suppurations of the attic are especially worthy of consideration (1) because of their insidious progress, (2) because of the important organs in their neighborhood, (3) because of the difficulty of reaching their point of origin; which reasons explain not only their gravity but their obstinacy.

The double advantage of the operation of Stacke is that it affords means of reaching the suppuration of the attic, and at the same time affords an opportunity of determining the existence of any disease of the antrum; in other words, it may be regarded both as an exploratory and curative operation.

Panse,[4] in reviewing the same subject, reports 57 cases of Stacke's operation, which he has modified in a measure by not withdrawing the membraneous portion of the external auditory canal, but, by carrying it forward, and by limiting the outer incision to the superior and posterior post-auricular region instead of carrying it further forward; the objection to these two procedures being, according to Panse, on the one hand liability to a necrosis of the outer limit of the osseous canal, and, on the other, a necrosis of the musculus attollens auriculæ. Of the 57 operations reported by Panse, cholesteatomatous masses were found in 13, and caries in 26; 34 of the cases were healed; four died; eight cases were not cured, and of these one underwent secondary operation, and one other was discharged with facial paralysis.

MacCuen Smith[5] reports 154 cases of middle-ear operations, chiefly of removal of the membrana tympani and ossicles. Of these operations 69 were in cases of non-suppurative disease of the middle ear, and were undertaken on account of marked impairment of hearing, distressing tinnitus, or vertigo. The results in these cases, as well as in those of suppurative disease, for relief of continued discharge, are stated to be excellent, although but six cases are reported in full.

Burnett,[6] who has previously reported cases of removal of the membrana tympani, malleus and incus in cases of non-suppurative disease of the middle ear, recently gives his results of operative interference in cases of auditory vertigo. "Tympanic vertigo," says the writer, "due to lesions of the middle ear, is a frequent occurrence. It is often not recognized, especially by the general practitioner, as aural vertigo. It is not unusual for tympanic vertigo to be attributed to intestinal disturbance, or to 'neurasthenia' instead of to an aural lesion. True tympanic vertigo, due to a lesion in the middle ear, chiefly from chronic catarrh of the tympanic cavity, is paroxysmal in character, and attended with tinnitus and deafness in the affected ear. It is caused by the inward pressure exerted in the labyrinthine fluid by the retracted and anchylosed ossicles. The foot-plate is thus unduly pressed into the oval window, and there held by the force made, paroxysmally, and for a longer or shorter period."

The author's theory that morbid pressure by means of the impacted stapes upon the fluid in the labyrinth is a local cause of vertiginous symptoms, was tested in an operation upon a case of chronic catarrh of the middle ear, with constant tinnitus and frequently recurring attacks of severe vertigo which had been superadded to deafness in the left ear within the previous two years. The malleus was found to be adherent to the promontory, and both this bone and the membrana tympani were removed in order to liberate the impacted stapes, with favorable results. The success of this and four subsequent operations of a like character, led Burnett to conclude that removal of the incus alone, or of the incus and stapes, the membrana tympani and malleus remaining in position, would liberate the stapes and the compressed labyrinthine fluid, as well as, or perhaps better than, total excision of the membrana and malleus, with less liability to inflammatory action.

As the result of ten operations, including among them resection of the long process of the incus, the following conclusions are drawn:

(1) That removal of the retractive force of the sound conductors upon the stapes is the efficient means of relieving the tinnitus, deafness and vertigo due to the lesions of chronic catarrh of the middle ear.

(2) That the removal of the retractive force upon the stapes can be accomplished efficiently and simply by removal of the incus alone, and even by resection of its long process.

(3) That the improvement in these cases is due to

the liberation of the stapes from the retractive power of the tensor tympani muscle and the consequent unimpeded action of the stapedius muscle, which, relieved from the antagonism of the tensor tympani, tends all the more to draw the stapes from the oval window, thus aiding in its isolation and improved mobility as well as removing the undue pressure inward upon the labyrinthine fluid.

(4) It would seem wiser, therefore, in most cases of chronic catarrhal deafness, tinnitus and vertigo, not to sever the stapedius tendon and remove the stapes, but to be content with the removal of the incus only.

(5) The progressive improvement in hearing noted in many instances must be due to the passive motion exerted upon the anchylosed stapes by sound waves, which are enabled to reach this bone more freely after the removal of the incus.

In reference to the operative removal of the membrana tympani together with the malleus and incus, Jacobson[7] describes the operation as follows: The membrana tympani, either the whole or a part, in case of perforation from suppurative disease, is incised close to its periphery, especial effort being made on the posterior portion to include the annulus tendinosus. The incision is best begun in the inferior segment, in order that the field may be kept clear from hæmorrhage, which is stilled with an application of absorbent cotton, either upon a probe or in the form of a tampon. When this has been effected, the tendon of the musculus tensor tympani is divided by means of an angular knife passed behind the long process of the malleus posteriorily and carried upward with the cutting edge in contact with the tendon; after division of the tendon, the knife is turned in the same plane backward until it comes in contact with the descending process of the incus, down which it is carried until the incudo-stapedial articulation is reached, when this is also divided, a precaution specially necessary, according to the author, in cases of anchylosis of this joint. The malleus, together with the membrana tympani, may now be extracted either by a small instrument resembling a lithotrite, or by means of a wire snare, care being taken in using the latter instrument to carry the wire loop well above the short process. When the membrana tympani is very much depressed, it has been found of advantage to thoroughly inflate the middle ear before the operation. If the operation is undertaken for the purpose of improving the hearing, the removal of the incus is, according to Jacobson, only necessary when that bone has become pathologically immobilized, but in the case of an operation undertaken for the relief of suppurative disease of the middle ear and necessitating the removal of the whole or a part of the membrana tympani together with the malleus, he advises that the incus also should be removed.

Gomperz,[8] in concluding his valuable paper on the development and condition of the question of excision of the membrana tympani and ossicula, gives a *résumé* of his personal experience in 46 cases, of whom 28 were men and 18 women. Two of the cases were between five and ten years of age, 9 between ten and twenty, 19 between twenty and thirty, 10 between thirty and forty, 5 between forty and fifty, 1 between fifty and sixty. These were all cases of suppurative disease of the middle ear treated upon a conservative basis for the purpose of determining the results obtainable without special operative interference. In 49 cases of suppurative discharge from the tympanic attic the pus made its exit in 17 cases through the membrane of Shrapnell. In 36 of the 49 cases, that is to say in about 73 per cent., the treatment by means of middle-ear syringing, insufflations and the like, resulted successfully. Ten of the cases remained under treatment but a short time (not more than a week), and then disappeared from observation, but in four of these the discharge materially decreased in that time. Three of the cases remained unimproved for so long a time that the extraction of the malleus and incus was decided upon. Setting aside 23 cases, which were considered inadequate to the question of the results of conservative treatment because of their uncertain value statistically, it was found of the remaining 26 that 23 remained healed for over a year, one was improved, and two unimproved. Of the 23 cases cured, six subsequently relapsed, — one, eight months later; two, one and one-half years; one, twenty-one months; one, four years; one, five and one-half years. Without exception, these relapses occurred in consequence of the collection of cholesteatomatous masses, after the removal of which by syringing, the ear again speedily healed. In only one of these cases was it found necessary to remove the malleus and incus, which was done with favorable results. Considering, therefore, that out of 26 cases 17 were definitely cured, the percentages would stand as follows: cured, 65 per cent.; cured, with subsequent relapse, 23 per cent.; improved 3.8 per cent.; unimproved, 7.6 per cent.

In view of his experience under the fact that after the removal of malleus and incus, the tympanic attic is likely to become the seat of epidermal accumulation, and that these are frequent causes of relapse, the author is of the opinion that the conservative method of treatment of the suppurative disease of the middle ear is not only not secondary in its value to the operative treatment, but is in advance of it.

Reports of Societies.

HARVARD MEDICAL ALUMNI ASSOCIATION.[1]

THIRD ANNUAL MEETING.

THE Association met at the Harvard Medical School at noon on June 27th, DR. J. R. CHADWICK in the chair.

The Secretary, DR. R. W. LOVETT, presented his report, showing that there were two meetings of the Council and of the Executive Committee respectively during the year, at which the committee to report on the Medical School was appointed, and arrangements for an extra *Bulletin* and for lectures by Dr. Wood, of Philadelphia, were made. The Secretary presented his resignation.

On motion, it was voted to change the title of the Association to the "Harvard Medical Alumni Association," in order that the fact that its members are graduates of the School may be emphasized.

As according to last year's rule the officers, except members of the Council, serve three years, the elec-

[1] The delay in publication of this report is due to not receiving the copy until the middle of November.

tion was for three Councillors and a Secretary, and resulted as follows:

Councillors whose term ends in 1897: Dr. Algernon Coolidge, Jr., of Boston, Dr. A. T. Cabot, of Boston, and Dr. J. F. A. Adams, of Pittsfield.

Secretary: Dr. Augustus Thorndike, Boston.

The Treasurer, DR. WALTER ELA, of Cambridge, stated that the Association, organized on April 30, 1891, now numbers over 1,100 members, of whom 13 were honorary. The members represent thirty-six States and Territories, the Dominion of Canada, and six foreign countries. More than half of the graduates of the Medical School have already enrolled themselves in the Association, which has lost 33 by death since its organization, and has added 108 new members since last year. There are 29 life members, an increase of 17. The life-membership fund, amounting to $600, is deposited in the Cambridge Savings Bank, and draws four per cent. interest, which will be considered current revenue. The Treasurer requests prompt remittance of the annual dues for 1893.

The Treasurer's Report was read and accepted.

DRS. LINCOLN R. STONE and S. W. LANGMAID presented the following report:

REPORT OF THE COMMITTEE ON THE HARVARD MEDICAL SCHOOL.

The year that has just closed has not been marked by any striking feature. The hope, the promise, of the sure success of the new four years' course held out in the report of the committee of last year has been fully realized, is an assured fact.

The entering class of 1892 had 153 new matriculants, — the largest class since 1872 with the exception of 1891, which was very large, caused, it was thought, by the fact that many came in that year to avail themselves of the last year of the three years' course. This class numbered 158 new matriculants; only five more than 1892.

The number of those with the degree of A.B., or some similar academic degree, has fallen in this year's class to 28.2 per cent. as against 53.9 per cent. in 1884. This percentage has fallen steadily from that year. In the College of Physicians and Surgeons of New York, on the other hand, the percentage of those with academic degrees has increased slightly, though perhaps this increase may be due to the decrease in the number of new matriculants. (These figures are taken from the Report of the Dean of the Medical School to the President of the University.)

The increase in the number of students is certainly a great cause of encouragement both to the Faculty and the friends and Alumni of the School. It will give them courage for the next step which they will have soon to take, — the requirement of the degree of A.B., or its equivalent before admission to the Medical School. The Law School has already made such a requirement, to take effect at the close of the year 1895–96. Even now, as was said in last year's report, the entrance examination should be made more strict, and, at least, equal to that for admission to the Freshmen class of Harvard.

In connection with this matter of having only those with an academic degree enter the Medical School, your committee cannot but feel that the time required to secure the degree of A.B. might be shortened, and some of the work in the last year at college might be in line with and count in the work of the Medical School. Or, if that is not allowed, why should not a degree be conferred if the student can, after a proper residence in college, pass the required examination and thus secure his A.B. in three years or less, and at the end of his four years in the Medical School, if he can secure his *cum laude* in his examination, take his A.M. and his M.D. at the same time? It does seem as if those students who intend to continue their studies and to enter the profession of Medicine, Law or Divinity, should not be compelled to spend so much more time, and to wait four years for a degree that they might secure in three; for time to them is more important, to say nothing of money, than to those who intend to go into business or devote themselves to a life of leisure after finishing their undergraduate life.

There have been some changes in the Faculty; notably the resignations of Professors Knight and Cheever. The resignation of Dr. Cheever calls for more than the mere mention of the fact. He has been connected with the School since 1861: first, as Demonstrator of Anatomy, in 1868 Adjunct Professor of Clinical Surgery, in 1875 Professor of Clinical Surgery, and Professor of Surgery since 1882. The ability, the thoroughness, the conscientiousness of his work is too well known to all to require further comment. He has given additional honor to a chair already distinguished by a Warren and a Bigelow. He has well earned his title of "Emeritus." May he live long to enjoy it!

Of the work of the School in its different departments, there is not much to be said; certainly nothing in the way of criticism.

In Anatomy, there has been an ample supply of material for dissecting, and in the lecture-room, to illustrate the bones, models made of paper pulp of remarkable accuracy and lightness are used. This collection embraces upwards of twenty models, representing all the principal bones of the body, enlarged from three to six diameters, and in addition, quite recently, a model of the base of the skull and face, enlarged six times, has been furnished. This collection supplies to the anatomical department almost unrivalled facilities for teaching osteology in a large lecture-room. In the dissecting-room, too, there are marked evidences of activity and progress. The work of the student is carefully noted, and he is encouraged to make careful observations and to note all anomalies in anatomical structures and relations, and his discoveries are preserved and become part of the anatomical history which is being made.

In Histology and Embryology, in Chemistry, Pathology and Bacteriology, the same activity is seen; earnest and active work on every side, and the capacity of the different laboratories stretched nearly to their utmost.

In Physiology, Associate Professor Howell, on whose appointment only a year ago the Committee on the Medical School were congratulating the Association, and whom the School is now to lose by his call to the chair of Biology at Johns Hopkins, has conducted some experiments in advanced work in the physiological laboratory, which seem to be of sufficient interest to speak of at some length, especially as he has finished his duties here. One series of experiments had for its object the determination of the relation of the calcium salts to physiological irritability. The experiments were made in part upon the heart (of cold-blooded animals) and in part upon nerve

fibres and voluntary muscle. With regard to the former, it was found that a heart supplied with blood from which the calcium salts had been removed by precipitation, was entirely unable to beat. The blood circulating through the heart, in this case, had the normal amount of proteids. If a small proportion of calcium chloride solution was added to the blood, the heart immediately began to beat with normal vigor. On the other hand, it has been shown that a heart fed upon an inorganic diet, calcium salts, *plus* a certain proportion of potassium and sodium salts, will beat as well as though supplied with blood for many (at least thirty) hours. The general conclusion is, that calcium salts are necessary in some way for the development of the internal stimuli which cause the heart-beats. With reference to nerve fibres and voluntary muscle, it was likewise found that the presence of calcium salts is necessary for functional activity. A muscle deprived of calcium will, however, go into *rigor mortis*, thus tending to disprove the theory that this latter phenomenon is essentially similar to a muscular contraction.

A second series of experiments was made to test the validity of a recent theory of blood coagulation. The theory assumes that the fibrin of the clot is essentially an insoluble compound of calcium with one of the proteids of the blood. The object of the experiments was to determine whether fibrin formed under various conditions contains always the same proportion of calcium. It was discovered that the proportion of calcium may vary within wide limits, thus indicating that the theory above stated is incorrect, although the presence of calcium or of strontium or magnesium salts is necessary to the formation of the clot.

In a third series of experiments a careful study was made of the effect of cold and heat upon the different varieties of nerve fibres found in the body, with especial reference to the degree of heat or cold at which the conductivity of a nerve may be suspended without permanent injury to it. It was found that nerve fibres of different physiological activities, though contained in the same nerve trunk, reacted quite differently in this regard. The work gives promise of developing a new method of isolating the different physiological varieties of nerve fibres, especially those contained in the sensory trunks.

In a fourth series an effort was made to learn something of the degeneration and the regeneration of vaso-motor and sweat fibres in cases of section and suture of nerve trunks to the limbs. The sciatic nerve of a cat was chosen for experiment. The work is not completed. As far as it has gone it indicates that in regeneration of nerve trunks the motor and sensory fibres regain functional activity before the vaso-motor and sweat fibres, the latter belonging to the class of non-medullated fibres. No previous work seems to have been done upon this point.

Your Committee, while acknowledging that the work of the School is so good, that the teaching of the Theory and Practice of Medicine and the Clinical Instruction is of the best, still feel that it may be open to question whether there could not be more use made of the great abundance of clinical material offered by the Boston Dispensary and private dispensaries and hospitals. The out-patients' rooms of the Massachusetts General Hospital and City Hospital, and the Boston Dispensary, show about 100,000 out-patients a year, and in the wards over 10,000 are treated, not including in this estimate the Eye and Ear Infirmary, the Carney, or other small or special hospitals. Of course, both medical and surgical cases are included in these figures. All of the upper classes of students have opportunity to act as assistants to the house-officers or to the surgeons or physicians to out-patients; and are instructed in the surgical rooms in bandaging and minor surgery. In the medical cases diagnosis and treatment are taught, but, of course, in a more or less hasty way — a "snap" diagnosis often being all that there is time for. The cases, too, are generally chronic, often dyspeptic. Of course, in addition to this comes the work done under the eye of the different professors or of the clinical teachers in the wards and in the lecture-rooms.

Without in any way attempting to disparage the value and importance of this teaching — on the contrary, sure of its usefulness and necessity — they cannot but feel that there is room for more and better work where the student is thrown upon his own resources under the general direction of some physician. It seems to your Committee possible to have students from the third and fourth classes take charge of a certain number of patients who otherwise would be treated by the district dispensary physicians. They might be directed to call in such physicians in cases of emergency, and report to him all the facts of the case. What an advantage to the student to see the early stages of disease, to make his diagnosis and direct the treatment of some acute case upon his own responsibility! Why not have this a compulsory part of his work (as in the obstetrical department, where he is compelled to have attended, at least, six cases of confinement), and to submit a full report of each case he has had the care of — diagnosis, treatment and temperature chart — to the clinical instructor of the class?

But it hardly seems necessary to enlarge upon the subject; to state it, is enough to commend its immediate adoption. That there may be difficulties is possible, but they can undoubtedly be overcome. On the part of the patient, it does not seem as if there would be any objection. If there is no trouble in finding women who are thankful to trust themselves to the care of a student while in labor, it does not seem possible that they would refuse similar service while they or some of their families are sick with measles, pneumonia, diarrhœa or consumption. With this, or something like this, added to the present methods of instruction, the Harvard Medical School will give to its students an education that combines, to a degree not yet attained in other medical schools, the best theory with the practice of medicine.

The course of six lectures by Prof. H. C. Wood, of Philadelphia, provided by this Association, excited a good deal of interest and was well attended. By his graphic style he held closely the attention of his audience while speaking simply of the dry details of certain well-known articles of the Materia Medica. It would be wise, undoubtedly, to have a similar course another year on some special subject of medicine or surgery.

The suggestion in last year's report on the Harvard Medical School, of giving additional importance to the department of Materia Medica and Therapeutics, including with it Hygiene in its broadest sense, and having at its head a man of "broad culture" and sound experience, meets with our hearty approval.

To secure such a man the School needs money, — it needs money, too, in all the other departments, — endowments large enough to enable the School to have the best men to be found, and to pay them salaries that will enable them to live without having to do outside work, which, of course, in many cases hinders them from doing the best they can in their special line of work. Then, too, with the growth of the School, with the new demands for biological, bacteriological and physiological laboratories, the expenses of the School increase in a much greater ratio than its resources. It is a cause for regret that the graduates of the Medical School, as well as those of the Law and Divinity Schools, are still denied a voice, or vote, rather, in saying who should govern them.

THE DINNER.

The annual dinner was at the Hotel Vendome, at one o'clock. About one hundred and sixty-eight members were present.

The President, DR. J. R. CHADWICK, opened the speaking with an address referring to the success which has attended the adoption of the four years' course at the Harvard Medical School. Gratifying as the increase of students is, he pointed out that the additional year calls for increased clinical opportunities, and these can hardly be supplied without a hospital under the absolute control of the Faculty. "That some friend or friends of the Medical School will endow such an institution must be," he said, "the aim of our hopes and efforts." Dr. Chadwick then spoke of the recent vote in the Board of Overseers against extending the franchise:

"I have said that in the early universities the degree in Arts was a prerequisite for admission to the other Faculties. This is not the case with us, although its desirability is not questioned. The last report of the Dean of the Harvard Medical School contains a table showing that, since 1884, the proportion of students entering the School who are graduates either of colleges or scientific schools has steadily declined until now they represent only 28.2 per cent., a little more than half the ratio of 1884, when it stood at 53.9 per cent." After attributing this difference to the policy which has so raised the requirements in the Academic Department as to deter aspirants for professional degrees from seeking the A.B. first, he continued: "This might truly be called, in phrase of medical terminology, a *boomerangoid* policy. While this is the most important reason for our seeking to have the suffrage in the election of Overseers extended to the alumni of all the departments of the University, I wish to call your attention to two instances of definite injustice under which the Medical School is suffering under the present government.

"In 1772, Dr. Ezekiel Hersey, of Hingham, gave the sum of $1,000, the interest of which was to be appropriated to the support of a Professor of Anatomy and Physic. In 1790, the widow of Dr. Hersey bequeathed the sum of $3,353.95 to the support of the same professor. In 1794 or 1795, Dr. Abner Hersey, of Barnstable, bequeathed £500 'for the encouragement and support of a Professor of Physic and Surgery.' In 1792, a legacy of £400 was left the College by John Cuming, of Concord, the income of which was for the 'Professor of Physic.' In 1812, Esther Sprague gave $2,000 'towards the support of the Professor of the Theory and Practice of Physic.' It is admitted that these funds were given 'to promote medical education as a matter of distinctive professional training.' How do you suppose the income of these funds is used? Two-fifths is allotted towards paying the salary of the Hersey Professor of the Theory and Practice of Physic in the Medical School, while the other three-fifths goes to pay the salary of the professor in the Museum of Zoölogy, who gives no instruction 'to promote medical education.' The Medical School has repeatedly made a claim for the use of the whole income of these funds to the Corporation, and at least once to the Board of Overseers, invariably without success.

"Secondly. You all know that the University Library has large special funds for the purchase of books for the use of the professors and students; that books are purchased on demand of the professors and sent to the different laboratories and departments for immediate use, and are recalled to the central library as soon as their immediate usefulness has passed. The claims of the Medical School to participate in this privilege have been persistently ignored.

"With such instances of injustice, narrowness and partisanship, it behooves all the professional schools to unite in making the extension of the suffrage in the election of Overseers the chief qualification of candidates for that Board."

Dr. Chadwick then alluded to the gift by Miss Lucy Ellis, of $2,000 annually for five years to the Department of Physiology and Pathology, and of a $100 scholarship bequeathed by the late Dr. O. W. Doe, '65, he also spoke of the extra *Bulletin* issued by the Association, and of the lectures by Dr. H. C. Wood, of Philadelphia.

DR. DA COSTA, of Philadelphia, spoke on medical education, which, he said, is a matter of constant dispute and agitation because medicine itself is a most progressive science.

"The chief difficulty in making a high standard universal lies in the number of the medical colleges. It is, indeed, a sorry admission that the medical schools in this country are the greatest enemy to medical progress, not in themselves but in their number. Some years ago there were nearly three hundred; now there are not far from one hundred and fifty, and they are dying at about the rate of three a year, without, it must be said, many mourners. A further reduction would be a national benefit. The remedy lies in their amalgamation. Let the absurdity cease of small towns having three, four or six of these struggling institutions, no one of which can have a vigorous life.

"There is now all over the country a growing disposition for the universities to take charge of medical teaching and to develop their medical departments with all the zeal they give to the others. We see it in Michigan; we see it in California and Colorado; we see it in Louisiana and Texas as strikingly as in our Eastern States. There is nothing but good in this. The power, the means, the spirit of the university go out to its branch; the university in turn gains by the reputation of its medical faculty, and by the recognition that medicine is an essential part of the new learning which leads on to the highest attainable civilization."

Dr. Da Costa then spoke in favor of exacting more stringent educational requirements for matriculation. He said that 129 out of 148 medical colleges in the United States and Canada have adopted some standard

of general qualifications; and even where the requirements are shadowy, they still indicate a move in the right direction. The country is not yet ready to have medical colleges demand of their students a degree in Art or in Science. The universities, he urged, must shorten their course, and in every way offer facilities to those who wish to study medicine. He gave some figures to show how rapidly the proportion of Bachelor of Arts has decreased in the leading medical schools, but he asserted that the average mental training of medical students is higher than ever; and he said that our American colleges must learn the system of the German universities, at which, during the past fifty years, only 23.1 per cent. of the students have been over twenty years old. He gave warning against trying to put too many subjects in the curriculum. "The medical student cannot master them all. . . . Teach some subjects thoroughly, and let the rest alone. . . . Allow him, after the first year, to choose for himself much more than he is now permitted to, with full knowledge of the subjects required at the final examination."

Dr. Da Costa also spoke of the need of large endowments; but most important, he said, are great teachers. "Who goes to Paris without thinking of Lænnec, Andral, Trousseau and Nèlaton? Who visits Vienna and does not have before him Rokitansky, Skoda and Oppolzer? Who can go to Berlin and not think of Langenbeck and Frerichs, or to London and be unmindful of Hunter, and Cooper, and Bright? Who comes to Harvard and does not remember the Jacksons, and Bowditch, and Bigelow, and Clark, and Ellis, and Storer, and Shattuck, and many others of fame?" He closed with a tribute to Dr. Holmes, and with a prognostication of progress at Harvard.

Dr. Abraham Jacobi, Professor of Children's Diseases in Columbia College, was next called upon. He pointed out the great influence which the profession at large, apart from instructors in the medical schools, has wielded in advancing the standard of medicine. Averting to the general requirements demanded of would-be medical students, he said that no academic examination in general education should be passed after matriculation, because after matriculation all the student's time should be devoted to his medical studies. He recalled how the general course has been lengthened by the addition of laboratory and clinical work. "We have too many schools, too many doctors, too many students. We can do with fewer doctors provided the quality of both the doctors and the people will continue to improve. We are, as a profession and a teaching body, responsible for the condition of things, medical and hygienic, which concern the State, the people at large and mankind."

Dr. Jacobi then related how in Germany, the medical students who graduated with honors were kept in the large cities, while the others went out into the provincial towns and villages. He spoke of the subjects to be studied in the fourth year of the extended course — clinical teaching, embryology, the history of medicine itself (which has been sadly neglected) and legal medicine and medical jurisprudence. He predicted that men would learn to think more quickly. He concluded by describing the different ways in which professors get their appointments, and the service done by the humbler practitioner not less than by the most brilliant original investigator.

The last speaker was Prof. W. S. Chaplin, Chancellor of Washington University, St. Louis. He announced that St. Louis has eleven medical schools and that this excessive number is due to the fact that the people do not understand what science, education, culture mean. It is also convenient for a specialist, he said, to make known the fact that he is a specialist by advertising himself as a professor in a medical school. He then gave an illustration of the worthy self-sacrifice of the professors in one of these very schools. The people of the West, he remarked in closing, are quick to learn, and as soon as they see examples of first-rate medical schools in the East, they will be certain to imitate them.

AMERICAN OPHTHALMOGICAL SOCIETY.

Twenty-ninth Annual Meeting at New London, Conn., July 19 and 20, 1893.

The Society was called to order by the Vice-President, Dr. George C. Harlan, of Philadelphia, Pa.

THE RELATION OF THE PATELLAR-TENDON REFLEX TO SOME OF THE OCULAR REFLEXES FOUND IN GENERAL PARALYSIS OF THE INSANE,

by Dr. Charles A. Oliver, Philadelphia.

The following formulations were offered:

(1) In some of the cases in the second stage of the disease, especially where the patellar-tendon reflexes were unequally exaggerated, there appeared to be an irregular and unequal spastic enervation of the two irides, causing irregularities in pin-point pupil forms.

(2) In a few cases, especially in the third stage of the disorder, where the patellar-tendon reflexes were unequally diminished, the pupil-size though small and its shape though somewhat irregular, seemed to be but little acted upon by any powerful mydriatic.

(3) In many cases, especially in comparatively young subjects in the third stage of the disease where the patellar-tendon reflexes were unequally diminished there appeared to be an unequal paralytic ennervation of the two irides; the pupillary dilatation manifesting itself at times, though not as a rule, in the eye with the greater amount of objective optic-head degeneration and retinal change.

(4) In a few cases (especially in men beyond middle life) in the third stage of the disorder, where the patellar reflexes were markedly diminished and where the ataxias were quite pronounced, there were marked temporary assymetries of pupillary form, one often being quite small and irregular for several examinations, whilst its fellow was large and ovoid or oval.

(5) In quite a number of cases, especially in the advanced stages of the disease (although seen in a number of cases in their earliest stages) where the patellar-tendon reflexes were unequally exaggerated or diminished, there was a failure of the irides to respond to even major degrees of light stimulus; this being true not only for those subjects exhibiting a true spastic myosis but more especially shown in those instances where with partial dilatation of the pupil, mydriatics failed to act.

(6) In many instances, especially in the older cases where the patellar-tendon reflexes were, as a rule, unequally diminished or even lost, there was not only failure of iris-response to the strongest light stimulus carefully thrown upon the retina, but where obtainable, the irides seemed to fail to react to the various

coarse and rough subjective and objective procedures necessary to be used in order to evolve both separated and associated efforts for accommodation and associated efforts for convergence.

(7) In some instances, where ciliary muscle innervation could be satisfactorily obtained, both the spastic excitation and the paralytic enervation at times found by subjective reading tests and objective study with the retinoscope, seemed to be in direct ratio with the patellar-tendon reflexes as the iridic changes.

(8) In quite a number of cases where there was marked inequality of the pupils with more or less want of reaction of the irides to light stimulus the patellar-tendon reflex on the side of the larger pupil seemed to be the one the more greatly diminished.

(9) In a number of instances, especially during the very earliest stages of the disease, where the patellar-tendon reflexes were beginning to lessen to unequal degrees, there often appeared momentary secondary ataxic dilatation of the pupil during exposure to strong light stimulation.

(10) In many cases, especially during the second stage of the disorder, when the patellar-tendon reflexes began to become irregular and inconstant, pupillary inequalities as expressive of unequal iris innervation and action, became more and more constant.

CLINICAL HISTORY OF A CASE OF SPINDLE-CELLED SARCOMA OF THE CHOROID WITH A STUDY OF THE MICROSCOPIC CONDITION OF THE GROWTH,

by DR. CHARLES A. OLIVER, Philadelphia.

The patient, a man thirty-four years of age, consulted the writer on account of trouble with the left eye. Five years previously he suddenly noticed that objects situated to the right became dimmed when he attempted to look at them with the left eye. This gradually and painlessly extended over the whole field of vision until in a little more than three years the eye became blind.

In June, 1890, a tumor of the choroid was discovered by Dr. J. H. Thompson, of Kansas city. There was a history of syphilis but treatment had no effect upon the growth and a diagnosis of sarcoma was made and operation urged but not accepted.

When seen by the writer in June, 1892, a large vascular growth was seen in the upper part of the globe. Immediate enucleation was advised and accepted. The operation was done the following day. The patient has recently been seen and is perfectly well with no evidence of return.

Microscopical examination showed the growth to be a spindle-celled sarcoma.

SARCOMA OF THE CHOROID,

by DR. EMIL GRUENING, of New York.

The patient, a woman aged thirty years, was seen April 17th on account of diminution of sight in the right eye. The ophthalmoscope showed the retina in the macular region pushed forward. This projection was about four discs in diameter. This had given rise to no symptoms with the exception of a scotoma. Sarcoma was diagnosed and the eye was removed. Examination showed the growth to be a spindle-celled sarcoma.

SARCOMA OF THE EYE-LID,

by DR. EMIL GRUENING, of New York.

This affection is exceedingly rare, the case reported being the only one seen by the author. The patient was a young man twenty-three years old. He came under observation January 1, 1893. Five years previously he had noticed a small swelling in the lower lid of the right eye. This bled freely and irregularly. It was operated on in another city but soon recurred. When seen it was as large as a hazel-nut and involved two-thirds of the lid with a nodular mass on the inner surface of the lid which readily bled. The skin covering the mass was freely movable. A small portion of the growth was removed and found to be sarcoma. The tumor with the entire thickness of the lid was then removed and the lid restored by a plastic operation.

DR. H. KNAPP in the discussion reported two cases of traumatic sarcoma of the lid, both terminating fatally.

TUMOR OF THE IRIS, PROBABLY TUBERCULAR,

by DR. GEORGE C. HARLAN, Philadelphia.

The patient, a male child, was born September 5, 1890. In February, 1893, weakness of the right eye with photophobia and lachrymation was noticed. The child was first seen March 6, 1893. There was some conjunctivitis but no chemosis. There was a small posterior synechia. A number of small yellowish-white rounded nodules were noticed on the periphery of the iris. These increased rapidly in size and others were added. The deposit increased rapidly and soon filled the upper outer third of the anterior chamber and completely covered the pupil. Intense photophobia of the sound eye developed and enucleation of the diseased eye was done March 15th. After the operation the condition of the child rapidly improved. Microscopical examination indicated that the lesion was probably tubercular although bacteriological examinations gave negative results.

REFLECTIONS UPON A DISASTROUS CASE OF OPHTHALMIA NEONATORIUM,

by DR. B. ALEX. RANDALL, of Philadelphia.

Dr. Randall referred to the great importance of strong clear-cut expressions in relation to preventable disease in order that the community and the profession may be properly aroused to the dangers of the situation and spurred to thorough and persistent efforts to combat them. Yet such expressions have danger to those using them and to others, since careful precautions may fail to prevent the disease or bring it to a successful termination. This point was brought painfully home to him by a disastrous case of ophthalmia neonatorium in which he could find no fault with the prophylactic or the therapeutic measures, yet both eyes were lost. Some authoritative statements as to the preventability and curability of the disease were repeatedly called to the attention of himself and the accoucher. He wished to protest against too uncompromising claims as to the powers of medical measures since such may be two-edged weapons which turn most seriously against their authors or other medical men who have really done all that human means could effect.

CLINICAL NOTES ON SOME REFRACTIVE AND MUSCULAR CASES,

by DR. B. L. MILLIKEN, Cleveland, Ohio.

In very high degrees of astigmatism the use of the ophthalmoscope is the most satisfactory method of testing refraction. Six cases were cited where attempts were made to correct by the ordinary means of

testing with no satisfactory results while the ophthalmoscope gave most excellent correctness. In one case, a lad of thirteen years with history of fronto-temporal headache for years, had a high degree of mixed astigmatism in the left eye which under a mydriatic gave no satisfactory results, but with the ophthalmoscope the following was obtained, the right eye having only a moderate degree of astigmatism:

O. S. + 4 D. cylinder axis 20° ⌒ 4 D. cylinder axis 110°. V = $\frac{6}{6}$.

This glass with the proper arc for the right eye gave great relief and has been worn with comfort.

In another case, that of a man aged thirty-nine, there was high mixed astigmatism in both eyes and especially marked in the right eye which with a mydriatic had to be worked out with the ophthalmoscope and gave the following:

O. D. — 10 D. cylinder axis 90° ⌒ + 7 D. cylinder axis 180°. V = $\frac{6}{6}$.

O. S. — 6 D. cylinder axis 100° ⌒ + 4 D. cylinder axis 10°. V = $\frac{6}{6}$.

These glasses have been worn constantly for two years with the greatest comfort, the man working all day at book-keeping. The ophthalmometer showed great irregularity in the images and could not be used with any accuracy in testing the refraction.

Several cases were reported showing what could be done with prisms in correcting muscular insufficiencies and the question was brought out as to the advisability of wearing prisms at various angles for the purpose of correcting both a lateral and a vertical muscular insufficiency with the same glass; for instance, in a case of a lateral insufficiency of say 1° and a vertical insufficiency of 1°, instead of making two prisms to correct, one at 90° and the other at 180°, place a 2° prism at 45° or 135°, right or left, as the case might be. The histories of several cases of this kind were given in which patients had worn the glasses thus with much benefit, and a trial of this kind was urged.

SEVERAL CASES IN WHICH THE VERTICAL DIPLOPIA TEST PROVED UNTRUSTWORTHY,

by Dr. Samuel Theobald, Baltimore.

Four cases were described in which the cover test showed a high grade of exophoria, both in distant and near vision, but in which the vertical diplopia test failed entirely to demonstrate the presence of the condition, in some of the cases even indicating esophoria. In one of these cases and also in a case of esophoria, the notes of which were given, it was found that when, during the application of the vertical diplopia test, the cover test also was employed, a squint would show itself in the excluded eye, which the vertical prism failed to bring out, and which would disappear upon the removal of the cover, though the vertical diplopia was still maintained, showing that the latter had no controlling influence over the action of the lateral muscles. The cases, such as described, in which the vertical diplopia-test proved untrustworthy are, however, comparatively rare and the writer still employs it daily and considers it of the greatest value.

AN ADDITIONAL NOTE IN REFERENCE TO THE CASE, USEFUL VISION MAINTAINED BY MEANS OF A TOTALLY DISLOCATED LENS, HERETOFORE REPORTED TO THE SOCIETY,

by Dr. Samuel Theobald, of Baltimore.

The feature of interest was that a fragment of the dislocated lens, the capsule of which had ruptured two years before, fell through the pupil into the anterior chamber where it remained for six months, resisting the solvent and opacifying action of the fluids of the eye so completely as to retain its transparence and its sharply cut angle. It closely resembled a bit of yellowish glass and might easily have been mistaken for a foreign body. As its presence in the anterior chamber began to cause considerable irritation, the pupil was dilated and it was caused to fall again into the vitreous chamber, its return to the anterior chamber being prevented by the application of a myotic. This was followed by the disappearance of the irritation which has not since returned. The insolubility of the lens fragment is the more remarkable in view of the fact that the patient was but twenty-two years old at the time the lens capsule ruptured.

A SERIES OF WOOLS FOR THE READY DETECTION OF COLOR BLINDNESS,

by Dr. Chas. A. Oliver, Philadelphia.

The following modification had been made by the writer in the Holmgren series.

Five individual tests are employed, pure green, pure red, rose, pure blue and pure yellow. Loose and separate skeins of wool were employed. The colors were made of equal relative intensity. The value of the color used in each test skein was expressed. The set was so constructed that it could be used by any intelligent layman.

The test was so constructed that passing color changes could be preserved and permanently kept for future comparison, and so that written and verbal expressions of the character and the amount of the sub-normal color perception could be given. The wools were made of one grade of manufacture and dyed with vegetable material.

After several years' trial the writer found that he could dispense with all but the five principal test skeins, five pure match skeins and eighteen confusion skeins of relative equal value to the pure match skeins.

AFTERNOON SESSION.

GOUTY RETINITIS, CHORO-RETINITIS AND NEURO-RETINITIS,

by Charles Steadman Bull, M.D., of New York.

The paper was based upon a study of the retinal changes found in over one hundred cases of gouty patients. Five of these cases (two with autopsy) were reported in detail. The points to which attention was drawn were:

(1) The changes in the fundus are always bilateral though rarely symmetrical in the two eyes.

(2) The degeneration in the walls of the blood-vessels and in the retina cause marked impairment of central vision, little or no impairment of peripheral vision, and never end in blindness.

(3) The loss of central vision is always progressive up to a certain point, unless the cause of the disease is recognized early in the outset and immediately and properly handled. Improvement of the vision after the disease is established cannot be expected.

(4) Hæmorrhages into the retina are rare except in the beginning of the disease. Their absence later is probably due to the fact that the strength of the vascular wall is increased by the deposit, though its elasticity is diminished.

(5) The most marked feature in the fundus is the development of the arterio-sclerosis and phlebo-sclerosis. This is seen by the ophthalmoscope in the vessels of the retina and the microscope shows that the degeneration exists as well in the vessels of the choroid and optic nerve.

(6) Another almost equally pathognomonic symptom is the peculiar yellowish granular exudation in the retina, located by the ophthalmoscope around the posterior pole of the eye and generally leaving the macula intact and proved by the microscope to be mainly in the nerve-fibre layer, though found in all the layers except that of the rods and cones.

(7) The changes in the optic nerve-fibres seem to be almost entirely intra-ocular and cannot be traced for any great distance back of the eye-ball.

RETINITIS PUNCTATA ALBESCENS,

by DR. MYLES STANDISH, Boston.

These cases are not uncommon, yet the literature of the subject is surprisingly small for a condition which presents such a striking picture to the ophthalmoscope. The majority of cases come on account of some discomfort in the use of the eyes, and the white rounded, glistening spots are discovered in the retina in the course of the examination. After a time, comfort in the use of the eye returns, but without the spots disappearing; what the substance is that produces the appearance is undetermined. A case was reported which was of special interest as it apparently filled out the clinical history of these cases in the predromal and acute stages.*

REMOVAL OF HARD CATARACT BY SUCTION,

by DR. LUCIAN HOWE, of Buffalo.

It is probable that every operator has occasionally experienced difficulty in completing the final act of extracting the lens. In order to obviate this difficulty, the writer had employed an instrument similar to a large dropping-tube, by means of which a partial vacuum could be made. The tube was applied to the protruding lens, enabling the operator to draw it out.

DR. FRANK W. RING, of New York, exhibited an

OCULAR MASK OF PAPIER-MACHE

to be used for the protection of the eye after cataract operation.

THE ARTIFICIAL RIPENING OF CATARACT,

by DR. EDWARD JACKSON, Philadelphia.

A series of cases were reported which had been treated by tapping the anterior chamber, drawing off the aqueous humor, and massage of the lens, through the cornea as suggested by Pooley and advocated by White.

The operation was followed by very little reaction; there being no iritis or posterior synechia in any case. In patients over fifty years of age, the operation was followed by rapid increase in the opacity of the lens and early maturity of the cataract. In patients under thirty-five years of age no effect upon the existing lens opacity was produced.

The author concluded that this method of ripening cataracts was certainly more efficient than that of Forrester — iridectomy and massage; was almost entirely free from danger, and was probably a better means of avoiding prolonged practical blindness than the extraction of the immature cataract.

A CASE OF TRAUMATIC DISLOCATION OF THE IRIS UNDER THE UNBROKEN CONJUNCTIVA, THE EYE DAMAGED BUT PRESERVED, TYPICAL SYMPATHETIC OPHTHALMIA IN THE OTHER EYE,

by DR. HERMAN KNAPP, of New York.

Mr. M., forty-five years old, came under observation December 21, 1892. Ten days before, his left eye had been struck with the head of a small pet dog with which he was playing. The eye had been red and black ever since, but not painful, the sight impaired. On the inner side of the cornea and two millimetres from its margin the conjunctiva was raised by a black mass, which proved to be the iris. The conjunctiva showed no wound or scar; the whole iris was found absent from its normal position; the lens was in place and transparent; there was no neuro-retinitis or isolated rupture of the choroid. Vision equalled $\frac{15}{200}$. The patient was directed to bandage the injured eye lightly, and not use the other eye, and keep quiet. Everything did well until twenty-nine days after the accident when symptoms of sympathetic inflammation appeared in the right eye. Under active treatment, the attack subsided, but relapses occurred, and vision in the right eye was completely lost. In the left eye vision equals $\frac{20}{70}$, and the displaced iris has shrunken to a flat blackish mass scarcely raised above the conjunctiva.

(To be continued.)

Recent Literature.

On the Chemistry and Therapeutics of Uric Acid, Gravel and Gout. Being the Croonian Lectures for 1892, delivered before the Royal College of Physicians of London. With additions. By SIR WILLIAM ROBERTS, M.D., F.R.S. London: Smith, Elder & Co. 1892.

In these four lectures, which should have received earlier notice, the author gives the results of an elaborate investigation of the chemistry of uric acid, gravel and gout. The principal conclusions arrived at concerning the occurrence in the body of free uric acid and urates in the physiological and in the pathological state are:

(1) That free uric acid is not known physiologically; neither in the body nor in the urine. It is known clinically and pathologically as crystalline sediments in the urine, and as gravel and calculus in the urinary passages.

(2) That neutral urates are not known physiologically nor pathologically.

(3) That bi-urates occur pathologically as components of gouty concretions in the tissues; that they are known in the urine only after this secretion has undergone ammoniacal fermentation; and that it is doubtful if they ever exist physiologically in the blood or tissues.

(4) That the quadri-urates are specially the physiological combinations of uric acid; that they exist normally in the urine and probably also in the blood; and that all the morbid phenomena due to uric acid arise probably from secondary changes in the quadri-urates.

There is an inherent tendency in normal acid urines to the liberation and precipitation of uric acid. Pathological gravel may, therefore, be regarded as due to an exaggeration of conditions which prevail, in a less pro-

nounced degree, in the normal state. The conditions of the urine which tend to accelerate the precipitation of uric acid are, the author concludes, high acidity, poverty in salines and in pigments, and high percentage of uric acid. And, conversely, the conditions which tend to postpone precipitation are — depressed acidity, richness in salines, richness in pigments, and low percentage of uric acid. On the interaction of these factors the occurrence or non-occurrence of uric acid, gravel appears to depend; and the most important of these factors is the grade of acidity.

When concretions are once formed in the kidneys or bladder, there is little prospect, in the author's opinion, that they can be dissolved by imparting solvent qualities to the urine. Good results may, however, be expected in the field of prophylaxis. The paramount indication of preventive treatment is to diminish the acidity of the urine by the administration of alkalies or alkaline mineral waters.

The author accepts the view that bi-urate of sodium in the crystalline form is the essential constituent of the chalk-like deposits found in certain parts and tissues of the body in cases of gout, and that the deposition of this substance is the actual cause of the joint troubles of gout. He formulates the following general theory of urate precipitation. In the normal state, uric acid circulates in the blood as quadri-urate, and is finally voided as such with the urine. But in the gouty state, either from defective action of the kidneys, or from excessive introduction of urates into the circulation, the quadri-urate accumulates in the blood. There, circulating in a medium which is rich in sodium carbonate, it gradually takes up an additional atom of base, and is thereby transformed into bi-urate, which is less soluble, and probably, also, less easy of removal by the kidneys. The bi-urate thus produced exists at first in the hydrated or gelatinous modification. But with the lapse of time and increasing accumulation it passes on into the almost insoluble anhydrous or crystalline condition; and then precipitation of it becomes imminent, or actually takes place.

The mechanical theory seems to the author to offer the most natural and complete explanation of the phenomena of regular gout. He does not accept the theory of a poisonous action which has been brought forward in explanation of the phenomena of irregular gout. He is inclined to attribute the latter also to the local action of slighter precipitations of urates upon the membranes of the brain or upon the fibrous sheaths of the nerve-roots.

In the consideration of the therapeutics of gout, the author recommends restricting the ingestion of nitrogenous food, and increasing that of vegetable food. The latter has no direct influence on the production of uric acid, but the free consumption of articles of vegetable origin tends to restrict the in-take of nitrogenous food, and thus has indirectly the effect of diminishing the production of uric acid. His experiments show that sodium chloride, even in very small quantities, always appreciably hastens the precipitation of the crystalline bi-urate. He therefore recommends gouty patients to restrict, as far as practicable, the use of common salt. In discussing the use of mineral waters, the author holds that gouty persons should entirely avoid waters which owe their activity to sodium salts, or should use them very sparingly, since sodium salts hastens the precipitation of sodium bi-urate. Waters which contain but a small quantity of mineral ingredients are the most useful. These act to dilute the blood, and lower its percentage of urates and sodium salts.

Carbonate of lithium and piperazine have been recommended for use in the treatment of gout on strictly chemical grounds. The author's experiments show that the addition of these substances to blood-serum or synovia had not the slightest effect in enhancing the solvent power of these media or sodium bi-urate; nor the slightest effect in retarding its precipitation from serum and synovia artificially impregnated with uric acid. Their beneficial action, if any, is not due, therefore, to their solvent action on the material of gouty concretions.

Brain Surgery. By M. ALLEN STARR, M.D., Ph.D., etc. 8vo, pp. xii, 295. With fifty-nine illustrations. New York: Wm. Wood & Co. 1893.

"It is the object of this book," says the author, "to state clearly those facts regarding the essential features of brain disease which will enable the reader to determine in any case, both the nature and the situation of the pathological process in progress, to settle the question whether the disease can be removed by surgical interference, and to estimate the safety and probability of success by operation." To accomplish the first object in every case is as yet beyond our attainments, and to state all the facts would require a treatise instead of the score of pages which the author has devoted to the exposition. What he has done is to collect, chiefly from American sources, a large number of cases of brain disease, where an operation has been performed, to add to them a number of original cases, and to attempt to draw deductions from these data. The result is a work which is interesting and not without value, but, nevertheless, it is far from satisfactory. It would seem as if it were time to make a critical estimate of the results attained by brain surgery in the last nine years, but, in point of fact, it is still in some respects too early, and the work before us bears evidence of haste and inaccuracy. Nearly a hundred pages of the book are devoted to the subject of trephining for epilepsy, and this chapter is a good example of some of the most serious faults in the work. The discussion practically is limited to Jacksonian epilepsy, and the author, in his preliminary remarks, states that the character of these attacks "denotes the exact position of the disease in the brain," apparently ignoring the evidence brought forward by various authors to show that the Jacksonian attack has comparatively slight localizing value. He reports thirteen cases of his own — one of which is manifestly a case of tumor of the brain and does not belong here — and claims that three were cured, yet in these, as in every other case, the convulsions recurred after the operation. In his own cases, and in those he has collected from literature, moreover, too little time has elapsed since the operation for us to say, even if the fits have not recurred, that the case is actually cured. Hence, the thirteen alleged cures in forty-two cases, cannot be accepted. Van Gieson's admirable study of the pathology of two of the cases —by far the best thing in the book — shows how little permanent benefit can be hoped from surgical interference. It is, nevertheless, true that trephining will cause a temporary cessation of the attacks in some cases, although the patient may eventually relapse into as bad a condition as before the operation. Hence we may accept, with some modifications, the author's

conclusions, that operation may be of benefit, although we doubt if it be curative, and that thus it may be justifiable. The next chapter is nominally on trephining for imbecility due to microcephalus, but the author seems to be in a state of confusion on the whole subject. Trephining for imbecility due to microcephalus, Lannelongue's operation for craniectomy receives no attention, but instead the various forms of cerebral infantile paralysis are discussed, and cases are reported where trephining was done to relieve paralysis or convulsions. The subsequent chapters on trephining for hæmorrhage, abscess, tumor, hydrocephalus, etc., are clearer and more accurate, but they contain little that is new. Trephining for persistent headache, which has more than once been of benefit, meets with no favor in his eyes. The work, on the whole, is below the author's reputation.

A Practical Treatise on Materia Medica and Therapeutics, with Especial Reference to the Clinical Application of Drugs. By JOHN V. SHOEMAKER, A.M., M.D., Professor of Materia Medica, Pharmacology, Therapeutics, and Clinical Medicine, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia; Physician to the Medico-Chirurgical Hospital; Member of the American Medical Association, of the Pennsylvania and Minnesota State Medical Societies, the American Academy of Medicine, the British Medical Association; Fellow of the Medical Society of London, etc. Second edition, revised. In two royal octavo volumes. Volume I, 353 pages: Devoted to Pharmacy, General Pharmacology, and Therapeutics and Remedial Agents not Properly Classed with Drugs. Volume II, 680 pages: An Independent Volume upon Drugs. Philadelphia: The F. A. Davis Company.

The first volume of this work is largely devoted to the consideration of the value of the natural forces and of mechanical and physiological agencies in the treatment of disease; and the prominence given to these subjects is unusual. Heat, Cold, Climatherapy, Electricity, etc., are among the topics discussed. The student and practitioner will find here much that is useful and suggestive, not usually included in a work of this character. The second and larger volume of the two contains an alphabetical list of drugs; and the physiological action and the therapy of each of these is discussed. The list is too long, and some of the drugs are considered in insufficient detail for the student, but the practitioner will find the volume excellent for reference. The index is printed in too small type for comfort.

The Physician's Pocket Day-Book. Designed by C. HENRI LEONARD, M.A., M.D., Professor of Medical and Surgical Diseases of Women and Clinical Gynæcology in the Michigan College of Medicine. Issued annually by the Illustrated Medical Journal Co., Detroit, Mich.

This pocket day-book is arranged to contain the daily record of visits for twenty-five or fifty patients a week for thirteen months, together with ninety-four obstetrical cases. The introduction has a list of doses and various tables for reference.

AT the University of Moscow the fees for the medical curriculum of five years, amount to only £80.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 23, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PATHOGENY OF BRONCHITIS.

THE relation of bacteria to bronchitis has been elucidated by two recent writers, Marfan and Claisse.

A large division of bronchitis comprehends specific infectious forms; another division, the non-specific bronchitis. Every bronchitis, however, according to Marfan,[1] is infectious.

The specific forms attend measles, whooping-cough, small-pox, influenza, etc., and are dependent on the microbe that causes the disease. These forms are "exogenous" or "hæmatogenous"; the germ is brought by the air or by the blood. Most bronchites are exogenous, but those of small-pox, glanders, malaria and secondary syphilis are hæmatogenous.

The non-specific infectious bronchites constitute a large and important class. Under this head are included common bronchitis (*a frigore*), the bronchitis that attends chronic naso-pharyngeal affections, chronic affections of the lungs and pleura, hay fever, gout, heart disease, Bright's disease, etc. To this division is assigned the bronchitis which is present as a complication in all adynamic and cachectic states, as in infectious endocarditis, diphtheria, typhoid fever, diabetes, etc. Bronchitis is the rule in typhoid fever, but it is only a secondary element, and is not due to the presence in the bronchi of Eberth's bacillus.

Marfan's explanation of bronchitis from "catching cold" is substantially as follows:

Acute bronchitis is sometimes occasioned by the respiration of a cold atmosphere which penetrates the bronchi suddenly and violently. But it is not by the direct contact of cold air with the mucous membrane of the respiratory passages that bronchitis is ordinarily produced. It is generally by a sudden chilling of the cutaneous surface, and especially when the body has been overheated by prolonged exercise and is perspiring.

Marfan remarks that some persons have a suscepti-

[1] Traité de Médecine, Charcot, tome iv.

bility to cold when this is limited to certain anatomical regions; for instance, one will have bronchitis if the feet are allowed to become cold, another, if he remains an instant with arms or chest bare, etc. Moreover, cold and damp climates and chilly seasons have a great influence on the development of bronchitis *a frigore*. The same may be said respecting sudden changes of weather. Infants, old people and feeble cachetic subjects are particularly susceptible, for reasons which are sufficiently obvious.

But how does a chill act in provoking an inflammation of a mucosa? The old medical writers supposed that the sweat glands were closed by the cold and that the excrementitious matters of perspiration were retained in the blood. Hence, a general toxæmia, with inflammatory manifestations in parts of least resistance. This notion is now abandoned. Experiments have shown that in animals which are overheated, there is considerable dilatation of the cutaneous vessels; the blood circulates there with force and abundance. If now a sudden chilling is brought about, the blood which distends the peripheral vascular network is cooled in mass and by repercussion cools the organism. This sudden loss of heat causes profound disturbances in the internal organs. Severe congestions result.

But the experimentation stops here, and cannot explain why the fall of the internal temperature engenders bronchitis.

The bacteriological study of the sputa completes the data furnished by experimentation.

Note in the first place, that the upper air-passages and bronchi contain microbes independently of any pathological state. Among these the four following species have been observed which have pathogenic properties: the staphylococcus pyogenes (aureus et albus), the streptococcus pyogenes, the pneumococcus, the pneumo-bacillus of Friedländer. Let now a bronchitis of whatever nature supervene, and it will be seen that these microbes are more abundant in the sputa; new species appear; proteï which are pathogenic and even pyogenic when inoculated in animals; two saprogenous microbes, the one resembling Eberth's bacillus, the other, the bacterium coli commune. Cornil and Babes remark that these microbes are found in all the bronchites: in bronchitis *a frigore*, in influenzal, tuberculous, morbillous bronchitis, etc. Marfan, besides those above mentioned, has also found the pneumococcus in the exudation of almost all the bronchites which he has examined. Pausini declares that the streptococci are the only micro-organisms met with constantly in the sputa, both in bronchitis and in health. He describes eight different species of these streptococci, several species of fungi, twenty-one species of bacilli, ten species of micrococci. Frick has studied the chromogenic bacteria which give to sputa their green color.

Marfan, in summing up these bacteriological results, asks what conclusion can be drawn therefrom concerning bronchitis *a frigore*? Although the direct demonstration has not been made, it is difficult not to think that all these microbes have a real pathogenic influence. Whether they live normally in the respiratory passages or whether they come from the atmosphere, it must be admitted that the cold favors their fixation and their pullulation in the mucosa of the bronchi.

The solution of the problem then consists in knowing why the perturbation caused in the organism by the cold, favors this development of micro-organisms. In the normal state the system defends itself against microbes by the bactericidal properties of the serum and the phagocytic properties of the anatomical elements. These two sets of properties are in part dependent on the nervous system. It is very likely that the profound perturbation produced by the cold on the internal calorification brings about a disorder of the vaso-motor innervation which causes congestion and places the organism in a state of lessened resistance, and just in those localities (respiratory passages, skin, intestine) where microbes are normally present we see inflammations set in of microbic origin which are properly designated infectious, non-specific.

It is easy to conceive that a first attack of bronchitis diminishes the power of defence of the bronchi and leaves behind certain microbes that are more virulent, and this naturally favors recurrences.

What is said of bronchitis *a frigore* is just as applicable to coryza from cold, and when the two co-exist, the explanation may be as follows: Either the cold acting in the same manner on the nasal and bronchial mucosa favors the microbian invasion, simultaneous or successive, of the two mucosæ; or the coryza alone is produced by the cold, and the microbes having acquired their virulence in the nasal fossæ invade later, by simple propagation, the tracheo-bronchial mucosa. There is nothing at the present time that indicates which view of this pathogency is the more correct. Certain it is, however, that bronchitis *a frigore* is generally preceded by a coryza; and it is regarded from a clinical point of view, a descending bronchitis.

The article of Claisse (*Semaine Médicale*, 1893, p. 297), adds to the above statement the notion of intoxications by microbe secretions. The presence of the microbe in the bronchi manifests itself by local effects on the tubes and by general toxic effects.

The local effects are expressive of the secretory reaction of the bronchial tree; this, in certain conditions, may lead to a more or less extensive obliteration of the air-passages and give extreme gravity to the prognosis. But the bronchial secretions may also have a marked toxic influence; this is a pathogenic factor that has been too much overlooked. The toxæmia explains the general phenomena, the temperature, and to some extent, the dyspnœa.

Claisse has made some interesting experiments to determine the nature and quality of these toxines, and has worked out the bacteriological problem with considerable success; but the details of these researches may be considered later.

EPIDEMIC INFLUENZA.

IN a further report to the English Local Government Board,[1] Dr. Parsons continues the excellent work on the subject of epidemic influenza begun two years ago. This report contains further observations upon the epidemic of influenza of 1889–90, and upon the succeeding epidemics of the spring of 1891 and the winter of 1891–92. It embodies much statistical information upon the incidence of the disease in its fatal form, upon age, sex and locality, and other conditions affecting the epidemic.

The severity of the different epidemics differed much in different localities. "No circumstances of soil, climate, occupation or sanitary condition afforded any satisfactory explanation of these differing incidences."

The death-rate from influenza was greatest in the rural districts. In London and 90 large towns it varied from 0.52 to 0.58 per 1,000 living, while in 192 rural districts the rate was 0.73 per 1,000. This is probably due to the fact that "the death-rate from influenza increases with advancing age; and while many of the rural areas have been more or less denuded of young people and adolescents, the old people have remained at home in the villages."

"Further experience goes to confirm the view that influenza is essentially propagated from person to person. Indeed, the evidence which is now forthcoming, tending to show that the disease has followed the lines of human intercourse, so far outweighs any that has been put forward in favor of its being due to 'atmospheric causes,' as to suggest that where these have been accepted as accounting for outbreaks, all the circumstances of the local prevalences in question have not been forthcoming." Dr. Parsons adds: "Similar conclusions have also been arrived at independently by numerous observers in this and in other countries, and the communicability of influenza may be said to be now very generally, though not quite universally, accepted." Several instances are cited in confirmation of this view, and too little weight is given to the other side of the problem.

Several interesting questions are considered in the report, such as — (1) the existence of media in which the contagion of influenza can live or multiply outside the body. (2) What are the circumstances which promote its spread at one time, and not at another? (3) As to immunity and the *individual*. (4) Does an epidemic in any way protect a *community* against recurrence? (5) As to the effect of locality or occupation. Mr. Alfred Fletcher, the successor of Dr. Angus Smith as inspector of alkali works presents some statistics which appear to show that workmen employed in such works are measurably exempt from influenza. (6) The relation of pneumonia to influenza. (7) Length of the period of infectiousness. (8) Clinical features of epidemics.

With reference to prophylaxis, the report discusses the practicability of isolation and of school closure and concludes that while instances show the value of isolation, it would be quite difficult to enforce it in practice. As to notification, "in the opinion of many able and thoughtful medical officers of health, the advantages to be gained from compulsory notification of influenza would not, in most districts, be commensurate with its cost."

The volume also contains Dr. Klein's report upon the clinical and pathological aspects of the disease. The materials for the investigation were mainly supplied from the Kensington Infirmary and from St. Bartholomew's Hospital. The following conclusions are presented:

"The researches now recorded have afforded certain affirmative results as to the microphytic elements of influenza; they are such as may be presumed to be constant in influenza; and they are in full agreement with the results obtained by Pfeiffer and Kitasato. Our investigations have shown a bacillus having peculiar morphological and cultural characters, always abundantly present in the bronchial secretion of patients suffering with influenza, diminishing in numbers as the disease abates, and disappearing when it comes to an end. The same species of bacillus is furthermore found occasionally in the blood of acute influenza; not very often indeed, but often enough to invalidate a suggestion that its appearance there is a matter of accident."

In referring to the German and other authorities upon the same subject, Dr. Klein does not consider the evidence as quite complete, and further says "what we now most specially want, for the demonstration of this bacillus as the materies of influenza, is evidence that this particular microbe does not occur in any other disease than influenza; and Pfeiffer and Kitasato would go so far as to assert this as a fact. Our own researches have not led us to doubt it; and we have only to give the obvious caution that not sufficient time has yet elapsed since Pfeiffer's discovery to establish their assertion, and perhaps we are as yet hardly safe in denying the presence of his bacillus elsewhere than in influenza."

The report is illustrated with photographs of human blood, bronchial sputum, influenza bacilli and cultures.

[1] Further Report and Papers on Epidemic Influenza (1889-92). By H. Franklin Parsons, M.D., and Dr. Klein. London: Eyre & Spottiswoode. 1893. A report of the Local Government Board.

FOOT-BALL.

MUD will soon give way to frost, and the foot-ball season for this year is drawing to a close. By the end of another week the three principal events of the season will have been decided, and the Sunday paper will have to seek other portraits for its gallery than those of frowsy youths in sweaters.

Of the growing popularity of the game among players and spectators there can be no question. The male child now emerges from swaddling clothes into quilted and padded knickerbockers, and lays aside his rattle for a pig skin. The greater the number of seats provided for those who desire to assist as onlookers at the

chief matches of the year, the greater seems to be the competition for them. The struggle for seats at the Harvard-Yale and Harvard-Pennsylvania games is almost as keen as will be the struggle for the score between the opposing elevens. Fashion unquestionably has much to do with this, and foot-ball is now the fashion. But behind the fashion of the thing, there is as unquestionably a genuine zeal for the sport itself, certainly among the players, and in a lesser measure among the spectators.

The game is not without its risks, and even its fatalities — as is unhappily illustrated elsewhere in this very issue of the JOURNAL. It may be made a medium for brutality, for betting, and for trickery, and has been such at times. The same, however, may be said of many, if not of all manly sports. That is an argument for regulating, not for abandoning them. Foot-ball as now played is not a good game for most boys below, or for most men above, a certain age. The game requires much, and develops much besides mere brute force. There is something to be had from contesting sports in the open air which mere gymnasium exercises, however skilfully conducted, cannot give. The blood which is sent tingling through the body need not be bad blood, and the contestants can and should so bear themselves that respect and not hatred for opponents is engendered.

We have no prejudices against fencing because it comes to us from France, against golf because its home is in Scotland, nor against polo, hunting and foot-ball because they are adopted from England. A sport which has nothing more than fashion to recommend it will not hold its own. Though foot-ball as now played really seems to us a poor game for a large number of spectators, it is, we believe, not likely soon to lose its hold upon its votaries, and that because it has many intrinsic merits as a manly sport.

We ourselves prefer the golf stick or the tennis racket, but we are forced to admit that we are quite beyond a certain age, and we are also willing to admit that there was a time when wallowing in the mud, even as a substitute, would not have been thought inglorious.

MEDICAL NOTES.

BERI-BERI AT PHILADELPHIA. — The steamer *Lenark*, from Java, which arrived at Philadelphia November 3d, brought eight of her crew ill with well-marked beri-beri. Thirty-one other men have been held under quarantine observation.

VIRCHOW'S SUCCESSOR. — Professor Weinhold has been elected Rector of the University of Berlin to succeed Virchow, whose term ended at the beginning of the present semester. The new Rector at once appointed Virchow to be a member of the University Senate.

FATAL FOOT-BALL ACCIDENTS. — At a game of foot-ball between high-school boys in Adrian, O., last week, one of the players was killed by having his cervical spine dislocated while "downing" the ball. This is the fourth fatal injury at foot-ball this year, three other players having had their necks broken and one his skull fractured. A sixth, probably fatal case, occurred in Farmington, Conn., on the 20th inst., in a game between the Yale Senior-Class team and the Farmington Athletic Club. One of the players on the latter team had his neck broken, and is unconscious, and totally paralyzed below the seventh vertebra. In England the deaths from injuries received in the game during the season from September 1st to April 1st, are said to have averaged twenty-four in each of the last three years.

CHICAGO PASTEUR INSTITUTE. — Since the inauguration of the Chicago Pasteur Institute, July 2, 1890, 302 persons have been treated by preventive inoculation against hydrophobia; 104 were bitten by animals recognized and ascertained to be rabid by the experimental proof made in the laboratory, or by the death of other persons or animals bitten by the same animal; 126 were bitten by animals recognized to be rabid by the symptoms of the disease shown during life, and 72 by animals strongly suspected to be rabid; 282 persons were bitten by dogs, 7 by horses, 7 by cats, 3 by skunks, 2 by wolves, 1 by a mule. The persons treated came from the following States: 185 from Illinois, 32 from Iowa, 23 from Indiana, 21 from Kansas, 9 from Ohio, 5 from Missouri, 5 from Arizona, 4 from Minnesota, 4 from Michigan, 4 from Louisiana, 3 from Tennessee, 3 from Kentucky, 2 from Texas, 1 from Wisconsin, 1 from South Dakota. One death was reported among the patients treated, thus giving a mortality of only 0.33 per cent.

BOSTON AND NEW ENGLAND.

A RECEPTION TO DR. HOLMES. — The College Club of Boston gave a reception to Dr. Oliver Wendell Holmes last Saturday afternoon. Mrs. L. S. Davis, the president of the club, assisted by Mrs. Alice Freeman Palmer, received the guests. About five hundred persons were presented to Dr. Holmes, who received them seated in a laurel-decorated chair in the parlor, under a bower of palms. During the evening Dr. Holmes recited "The Last Leaf," "Dorothy Q," and "The Chambered Nautilus."

FREE VACCINATION IN BOSTON. — In view of the recent outbreak of small-pox in Boston, the Board of Health has issued the following notice: "Vaccination without charge will be given at the Shurtleff Schoolhouse on Dorchester Street and the Mather Schoolhouse, Broadway, both in South Boston, from 4 to 5 P. M. and 7 to 8 P. M., every day this week. The office of the Chardon Street building will be open daily, as usual, for free vaccination, from 10 to 12 A. M."

GAS SUFFOCATION IN BOSTON. — Much complaint is made in Boston concerning the variable pressure of the gas-supply, which makes it unsafe to leave a light turned low. Many narrow escapes from suffocation

have been reported, and it is suggested that some of the many recent "suicides" by gas poisoning may have been entirely unplanned and accidental.

SMALL-POX IN BOSTON. — Three new cases of small-pox have occurred in Boston the last week, one being in South Boston and two in Roxbury. All of the patients at the hospital are doing well. The *Catalonia* which brought the disease here, returned to port on the 19th from Liverpool. On the voyage back to England one case of small-pox occurred, and the boat was fumigated at Liverpool. No cases occurred on the last voyage, but the vessel will again be fumigated here. On arrival, all of the passengers who did not show new vaccination marks were re-vaccinated.

A GIFT TO A LOWELL HOSPITAL. — In addition to previous liberal donations, Mr. Thomas Downing has given St. John's Hospital, Lowell, $1,000.

SCARLET FEVER AT AMESBURY. — The epidemic of scarlet fever at Amesbury, Mass., still continues, there being at present over forty cases in the town. Since last week, eight more schools have been ordered closed, making ten in all. The death-rate has not been excessive as yet.

NEW YORK.

ACADEMY OF MEDICINE AND THE NEW YORK INFANT ASYLUM. — At a regular meeting of the New York Academy of Medicine, held November 16th, Dr. John A. Wyeth introduced a series of resolutions pledging the approval by the Academy of the protest and resignation of the Medical Board of the New York Infant Asylum in consequence of the dismissal from its service of Dr. Robert Milbank. In support of them, he stated that within a few months' past, Dr. Milbank, a reputable physician and a Fellow of the Academy, who was one of the visiting staff of the Infant Asylum, had, after years of faithful service, been dismissed by the President of the Board of Managers, and that another physician had been appointed to fill his place. No charges of any character were preferred against him, and there was no question as to his qualifications for the performance of his duties. The Medical Board, while held responsible for the welfare of the inmates of the institution, were not consulted, either as to the dismissal of Dr. Millbank or the appointment of his successor. They protested against this action of the managers, and, being informed that if they did not like it they could resign, did resign. After an animated discussion, the resolutions were finally tabled. At the same meeting resolutions were adopted which called attention to the inefficiency of the present coroner system, and requested the Constitutional Convention, which is to meet at Albany, in April next, to consider the propriety of abolishing the office, and suggesting the enactment of laws providing for a system of medical examiners such as now exists in the State of Massachusetts.

THE LEAHE AND WATTS ORPHAN ASYLUM. — At the semi-centennial celebration of the Leahe and Watts Orphan Asylum, held at the new building of the institution near Yonkers, on November 16th, the Rev. Dr. Morgan Dix, the President of the Board of Managers, announced that a separate hospital building would be erected in order to properly guard against the spread of any contagious disease among the children.

CARE OF DEPENDENT CHILDREN.—November 15th and 16th a conference on the care of dependent and delinquent children, was held under the auspices of the State Charities Aid Association. During the course of the proceedings Mrs. M. C. Dumphy, superintendent of the city institutions for children on Randall's Island, advocated the employment of efficient hired attendants to take the place of the "work-house women" now assigned there, as she believed the association of the children with such women demoralizing. Dr. Stanton Cort, of the University Settlement, advised the abolition of rear tenements, which now give rise to so many unsanitary conditions, and the converting of the centre of city blocks in poor localities into parks and play-grounds.

SMALL-POX. — During the past week cases of small-pox have occurred in the Tombs prison and in Roosevelt Hospital, and a large number of persons were exposed to the contagion in each instance before the patients were removed. The disease is less prevalent, however, than it was a few weeks since, and the Board of Health is carrying on the work of vaccination on a more general scale than ever before.

MORTALITY. — During the week ending November 11th, the death-rate of the city was the smallest ever recorded. The exceptionally fine weather for this season of the year, as well as the unusually clean condition of the streets, is no doubt in some manner accountable for this happy result. The number of deaths reported for the week was 641, which represents an annual death-rate of only 17.46 per thousand of the estimated population, against 18.40 the week previous. The official sanitary report states that if it had not been for the prevalence of diphtheria, the rate would have gone below 17 per thousand, fixed by Dr. Farr as the rate for very healthy country districts. During the week there were 53 deaths from diphtheria.

Miscellany.

"A CHESTERFIELD GORILLA."

THERE recently died in a Berlin menagerie a gorilla of great elegance of manner. Its habits of life were regular and most precise, and the account given of its daily occupations reads much like the court bulletins of the Grand Monarch. It was accustomed, it is said, to wake at eight o'clock in the morning and take a glass of milk. Certainly this conformity of time, rather than daylight, marked an advance from the animal to the conventionality of man. It is not said whether the milk was brought to the gorilla or called for. The account goes on:

"At nine o'clock it made its toilet with as much care as a civilized man, and ate its breakfast a few

minutes afterward. This consisted of two Vienna loaves, Hamburg smoked meat, cheese and white beer.

"Another bit of refinement in preferring a light beer for breakfast, especially after a careful toilet.

"At one o'clock in the afternoon it had a cup of chicken soup with carrot, rice and potatoes and an egg. Its evening meal consisted of fruits, bread and butter, and a cup of tea."

It will be noticed that the chief attentions of this gorilla were gastronomic; but the evident care bestowed upon the selection of its viands was truly civilized and human. It is not stated what was the cause of death. It is to be hoped it was not the inadvertent use of a dark beer or a hasty toilet.

TOXICITY OF THE BLOOD OF THE COMMON TOAD.

MM. PHISALIX and Bertand[1] have found in the blood of toads certain active principles having the same poisonous effect upon frogs and mammals as the venom secreted by the cutaneous and parotid glands of toads. When injected into frogs they produce paralysis, beginning in the hind limbs, slowing and arrest of the heart, and contraction of the pupil. They are produced by an internal secretion of the cutaneous glands, and to this internal secretion must be attributed the immunity of toads, as in venomous reptiles, for their own poison.

THERAPEUTIC NOTES.

NAPHTHALENE AS A TÆNIFUGE. — The following dose of naphthalene has been found by several observers in the *Revue Médicale de Louvain* an excellent tænifuge and free from any toxic effect.

℞ Napthalene	30 to 50 centigrammes.	
Ol. ricini	15 grammes.	
Ol. bergamoti	10 drops.	M.
Sig. To be taken at one dose, fasting.		

A single dose is usually sufficient for children. For adults the naphthalene is best given in a cachet containing one gramme and followed at once by 30 grammes of oil. Crequy recommends a combination of calomel and malefern as being with him the most successful.

℞ Calomel	80 centigrammes.
Extract of malefern	8 grammes.

To be divided into sixteen capsules, one to be taken every ten minutes.

TREATMENT OF TONSILLITIS. — Fabre at the recent Congress at Besancon reported forty cases of tonsillitis successfully treated by inhalation of hot air charged with creasote and carbolic acid. The cough was at once relieved, and a resolution obtained in two days. In ten cases of threatened suppuration the painful deglutition was relieved after an inhalation for half an hour. The softened areas disappeared on the second inhalation. The mixture used was beech-wood creasote, five grammes, and crystallized carbolic acid, fifty centigrammes. In the only case of diphtheritic tonsillitis thus treated, the tonsils which were covered with thick false membrane became after three inhalations perfectly clean. The mucous membrane soon recovered its normal appearance, and the glandular swelling rapidly diminished. In this case the amount of carbolic acid was increased to one gramme.

Amesbury	10,920	2	2	—	—	—	—	—

Deaths reported 1,970: under five years of age 666; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 299, consumption 254, acute lung diseases 221, diphtheria and croup 147, diarrhœal diseases 56, typhoid fever 38, scarlet fever 23, cerebro-spinal meningitis 13, whooping-cough 10, measles 7, malarial fever 2, small-pox 2.

From scarlet fever Philadelphia 8, Boston 5, New York 3,

Milwaukee, Cambridge, Lynn, Somerville and Malden 1 each. From cerebro-spinal meningitis New York 5, Washington, Cleveland and Worcester 2 each, Boston and Somerville 1 each. From whooping-cough Philadelphia 3, New York 2, Boston, Worcester, Lowell, Cambridge and Haverhill 1 each. From measles New York 4, Philadelphia, Milwaukee and Springfield 1 each. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending November 4th, the death-rate was 20.2. Deaths reported 4,005: acute diseases of the respiratory organs (London) 369, diphtheria 108, scarlet fever 81, diarrhœa 74, fever 70, whooping-cough 61, measles 57, small-pox (Birmingham 4, London, Bristol and Bradford 1 each) 7.

The death-rates ranged from 9.6 in Croydon to 26.7 in Hull; Birmingham 22.7, Bradford 20.5, Bristol 14.6, Gateshead 15.5, Leeds 17.3, Leicester 15.0, Liverpool 26.0, London 20.5, Manchester 20.0, Newcastle-on-Tyne 20.9, Nottingham 15.1, Portsmouth 14.6, Sheffield 20.1, Swansea 16.1, West Ham 19.7.

METEOROLOGICAL RECORD,

For the week ending November 11, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer.			Relative humidity.			Direction of wind.		Velocity of wind.		Weather*		Rainfall in inches.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 11, 1893, TO NOVEMBER 17, 1893.

The leave of absence granted CAPTAIN HENRY P. BIRMINGHAM, assistant surgeon, U. S. A., is further extended one month.

Leave of absence for one month, is granted FIRST-LIEUT. CHARLES E. B. FLAGG, assistant surgeon, with permission to apply for an extension of twenty days.

LIEUT.-COL. CHARLES R. GREENLEAF, deputy surgeon-general, is relieved from duty in the office of the Surgeon of the Army, and will repair to San Francisco, Cal., and assume charge of the medical supply depot in that city, relieving LIEUT.-COL. JOSEPH P. WRIGHT, deputy surgeon-general, who, upon being thus relieved, will repair to St. Louis, Mo., and assume charge of the medical supply depot in that city.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday, December 6th, at 8 o'clock, P. M., by Dr. M. H. Richardson. Subject, "Abdominal Emergencies." Physicians are cordially invited.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, November 27, 1893, at 8 o'clock, P. M.

Dr. C. J. Blake: "Fixation of the Stapes," illustrated by lantern slides. Discussion opened by Dr. J. O. Green.

Dr. Paul Thorndike: "Notes on Phosphaturia." Discussion opened by Prof. E. S. Wood, M.D.

Members are kindly requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., *Secretary.*

RESIGNATION.

C. S. GORDON, M.D., of Portland, Me., has resigned the Professorship of Gynecology in the College of Physicians and Surgeons of Boston.

BOSTON MEDICO-LEGAL SOCIETY.

RESOLUTIONS ON THE DEATH OF DR. CARTER.

At the meeting of the Boston Medico-Psychological Society held October 19th, a committee was appointed to prepare resolutions upon the death of Dr. Cyrus F. Carter. This committee presented the following memorial:

"The Boston Medico-Psychological Society feel that in the death of Cyrus Faulkner Carter they have lost a valued and beloved member. Dying at the early age of thirty-two years, when it seemed that his life-work had just begun, by his generous nature, by his faithfulness and by his skill, he had endeared himself to all with whom he came in contact.

"Death has taken from the Society and from the medical profession a man of great attainments, of rare promise, respected, loved."

RECENT DEATHS.

HOWLAND HOLMES, M.D., M.M.S.S., died at Lexington, November 16th, aged seventy-eight years. He graduated from Harvard College in the class of 1843 and from the Harvard Medical School in 1848. He had been for many years prominent in all town affairs at Lexington.

CHARLES WARRINGTON EARLE, M.D., President of the Board of Directors of the College of Physicians and Surgeons and of the Women's Medical College of Chicago, died in Chicago, November 19th, aged forty-eight years.

JOHN FRISSELL, M.D., died at Wheeling, West Virginia, November 16th, aged eighty-four years. He was one of the oldest alumni of Williams College, having graduated in the class of 1831. After receiving his M.D. in 1834 he moved to Wheeling, where he has since been one of the best known surgeons.

BOOKS AND PAMPHLETS RECEIVED.

Connecticut State Medical Directory, Containing a carefully prepared list of Physicians, Dentists and Druggists, together with Colleges, Hospitals, Medical Associations and Societies throughout the State. Danbury, Conn.: The Danbury Medical Printing Co. 1893.

A Text-Book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge and Fellow of Trinity College, Cambridge. With illustrations. Sixth edition. Part I comprising Book I. Blood, the Tissues of Movement, the Vascular Mechanism. New York and London: Macmillan & Co. 1893.

Exercise for Pulmonary Invalids. By Charles Denison, A.M., M.D., Professor of Diseases of the Chest and of Climatology, University of Denver; Ex-President of the American Climatological Association. Read before the Congress of Medico-Climatology of World's Fair Congress Auxiliary, June 1, 1893. Denver, Colo.: Chain & Hardy. 1893.

Annual of the Universal Medical Sciences: A Yearly Report of the Progress of the General Sanitary Sciences throughout the World. Edited by Charles E. Sajous, M.D., and seventy associate editors. Illustrated with chromolithographs, engravings and maps. Five volumes. Philadelphia, New York, Chicago and London: The F. A. Davis Co. 1893.

Healthy Hospitals; Observations on some Points Connected with Hospital Construction. By Sir Douglas Galton, Late Royal Engineer, K.C.B., Hon. D.C.L., LL.D., F.R.S., etc., Assistant Inspector-General of Fortifications; Director of Public Works and Buildings, etc. With illustrations. Oxford, at the Clarendon Press. London: Henry Froude & H. K. Lewis. 1893.

A System of Genito-Urinary Diseases, Syphilology and Dermatology. By various authors. Edited by Prince A. Morrow, A.M., M.D., Clinical Professor of Genito-Urinary Diseases; Formerly Lecturer on Dermatology in the University of the City of New York: Surgeon to Charity Hospital. With illustrations. In three volumes. Volume II. Syphilology. New York: D. Appleton & Co. 1893.

The Students' Dictionary of Medicine and the Allied Sciences, Comprising the Pronunciation, Derivation and full Explanation of Medical Terms, together with much Collateral Descriptive Matter, Numerous Tables, etc. By Alexander Duane, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute; Reviser of Medical Terms for Webster's International Dictionary. Philadelphia: Lea Brothers & Co. 1893.

Rules to be Followed in the Effort to Prevent Mural Abscesses, Abdominal Sinuses and Ventral Hernia after Laparotomy. The Importance of Understanding the Function of the Levator and Ani Muscle in the Treatment of Injuries of the Floor of the Vagina. The Diagnosis and Treatment of Intestinal Obstructions, and the Management of Greatly Distended Intestines during Laparotomy. Secondary Hæmorrhage after Ovariotomy: Can we Prevent It? The Prevention and Management of Pelvic Inflammation in Puerperal Women. Counter-Drainage after Cœliotomy. By Horace Tracy Hanks, M.D., New York. Reprints. 1891-92-93.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XX

ANEURISMS (CONTINUED).

AN aneurism is defined as a sac containing blood which communicates with an artery. We spoke of the mode of its formation in the last lecture. I said that coagulation of blood in the sac with successive layers of fibrin and clot was nature's method of trying to cure it. I should add, also, that nature throws out another safeguard on the outer side of the sac as the aneurism progresses. The sac of the true aneurism, owing to the ulceration of the inner coat of the artery and the giving way of the middle coat, finally consists wholly of the outer coat of the vessel. Its sac pulsates and stretches and throbs with every beat of the heart; and of course impinges on all the neighboring tissues, and gradually absorbs them. In doing this it cannot fail to light up an inflammation in the connective tissue round about; and, accordingly, we have a thickening of the sac on the outside produced by an inflammatory process in the connective tissue around it. Thus, then, we have nature trying to establish a series of buffers inside to check the flow of blood inside the sac; and on the outside, by the inflammatory products of the connective tissue, resisting the pulsation within. In spite of all this, in a large aneurism, where it has got well under way, the disease goes on and the force, like all hydraulic pressure, is irresistible and absorbs everything before it. Curiously enough it is said that cartilage is a tissue which resists the longest. Bones yield before cartilages; soft tissue, of course, very rapidly.

The pressure on muscles and on veins and on nerves gives rise to great interference with the circulation of the part; and in concealed aneurisms in the deeper parts of the body as in the trunk, usually gives rise to great pain which is ascribed to rheumatism, to neuralgia, to various causes, for a long time before the true trouble becomes apparent. The bones are absorbed; the bodies of the vertebræ are eaten off; the sternum is eaten through. An aneurism presents itself at some unexpected point where previously there was nothing but bone and hard tissue, and then it goes on pulsating and thinning.

Its usual duration is said to be from two to four years. It generally terminates fatally, and usually by rupture. Occasionally it undergoes an inflammatory process and suppurates; and, rarely, in that way cures itself. In other words, by the time the sac bursts, so great a mass of protective lymph has been thrown up around it that the discharge is mostly of pus; shrinking takes place, and occasionally the aneurism is cured. More often, however, it bursts, with a fatal result.

The arch of the aorta seems the most subject to aneurism, and next to that the three or four larger vessels. The popliteal is a favorite place, next to that the femoral, then the carotid. The popliteal, apparently, is a favorite site for aneurism on account of the constant flexion and extension to which the vessel is subjected in the movement of the leg; and if a change begins, as it often does, by atheromatous deposits in the artery, there is the place where it is very likely to stretch and bend and be forced to give way, sooner than in other parts of the body. This is the true aneurism.

There are other varieties. In the first place, it is quite evident that we may at any time have a traumatic aneurism. This may be produced by a gun-shot wound by a ball. It is not necessary that the ball should pierce the artery to give rise to an aneurism, but run across, and wound and bruise its coats. A cut or stab will give rise to an aneurism. The blood is poured out into the cellular tissue. A species of connective-tissue sac is formed about this blood. It slowly forces its way into all the interspaces of the part, as the thigh, until finally the fascia lata itself may become the sac of the traumatic aneurism; the patient still surviving, on account of the slow daily and weekly loss of blood not affecting him so rapidly as a sudden gush from the wound; and in some of these cases in the false sac of a traumatic aneurism, several pints of coagula have been thrown out.

Then there is the dissecting aneurism, in which the dilatation and the leaking of the blood takes place between the coats of the vessel, and runs along its course until it finally makes a long oblong sac between the outer and middle coats of the artery, and dissects often for a good ways into the tissues.

Then there are other forms where an artery and vein happen to be wounded together, and arterial blood has been poured into the vein. This occurred frequently in former times when venesection from the vein at the bend of the elbow was so common. The vein overlying the artery on the inner side of the arm, frequently in puncturing the vein the artery was punctured. A varicose aneurism was formed between the two, and the current ran together. In these cases a curious pulsation is heard; a whirring sound; the limb is swollen and enfeebled. There is more or less pain. The collateral vessels all become very much enlarged; but this process may go on for a good many years without leading to a fatal result.

What are the signs of aneurism?

Obviously a pulsating tumor; but this pulsation must be of a peculiar kind, and, as a rule, accompanied by a peculiar sound, to make it sure that it is an aneurism. The pulsation must be expansile; not merely beating up, but dilating. The sound is like the placental souffle, and synchronous with the pulsation of the heart. All tumors, however, which pulsate in this curious manner, and have a bruit, are not aneurisms, inasmuch as some varieties of soft erectile tumors and some of the softer forms of cancer pulsate and give a bruit in this same way; so that we must judge somewhat by the shape and size of the tumor; the history of the case; its effect on the circulation of the parts below, etc., to decide whether it is an aneurism or not. Every lump that is elevated on the artery and appears to give the sign of pulsation also, may not be an aneurism; because small solid tumors like adenoids, in which the glands, especially of the femoral triangle, overlying an artery, are lifted in pulsation, are frequently mistaken for aneurism. That is also true in the neck, where an enlarged lymphatic, particularly if located opposite the bifurcation of the external and internal carotid, is frequently thrown up with a marked pulsation, and mistaken for carotid aneurism.

[1] These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

The other more reliable signs of aneurism are these: first, that compression of the main trunk of the vessel above the suspected point stops the pulsation in the aneurism, (that, of course, would go without saying); second, that compression of the vessel below the suspected point always increases the pulsation in the sac of the aneurism; and, third, that the natural pulse in the vessels below the aneurism is enfeebled and sometimes lost.

Extensive pulsation in the site of a great vessel; a noise heard like the placental souffle; the ability to check the pulsation and the noise by compressing the vessel above; increase in the noise and pulsation by compressing the vessel below; and an enfeebled pulsation in the vessels supplying blood to the parts further down on the limb, are classical signs of aneurism. It is quite easy to find these in the popliteal, not difficult in the femoral, but in any portion of the abdominal or thoracic aorta these signs must mainly be wanting. They are out of sight, out of reach, perhaps may not affect particularly the circulation in the two legs below. The pulsation of the abdominal aorta itself, in the feeble, anæmic, emaciated person, may frequently be mistaken for aneurism when no aneurism whatever exists. You will find in the very sick and enfeebled, whose abdomen is retracted with emaciation, that by putting the hand just above the umbilicus in the central line and pressing moderately, you get quite a forcible and steady pulsation synchronous with the beat of the heart; this is simply the overaction of anæmia. So that all the signs may fail in the case of an internal aneurism, except possibly you may hear the bruit, or judge of what is taking place by the long-continued pain which it produces.

How shall an aneurism be treated?

There are two modes. We might apply both measures to either form of aneurism in the leg or arm, but we could not apply operative measures to aneurism inside the thorax and abdomen. One class of measures are called constitutional, and the other operative. The constitutional measures are adapted only for the treatment of those aneurisms which are beyond the surgeon's reach, about the heart, in the thorax, in the abdomen.

The local or operative measures, of course, are adapted to all other classes of aneurisms, in the limbs and neck, where the vessels can be got at.

Valsalva, long ago, and Tufnel proposed certain methods for treating aneurism constitutionally, which are not without their effect; and indeed, as this is the only resource in these aneurisms inside the body, we are forced to adopt this treatment or none at all; and we may safely say, I think, to the patient, that if the Tufnel or Valsalva treatment does not cure, at any rate it relieves pain a good deal; prolongs life; renders existence comfortable; and postpones the day of the final rupture of the aneurism.

These constitutional measures consist of two things — first, trying to reduce the vigor and celerity of the current of blood in the sac by keeping the patient perfectly still in the horizontal position and allowing him to make no effort whatever; and also to give internally medicines which will check and slow the pulsations of the heart to a certain degree, such as digitalis, veratrum viride and strophanthus. The use of these medicines to slow the current, and absolute rest on the part of the patient, tend to quiet down the cardiac circulation; to diminish the number of throbs that have got to go through the aneurismal sac day and night; to reduce the distensile force of the blood; to favor the formation of clots, and check the growth of the aneurism. There is no doubt that a great deal may be effected in this way.

Anything that diminishes the throbbing and the force of the pulsation, diminishes in the same degree, pain, which is, as a rule, due to pressure on sensitive neighboring parts. A good deal is effected by selecting the diet of the patient, and giving food only of that kind which will be sufficient to sustain life without stimulating the arterial circulation. A reduced diet, not starvation, but reduced; the avoidance of all stimulants of every kind; perfect rest in the horizontal position; remedies to reduce the action of the heart; and, in addition to this, Tufnel thinks he got a good deal of benefit from large doses of iodide of potash. The bromides have been used also with some effect. In this way an aneurism of the arch of the aorta, or the thoracic or abdominal aorta, or aneurism of the innominate, which are beyond reach, may be prolonged and quieted; and the patients may be kept going several years. If they are content to lead such a life, reclining in bed, pulsation will be brought to its lowest ebb, and occasionally cures have been effected. Occasionally spontaneous cures have occurred in aneurism without any treatment whatever.

Now as to the treatment of those aneurisms which are in the limbs. It is what is termed operative; but it is not of necessity the using of the knife. The number of modes of attacking these aneurisms that have been proposed is very great, and I will briefly run them over.

Incision, ligation, compression, acupressure, flexion, manipulation, galvano-puncture and the introduction of solid substances into the sac.

Antyllus, far back in Grecian times, attacked aneurisms boldly by opening the sac and seizing the vessels where they entered and emerged. This was done without ether and without antiseptics, and with almost none of the assistance that we have now. He saved a good many cases; and was a strong advocate of this method of treatment. The incision was made boldly through the skin. An assistant seized the artery above. The artery was tied at its entrance into the sac, and then the point of exit sought and the artery tied where it left the sac. The sac shrivelled up; slight suppuration took place. If the ligatures ulcerated out without subsequent hæmorrhage, the patient recovered. Unfortunately it was found, that the same condition of the artery which made the sac often lead to incomplete healing of the ligature. Secondary hæmorrhage took place in a good many cases.

The next mode of treatment was introduced by John Hunter, and consisted in tying the artery to control the aneurism at a distance from the sac, where it was healthy. He would tie, for a femoral or popliteal aneurism, high up in Scarpa's triangle, high up in the groin; and he would tie, for instance, for an aneurism of the radial, high towards the elbow; tying at a distance from the sac, between the sac and the heart. This was the usual method employed when the ligature was used to cure an aneurism — to tie at a distance from the sac, between the sac and the heart; because you are reasonably sure of having an elastic and healthy artery to hold the ligature; which is not the case within an inch, or half an inch of the sac itself. The immediate effect of tying, for instance, the femoral in

Scarpa's triangle, for popliteal aneurism, is to arrest at once the whole circulation in the sac of the aneurism. Speedily great changes took place in the foot and limb below. Curiously enough, owing to some disturbance of the vaso-motor nerves probably, the temperature of the leg and foot rises after the ligature is applied. This is, however, of short duration, and after an hour or two the temperature of the leg and foot begins to fall, and steadily falls below the normal level, owing to the cutting off of the arterial supply of blood. You have a shrunken, pallid, cold foot and limb; severe pain as a rule. The circulation wholly ceases, for the time, on account of the cutting off of the main supply, which has gone through the femoral and the sac.

What possible protection is there on the part of nature to prevent this stoppage from being permanent, and the limb immediately mortifying and sloughing in consequence of the sudden and complete arrest of circulation? We now have take place a marvellous process called collateral circulation. We know the infinite anastomoses in arteries and veins. We know that pulsation extends through numerous branches which interlace, and wind about in every possible direction, in between the muscles and fascia, to supply the different parts of the limb. Some of these branches dilate, and thus is established the collateral circulation. If the femoral is tied at the apex of Scarpa's triangle, it is tied below where the great posterior trunk is given off. This circulates blood through the muscles of the upper part of the thigh. Gradually the smaller vessels dilate; and arteries, hardly appreciable before, become of considerable size. The limb is eventually supplied by a score of little vessels dilated, where it was before supplied by one principal stem. A similar change takes place when the carotid is tied. It takes place also when obstruction of the vessels takes place about the aorta, from the junction of the perforating artery from the sternum, and the superficial epigastric artery, going up in the sheath of the rectus, and forming a large loop of connection; this dilates so that those vessels become of large size, in obstructions in the abdomen.

Obviously success in curing an aneurism by ligature must consist in several things — first, that the current shall be completely cut off in the main artery, which supplies the sac; and sufficiently far away from the sac to prevent the chance of the ligature giving way prematurely on account of the atheromatous and rotten condition of the vessel near the sac itself.

Second, that it must be so tied that sufficient smaller vessels may be left to take up and establish the collateral circulation in time to save the limb below from dying from want of arterial blood. Those two problems have got to be carried out. Now a certain percentage of ligations of large vessels after Hunter's method are successful, and a very considerable percentage fail; not only to cure the aneurism, but to supply the limb. Of what use to cure the aneurism if subsequently you have to amputate the limb? You could have done that before. In a very considerable percentage after the Hunterian method the leg and foot mortify; and this is the great drawback against its performance.

Other methods have been introduced which seek to obstruct the current in the artery, which I will only mention here, inasmuch as they are of the same class, and might as well be mentioned at the same time.

On account of the danger of suppuration and secondary hæmorrhage, Simpson introduced what is called acupressure, to compress the vessel by steel needles. The needle was passed in, and passed under the vessel, and left in the sartorius muscle, for instance; and placed in such a way that it was held between the vessel and the superficial muscles. The artery was merely crossed and compressed by the needle for a limited space of time. Twenty-four to forty-eight hours was ample to secure permanent obstruction of the femoral, in such cases. The needle was slipped out; the muscles fell back into place; but the artery was plugged.

This was a great advance over the old method. This was the first stage towards the better securing of vessels; but we, of course, have got by all that, since we have the antiseptic and organic ligature, made up of structures which either fail to excite suppuration, or are absorbed after the wound closes. Cat-gut ligatures are absorbed. The silk which is prepared antiseptically probably remains; although it is possible it may be finally absorbed. Its fibre is much stronger than is that of the cat-gut, and resists much better. By one of these means we can now tie these large vessels and not expect to have them suppurate, or have any secondary hæmorrhage. That might encourage us to return to the method of Antyllus; and, in fact, it is now occasionally used with success.

With all due respect to these great men, it is evident that all these methods are unphilosophical, in that they do not follow the dictates of nature. Nature tells us to try to slow the current; to try to promote coagulation of blood; and to try to give time for the parts to harden; but not to cut off the blood instantly, for that she never does. Hence the method by digital compression has proved to be the most successful, inasmuch as it imitates more closely the processes of nature herself. Formerly compression was applied rudely by means of a bag of shot, or an apparatus rigged with two or three screws and pads, so that you could push down one on one part, and another on another part of the artery; and these measures were often successful. Occasionally they failed; and they failed, I think, because the mistake was made of applying them too forcibly. It is not necessary to stop the current in curing an aneurism. It is only necessary to slow the current; take off the pressure and then apply it again; and frequently the aneurism can finally be permanently obstructed and stopped by the formation of successive layers of clots. The danger in the earlier times, in the use of compression, was that it was used so forcibly. The hand was never employed; but mechanical means wholly. These mechanical means were applied and kept on as long as it was thought the integrity of the parts would stand it; and the process continued for several days. The result was frequently œdema, sloughing, abscess, cellulitis, such a condition of the limb that afterwards no further operation could be attempted on the vessel or the part, provided this first method of treatment failed. Hence, if you are going to ligature an artery for an aneurism, do not touch it by any other means first; but if you are going to try compression, these measures may be used; but you must not expect a favorable opportunity to ligature the vessel afterwards, because the parts will almost always be so changed by œdema, that the ligature will fail, and secondary hæmorrhage occur, and antiseptic methods prove an entire failure. Either ligature or compress.

If we compress, it is best done by the hands of numerous assistants, and done with the fingers; holding them so as to almost entirely obstruct the current in the artery for a few minutes at a time. The human hands will not keep up pressure on the artery long. They have to be relieved as often as once in ten to fifteen minutes. It is not desirable that absolute stopping of the current should occur for any length of time. It may be held still a little while, and allowed to filter, the effect being carefully watched in the diminished pulsation in the sac; in its thickening; and the temperature of the parts being watched to see if any inflammatory changes are taking place. It is the most philosophical and best way of treating aneurism when it can be done. Obviously it cannot be used as well for the carotid, as for the femoral or axillary. In pressing over the carotid we have to press down upon the pneumogastric nerve. We generally give rise soon to great pain and distress and symptoms of irritability of the whole sympathetic system; consequently consecutive and long-continued pressure on the carotid is not generally well borne. In such a place we have only one other resort, and that is the ligature.

We have by no means finished all these methods that have been tried; and I will not dwell long on them; but will allude to them, in order that we may understand what was done, and why.

There is the method by partial compression. In popliteal aneurism the leg was tied up in extreme flexion. It pains terribly. The patient cannot stand it long. It requires large doses of morphia. The leg has to be tied up and let down. Slow obstruction of the current in the popliteal vessel; plugging of the vessel and stopping of pulsation in the aneurism sometimes in four or five hours, very often in twelve hours. This method in the popliteal region, and at the bend of the elbow, is a very effectual method; and if it is not persisted in too harshly, it is frequently successful. You must be patient. It is a mode of treatment that has not infrequently been successful, and has occasionally been disastrous by being persisted in too long; by making the aneurism slough and leading to secondary hæmorrhage. You cannot appreciate the amount of pain that the patient undergoes when the leg has been tied up in the flexed position for a short time. The pain is intolerable. The leg is occasionally relaxed a little and then brought up again. Large quantities of opium are given. You do not have this pain with gentle manipulation of the fingers on the groin, not to such an extent; though in almost all the immediately compressing methods the patient has to be supported through the treatment by the internal use of opium, to quiet the nervous system, to a moderate degree.

Manipulation. — That would seem to be a very rash method; and yet it was formerly applied; consisting in taking the sac of a large aneurism and kneading it with the fingers so as to force the blood to coagulate. The result was breaking up of clots in the part, travelling of emboli, and usually disastrous results.

Galvano-puncture is pretty much like the injection of astringents into the sac. By that is meant the throwing of the galvanic current through the sac and causing the blood to coagulate by the process of electrolysis. The blood coagulates around the two poles of the galvanic current carried through. In small aneurisms, if the parts around can be secured from the travelling of clots, no doubt it would succeed. In larger aneurisms it is dangerous.

Ergotin has been given subcutaneously to contract the walls of the vessels. Bear in mind that here you are dealing with a two-edged sword. You are not only contracting the walls of the vessel itself, but diminishing the circulation in the limb beneath; and spontaneous gangrene has followed the use of ergot, without any aneurism at all. Ergotism from eating spurred rye, has been followed by epidemics of gangrene in various parts of Europe. Ergotine will contract the coats of the vessels in the parts where you do not want them contracted, as much as in the parts about the sac, where you do.

The Introduction of Substances into the Sac. — That is a very curious phenomenon. It is applicable principally to the arteries of the thorax and the abdomen and the innominate, for instance, parts usually treated by what are called constitutional measures. This consists in taking a very fine roll of silver or nickel-plated wire, puncturing the sac, and passing in, perhaps, yards of fine wire. The result is coagulation of fibrin around these little fibres; immense increase in coagulability; occlusion of the aneurism; in a few cases cure; in many cases suppuration and death. It may be tried as a last, and I would say almost desperate resort in the case of innominate or thoracic aneurism, where the sac can be got at; and where the methods of rest, sedatives, starvation and drugs have failed; where the sac has increased, and the patient is going to die, it is quite justifiable to try this method, provided the patient understands it, and wishes to have it done. A few cases have succeeded, but not a great many.

We are reduced then I think, after all, in the operative treatment of aneurisms to only two methods. One is to tie the vessel; the other is to compress it. It may be done in a great variety of ways, and is frequently curative. The danger of too sudden ligation, or of sudden compression, is that there is not time enough to establish the collateral circulation, and that the parts below will die, and mortification take place. This may not extend up very far. Sometimes the patient loses a toe, or several toes; sometimes the process stops at the instep; and sometimes involves the whole leg; and where such a result does occur we might just as well have amputated the leg before and saved all this trouble, as amputate it afterwards for spontaneous gangrene. A distinguished physician in London, a few years ago, preferred amputation of the thigh to the tiresome and unsuccessful treatment of a large popliteal aneurism; and he promptly recovered from the operation. There is an open question, in case of a large aneurism, where there is a good deal of doubt whether you can cure it without gangrene, in regard to the proper method of procedure. Undoubtedly the majority would say they preferred any chance of ligature or compression, rather than the chance of losing a limb.

Venous aneurisms, or as they are sometimes called, varicose aneurisms, which consist in a communication between the artery and vein, in consequence of a wound which has failed to kill the patient by bleeding; which has let the arterial blood run out into the vein; are frequently of long duration; not always fatal; do not always increase fast; and do not always call for surgical interference. Unfortunately they often happen in inaccessible parts of the body; for instance, stabs in the groin and wounding of the iliac, so that the iliac arterial current communicates with the iliac vein. Such a case gives rise to an enormous buzzing tumor inside

the abdomen, which is heard with a whirring, rasping sound, pretty much like the saw, or a planing machine. This gives rise to pain and œdema of the leg; retraction in order to favor it; and to incapacity; but not necessarily, or rapidly, to destruction of life. If these cases can be reached early, they may be cured, frequently, by compression; and that is the most judicious form of treatment to apply. If they are small and very accessible, they may be laid open, and the artery and vein thoroughly tied.

THE TREATMENT OF HALLUX VALGUS.[1]

BY JOEL E. GOLDTHWAIT, M.D., OF BOSTON.

It seems hardly necessary for me to offer an apology for presenting a paper upon this subject, when it is considered, that comparatively few persons go through life without suffering to a greater or less degree from this affection, or from conditions which are directly the result of it; and when, furthermore, it is considered that while the deformity itself, as well as the resulting conditions are truly surgical affections, with definite modes of treatment for their control, still the large majority of the cases seek relief from their troubles at the hands of chiropodists, men of very little, if any, medical or surgical training.

While the title of the paper deals only with the treatment of Hallux Valgus, nevertheless, as the etiology has a decided bearing upon the treatment, a certain amount of time must be given to its consideration.

While the disease is essentially a disease of adult life, nevertheless, clinically, a congenital form is recognized, as with Hallux Varus, although it is of much less frequent occurrence. The deformity in these cases may be due to muscular contraction, or to an abnormal development of the bones, so that one articular facet is longer than the other.

Flat-foot is undoubtedly responsible for a certain number of cases; the reasons being purely mechanical ones. Instead of the step being completed with the weight of the body squarely upon the ball of the great toe, it is thrown upon the inner side, thus stretching the internal lateral ligaments, and pressing the toe forcibly against the others. Aston Key [2] describes the same condition by attributing it to excessive weight received upon a weak tarsus and metatarsus from overstanding, the great toe being gradually forced outwards by the oblique bearing of the foot, on the inner plantar surface, when the arch of the foot has given way.

In the large majority of cases, however, the condition is directly attributable to the wearing of improper shoes; either too short, too narrow, too pointed, or some form that does not give as much room for lateral spreading of the toes as is possible at the metatarsophalangeal articulations. Hueter [3] mentions the shoes and the shoemaker as the sole cause of the deformity; as do also Bradford and Lovett.[4] With either of these the resulting deformity is the same; the toes are crowded together and the great toe pressed against or drawn over or under the others. The deformity is necessarily increased in walking or standing, as there is distinct widening across the ball of the foot. To quote from Bradford and Lovett: [5] "The boot is not stretched at its extreme end, and it inevitably becomes in a degree conical in shape on this account, being broader across the ball of the foot than at the tip end. In the act of walking the foot necessarily slips inside of the boot to a certain extent, and if the shoe slips backwards and the foot forwards, a certain amount of pressure will come upon the inner side of the end of the great toe."

In the treatment of this condition it is rarely the deformity itself which causes the patient to seek advice, but, rather, some of the conditions which are the direct result. As the toes are crowded together, the folds of skin at the sides of the toe are pressed against the edges of the nail. These become irritated and sensitive, then hypertrophy as the result of the constant irritation, and later on, ulceration; and the painful "ingrowing nail" results. In the treatment of this the correction of the Hallux Valgus is necessary.

As the deformity develops and the toe is drawn more and more to the side, the head of the metatarsal bone is more and more uncovered, and there is constantly increasing pressure against this point, which normally should be protected. As a result, the skin thickens and becomes calloused; and the exposed end of the bone from the constant irritation becomes enlarged. This, at first, is chiefly due to periosteal thickening; but, later on, bony deposits replace and increase the enlargement, particularly at the age when the deposits common in chronic rheumatoid arthritis are seen.

While these changes are taking place upon the exposed side of the bone, on the inner side the articular surfaces of the phalanx and the metatarsal bone are crowded together. This produces atrophy of the articular cartilages, and, if continued, the bone becomes exposed and true caries may result.

On the exposed side of the foot, as the thickening at the head of the metatarsal goes on and the skin over it becomes harder, a bursa forms between the two, which may or may not communicate with the joint. Under the continued irritation of walking this bursa enlarges, and later on becomes inflamed, — the so-called "Bunion."

Preventative treatment is, of course, the best for this condition, and consists in keeping the feet in the natural position from infancy; the arch of the foot should be maintained, especially in persons who are obliged to stand a great deal, and above all, proper shoes should be worn. After the deformity has occurred, the first part of the treatment consists in the removal of the cause; nothing like a tight shoe should be thought of, a wide and easy one being worn, and in connection with this stockings of good length should be worn. Key suggests having shoes made with a separate compartment for the great toe.

For the correction of the deformity various methods are in use. One of the simplest consists in wearing a piece of felt or roll of cotton between the first and second toes. This presses the great toe into place; but it has the disadvantage of leaving a considerable space between the two toes, so that when the pad is removed it is easy for the deformity to recur.

A method suggested by Sayre [6] consists in using a

linen or buckskin cot made to fit the toe, to which is attached a few inches of elastic webbing, and to this, again, is attached a piece of adhesive plaster to go around the heel. This is retained in place by two other strips of plaster which encircle the foot. This makes a comfortable appliance for use, especially in the acute cases.

Various appliances have been suggested, which would exert more force for correction than the Sayre device, such as hard-rubber, gutta-percha, or pasteboard splints, to which the toe is bound, so as to pull it back into place. In this class is the Bigg's apparatus which consists of a piece of steel with an opening cut so as to avoid pressure on the bunion, which is fastened to the inside of the foot and the toe pulled up to it. The difficulty with all of these has been to adjust them in such a way that they could be worn without great discomfort.

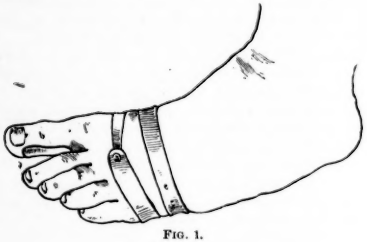

FIG. 1.

FIG. 2.

FIG. 3.

In order to get something that could be tolerated in walking, and at the same time be efficient in correcting the deformity, I have been experimenting during the summer, and after personal use, offer the two forms of apparatus that are shown in Figures 1, 2 and 3. Both can be worn inside an ordinary shoe, and at the same time exert pressure enough to hold the toe in the correct position. This pressure can be increased from time to time, if it seems necessary, by simply rebending the splint. The appliance is so fitted that no weight comes upon it in walking, the ball of the toe and ball of the foot both being free. The band which extends up on to the dorsum of the foot should be carried back far enough so that the painful joint is avoided, and should then be curved forward nearly to the base of the toes, so that flexion of the foot is not restricted. The long arm which follows the side of the foot in the splint (Figs. 1 and 2) makes it possible to exert more force for correcting the deformity, and also serves to more perfectly immobilize the splint than is possible with the appliance Fig. 3. Both splints are made of light spring steel, and should be carefully fitted before being tempered. Leather straps encircling the foot hold the appliances in position.

At times there is so much bony change that splints are not sufficient and some bone operation becomes necessary. If there is comparatively little inflammation about the joint and the bone is not very much changed in shape, a wedge-shaped piece may be removed from the head of the metatarsal bone as near the joint as possible and the toe drawn into place and secured by splints and a fixed bandage until the wound has healed. The bursa should be removed at the same time.

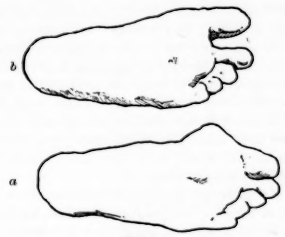

FIG. 4.

I wish here to show the casts of the foot of a patient upon whom I operated, in this way, about two months ago at the Carney Hospital. The patient was a woman about thirty-five years of age, with the marked deformity (Fig. 4, *a*) of the great toe which had existed for many years. A wedge-shaped piece of bone was removed from the head of the metatarsal, and the position corrected, as is shown by (Fig. 4, *b*), which was taken a few days ago.

At times, the change which has taken place in the head of the metatarsal bone is so extensive, and the bone is in such an unhealthy condition that the wound does not heal after the osteotomy, and a troublesome sinus remains. In other cases the thickening is so great that it is readily apparent, that even though an osteotomy were performed, the prominence at the joint would remain and cause trouble. For these cases the operation described by Hueter,[1] which consists of complete excision of the head of the metatarsal bone, is to be performed. The base of the phalanx, with its muscular attachments, is not disturbed. After the removal of the piece of bone the toe is drawn into place and the wound loosely closed, or is allowed to granulate. The bursa should be removed at the time of the operation, as with osteotomy. The results after this operation have been very satisfactory, leaving a straight toe and a very useful foot.

Tenotomy is suggested as a form of treatment, but the cases must be very rare that can be corrected wholly by this method.

Painful inflammation of the bursa may result from the constant irritation, and this may go on to suppura-

[1] Gelenk-Krankheiten, p. 345.

tion, and from this a more or less extensive cellulitis may develop. With this there is apt to be marked sensitiveness of the joint, rendering motion very painful, and for this condition rest and poultices or cold compresses are necessary, with possibly incision later on. The joint should be protected by bunion plasters or rings of saddler's felt, and a large soft shoe (or one made after the pattern of the Chinese shoe) should be worn.

Whatever be the operation or whatever the treatment, the importance of wearing proper shoes should not be lost sight of. The sole should be wide, so that the foot may have abundant room to spread out in walking or standing, and there should be plenty of room for the toes to be extended in the line with the metatarsal bones.

APPENDICITIS.[1]

BY A. WORCESTER, A.M., M.D.

(Concluded from No. 21, page 509.)

LET us now consider the treatment, and the reasons for the continued disgraceful diversity of opinions regarding the question.

Many writers upon the subject have apparently never seen a case of appendicitis. Having recognized its sequelæ at either ante-mortem or post-mortem examination of the abdomen, they imagine that they have recognized the disease itself. No other evidence of this general ignorance need be mentioned than the custom in medical journals as well as in the lay press of reporting deaths from appendicitis. Now nobody ever did die of appendicitis nor ever will. For the appendix being a perfectly useless organ, even its annihilation cannot injure the body except indirectly. But, just as the most harmless fellow citizen, who never would be missed, after his death, if his corpse be not decently removed, may endanger the life of the community, so our innocent little appendix after its death is apt to become an offensive source of trouble in our midst. And to treat with salts a patient in whose abdomen lies a putrefying appendix (as was lately recommended by a distinguished surgeon who maintained that once dead the appendix had done all the harm that it could do) is as reasonable treatment as it would be to depend upon flushing with sea-water the leaking sewers of a house where a cholera corpse was left lying in state.

There is, however, nowadays, excepting perhaps in the State of Maine, no theoretical opposition to the prompt removal of a gangrenous appendix. The question is as to the propriety of removing the inflamed appendix before the gangrenous stage is reached, or rather before the existence of gangrene shall have been confirmed by the inception of peritonitis or of a localized abscess. There could not be two sides to this question, were it not for the unfortunate fact that some still think themselves able to discriminate in cases of appendicitis which ones will eventuate in gangrene; or think themselves at least able to determine just when in any given case the inflammation assumes a gangrenous character. To this conceit should be ascribed the continued terrible mortality from the sequelæ of appendicitis. For, even admitting that a few experts have this extraordinary ability, which I deny, there is even so no safety in the ordinary practitioner's fooling himself with either his own or his consultant's guesswork. The physician who undertakes to treat his cases medically until gangrene occurs, and then to shift all responsibility upon the surgeon, will often find that he calls in the surgeon either a day too soon, to his own mortification, or, if a day too late, to his patient's.

If those who believe that they themselves have acquired the skill to distinguish at the onset of the disease the mild from the fulminant variety would only remember by what experience such supposed skill has been acquired, it does not seem possible that they would advise the inexperienced to follow in their footsteps. Yet this is one effect of their teaching, and the only other logical deduction is the necessity resting upon all more modest practitioners of putting their patients to the expense of sending at once for the assistance of these would-be specialists.

Feeble attempts have been made, it is true, to inform the profession how to differentiate the sure-to-do-well from the sure-to-do-badly cases. But in these attempts no two authorities agree, and, indeed, no authority of this year agrees with his own last year's deliverances. Apparently, the present position of these would-be diagnosticians is that one must be guided not by intelligible rules, but by impressions, which may be acquired only by long experience in watching cases go well, or from bad to worse, as fate may decide. Such experience apparently leads to the specialty of knowing nothing about appendicitis, however great proficiency may thus be acquired in dealing with the after-effects of the disease.

It is, however, not only that no one has as yet been able to formulate any serviceable method for making this very desirable diagnosis of the varieties of appendicitis without abdominal section, but it is also to be borne in mind that in the very nature of the problem no such method need be expected. For there are many conditions frequently attending even the apparently mildest forms of appendix inflammation, all of which are unrecognizable from the outside, yet any one of which being present makes it certain that in that particular case either a perforation or a gangrenous sloughing off of the organ will occur. Thus who can reasonably hope for ability ever to tell with what kind of micrococci an inflamed appendicitis is loaded; or how thin its walls have become, and at what hour the perforation will occur; or in what position the appendix lies, and the direction in which its foul contents will then be shot?

If we are only to stand by with salts and sympathy and close observation in these cases, all of these awkward questions must be satisfactorily answered, or there will be more funerals; and, until such questions can be satisfactorily determined, it is the plain, unavoidable duty of the medical attendant in every case of appendicitis, and as soon as the diagnosis is made, to put his patient under surgical treatment. An hour's unnecessary delay in so doing is inexcusable, if not criminal, negligence.

This, I am well aware, is not yet generally acceptable doctrine to the profession.

It is easier to understand the position of the physician than it is that of the average surgeon as regards this duty of immediate surgical treatment. The physician sees more than half of the cases, which perhaps, may be of appendicitis, do well under medical treatment; and where death or other grave disaster ensues

[1] Read by invitation before the Essex South District Medical Society, September 19, 1893.

the physician generally is able to transfer a large part of the responsibility to the shoulders of some surgeon. So long as surgeons dally with these cases, waiting for evidence of inflammation of something besides the appendix, it need not be expected that physicians will be in a hurry to transfer their appendicitis patients, and we shall continue to hear the sickening story of cases where at first all the doctors present were sure that it was only a mild catarrhal attack, but where suddenly the disease became fulminant, and where finally, at the last hour, the rigid abdomen was found to be full of stinking pus.

Those who oppose the rational radical treatment of appendicitis may be divided into four classes. Some do not know how to make the diagnosis. Some think they can diagnosticate even the varieties of the disease; others believe such knowledge possible; and finally, some have such an exaggerated fear of abdominal surgery that they allow their patients to take, instead of the chances under operation, the chances of not suffering any ill effects from the disease.

Attention has been given already to several of these objections. And now as regards the hope of future ability to tell beforehand which cases will surely do well without surgical intervention. Even if such knowledge be obtainable, will it come from the present custom of watching some cases recover only to recur, or will it come from the too late operations, or even from evacuating abscesses that might have been prevented? Will not such knowledge come, supposing that it is within the bounds of hope, rather by the prompt than by the delayed use of the knife? And can it be doubted that more lives would thereby be saved?

It remains for us now to consider the objections founded upon the imaginary dangers and disadvantages of even a needless explorative laparotomy. The real danger and disadvantage is trifling in comparison with that of delay in applying prompt surgical treatment. There is the fortnight's confinement to bed and the remote chance of subsequent hernia. But supposing the abdominal section to have been proven needless, there is then no danger whatever from subsequent hernia. The different layers of the abdominal walls can be fastened by buried sutures, and even if hernia should result, its radical cure is afterwards a simple matter.[2]

But only very seldom will an abdominal section, made under the diagnosis of beginning appendicitis, prove useful only in eliminating that disease by exclusion. Generally, the inflamed appendix can then be easily removed, and the disease eliminated by the excision; and where there is doubt as to its condition, or where there is difficulty in extricating it, then the early incision will be far more likely to prove to be a valuable sluice for a subsequent foul discharge than to be a source of danger or even of inconvenience to the patient.

I have several times seen fæcal concretions, and sometimes even the gangrenous appendix itself, discharged through incisions which at the time of operating seemed to be almost profitless. This result may be especially hoped for when there is a history of previous severe attacks.

Those who object to the immediate operation on account of its supposed dangers and disadvantages surely can never have seen employed the treatment they ignorantly condemn. For no surgeon who has once amputated a gangrenous appendix before it has perforated, and before either a localized abscess or a general peritonitis has developed, can ever question the immeasurable advantages of so treating the disease.

From such treatment no deaths have ever resulted, so far as I am aware. Nor have I known of any hernia or other subsequent trouble to result. Patients so treated certainly do not suffer recurrences of the disease.

After delayed surgical treatment, all kinds of troubles and disasters may be expected, and are, indeed, often unavoidable. And it is just here that the blunder of reporting cases of the sequelæ of appendicitis as cases of the disease itself, works such mischief; for timid practitioners hesitate to allow the early use of the knife where the disease is in its original mild stages, thinking thus to avoid the terrible revelations belonging only to delayed surgery. It would be as reasonable for such men to object to timely surgery because of the frightful revelations of the after-effects of appendicitis discovered so often only at the autopsy.

One last objection to the treatment herein advocated remains for consideration. Its necessity and even its propriety is still questioned, and by surgeons and physicians of large experience and great prestige.

Believing, as I firmly do believe, in the necessity of treating the disease surgically as soon as ever the diagnosis is made, and that every death resulting from appendicitis where the patient was not given the benefit of immediate surgical relief, is due to malpractice, I can but hold as responsible for the continued death-roll both those who advocate other methods of treatment and those who even tacitly approve the propriety of delay in such cases; for until the leaders of the profession either endorse the rule of immediate surgical treatment in every case, or furnish some other intelligible rule, it need not be expected that the present death-rate will be diminished.

Meanwhile, general practitioners make a great mistake in weakly depending upon the leaders of the profession in the simple emergency of an attack of appendicitis. There is too much of this shifting of responsibility business, nowadays. In the cities it may pay; it certainly does not pay in more sparsely-settled regions where the loss of patients cannot be well afforded, and where the grave-stones stare at us so uncomfortably, as we ride by on moonlight nights.

And then appendicitis is only one of several emergencies requiring prompt abdominal section. In some, as for instance in strangulated hernia, the doctor who waits long before operating, is not generally considered a first-class practitioner. And yet the operation of amputating a gangrenous appendix is surely neither more imperative nor more difficult.

In the surgical treatment of the later stages of the disease, and of the frightful conditions following it, there is no limit to the skill and equipment needed. Even so, failure will often occur. But in the early operation ordinary surgeons will succeed.

Perfect asepsis is, of course, requisite. So it is in the simplest surgery, and only fools disregard it. There is then no danger in cutting down through the abdominal wall directly over the point of greatest tenderness and of greatest resistance, as discovered by previous palpation. The incision should be a clean knife-cut throughout. Before incising the peritoneum,

[2] The truth of this last statement has since been verified by the personal experience of the writer.

it should be picked up with the forceps and at first nicked through by the knife, to avoid wounding any underlying gut. For those who can recognize the large intestine when they see it (and those who cannot do so can readily learn by a little careful study at an autopsy) there is not much difficulty in finding the appendix. The longitudinal bands on the colon and cæcum run straight down to the base of the appendix.

In cases where the surgery is delayed, it may be impracticable for an inexperienced surgeon, or even for an adept, to remove the appendix. But in cases of immediate operation the appendix can easily be brought up out of the belly wound and cut off by a V-shaped incision, which will allow the inversion of its edges and the approximation by Lembert sutures of their peritoneal coats.

If there is any gangrene of the outside of the appendix, it is not safe to close the abdominal wound: some gauze must be loosely stuffed into the cavity where the organ lay, which can be removed on the second or third day. But if the appendix has no gangrenous surface, then, after careful wiping out the region involved, the abdominal walls can be safely closed by layers, with buried sutures.

Such, in brief outline, is the operation by which patients suffering with appendicitis may be surely saved not only from death but from the chances of recurrence and of long-suffering.

I now beg to offer the following conclusions:

(1) Appendicitis itself is not a serious disease, for it is the inflammation of a worthless part of the body. It is, however, apt to recur. And any attack if left to nature or to medical management may cause a fatal purulent peritonitis or a localized abscess.

(2) Appendicitis can be as readily recognized as can any other local internal inflammation. This diagnosis, however, is easiest in the earliest stage of the disease.

(3) No rules can be formulated for differentiating the varieties of appendicitis, and of thus foretelling which cases will recover and which will cause dangerous or even fatal consequences. For there is no known way, except by abdominal section, of ascertaining the rate of progress or the extent of the inflammation in any given case; nor of determining the virulence of the contents of the organ, or its anatomical situation.

(4) The only rational treatment of the disease is its immediate ending, by excising the organ, before its own death or damage causes like results to its owner. This, at the beginning of the attack, is a feasible and an absolutely safe operation.

(5) The mortality in properly treated cases of appendicitis is *nil*.

Clinical Department.

A FEW CASES OF MILD MENTAL DISTURBANCE.[1]

BY LUCIUS W. BAKER, M.D.,
Superintendent Riverview Sanitarium for Nervous Invalids, Baldwinville, Mass.

The family physician is usually first consulted in regard to nearly every case of insanity, and his advice is desired as to the best counsel to be followed. He may not always be familiar with the rarer forms of mental disease, but he should be able to recognize and deal with those cases most likely to be met with in the routine of daily life. The few cases herewith presented are reported, not for their rarity or for any special peculiarity, but as illustrative of those cases which are constantly coming under the observation of the general practitioner.

Case I. Mrs. A, age twenty-five, about three months after her first confinement began to show symptoms of acute mental disturbance. She was of a refined, gentle disposition, but became profane, incoherent with constantly varying delusions. She had refused to care for her baby, and several times attempted to destroy it; had jumped from a two-story window, and tried to leap from a carriage while passing over a bridge. When admitted, she was poorly nourished, sleepless, and rambling in her conversation, was abusive to her attendant, refused to undress at night, and it was with great difficulty that she could be bathed. She was constantly attempting suicide by choking herself with her hands, and unless her grasp was forcibly removed would persist until her face was livid. This condition continued unchanged for about a month, when she became more quiet and manifested some interest in her surroundings; she could then be induced to engage for a short time daily in some fancy work, and spent much time in the open air. Her mental condition improved quite rapidly, and she was discharged well in about five months from the time of admission.

She has since passed safely through another confinement, and still remains in good physical and mental health.

Case II. Mrs. B, a bright, well-educated lady of twenty-five, of a strongly marked neurotic temperament. For nearly two years before admission she had had the delusion that her eyebrows and eyelashes were diseased and falling out, and that in consequence she had become so repulsive in her appearance that she was unfit to mingle in society. She was greatly depressed, and remained in strict seclusion as far as possible, spending much of her time before the mirror lamenting her sad lot, and would only go out when closely veiled. She was continually applying various preparations in hopes of preventing the progress of the supposed disease; and when I first saw her had succeeded in exciting some inflammation of the skin. Was seen by Dr. J. C. White, of Boston, in consultation, who decided that the eyebrows were free from disease.

She remained under my observation for about four months, during which time she was kept much in the open air and the presence of the delusion was largely ignored. She was a fine musician, and was urged to play and sing as much as possible. Gradually her mental trouble disappeared; she regained her health and spirits; and so far as I have been able to learn, has continued well.

Case III. Mrs. C, age thirty-five, was of an intensely active disposition. Soon after leaving the seminary she had an attack of neurasthenia, from which she recovered, married and went as a missionary to China, where with her husband she labored hard for six years. She then gave out, returned to America, and in April, 1890, entered a nervine asylum, where she improved physically; but as she gained in strength her inactive life became very irksome, and she then began to be mentally disturbed. For about a week before coming under my care she had been sleeping

[1] Read before the New England Psychological Society, September 26, 1893.

poorly, had headaches, and imagined that her room was arranged so that constant watch was kept upon her movements and that what she said or did was conveyed at once by means of the steam-pipes to the superintendent's apartments. She also believed that she had died and been brought to life again. During her residence with me of three months, she had varying delusions, and once wrote a long astronomical jumble which she wished to have published in the New York *Tribune*. As she gained in flesh and strength, she began to sleep better, her delusions passed away, and she has since remained in perfect mental health.

CASE IV. Mrs. D, age fifty-five, three months after an attack of the grip began to sleep poorly and lost her appetite. She was, however, obliged to work quite hard during the following summer; but in September, 1891, suddenly lost her self-control, and for a time was quite hysterical. She was then restless, sleepless and quite depressed, but without positive delusions, and had lost all interest in her home, to which she was usually much attached.

Within a month after admission she had gained three pounds in flesh, and was sleeping better. She was obliged to return home and care for a sick husband, when the old symptoms returned, and she came back, remained for two months, improved, and went home again on trial with the same result. She returned again and stayed four months, when she was discharged quite well, but with the caution to avoid housework for a year. This she did for some time, and is now as well as usual.

CASE V. Miss E, age thirty, a school-teacher by profession, had been working very hard and been out of health for about a year, but for some years had been a poor sleeper and had taken various hypnotics and other drugs. She was admitted to the Adams Nervine Asylum a few weeks before coming to me. While there she began to believe that a gentleman with whom her family had had some financial disagreement had furnished false information about her, that her letters were opened, and that she was constantly watched. She refused to take her medicines, and conducted herself generally so badly that she was sent away from there and came under my care. She was then somewhat anæmic, quite thin (weighing but eighty-seven pounds), possessed of varying delusions, and nervously prostrated. Soon after admission she attempted to run away but was easily persuaded to return. With rest, full feeding and cod liver oil, her mental condition steadily improved, and within a few months she had gained thirteen pounds in flesh, but regained her physical strength quite slowly. She remained under my observation for about a year, and since her return home has continued to improve and will probably completely regain her health.

CASE VI. Mrs. F, age forty-five, about two months before admission began to sleep poorly, lost all interest in her household affairs, and believed that she was cursed of God, that she was dishonest, had done evil, that she must go about telling the wicked things she had done, and that then she would be arrested and imprisoned, which would only be what she deserved. She paid but little attention to any one, and would sit for hours twisting a string or handkerchief between her hands. Had been taking teaspoonful doses of paraldehyde at bed-time and repeated the dose in the middle of the night. This was soon discontinued, and she was given twenty grains of chloralamid nightly, which was gradually reduced and soon dropped altogether. She was placed upon a generous diet, with tonics, kept much in the open air, and steadily but slowly improved, and returned home in three months. When last heard from she was as well as ever.

CASE VII. Mrs. G, for three years past has had profuse hæmorrhages from a uterine fibroid. September 30, 1892, the uterus and appendages were removed at St. Margaret's, Boston, by Dr. J. W. Elliott. Convalescence from the operation was satisfactory, and she returned home in five weeks, but soon became depressed and wakeful, and complained of pains in the head and back of the neck, and was in bed most of the time. Slight delusions then began to appear; she had committed an unpardonable sin in leaving the hospital so soon, and had erroneous ideas as to her surroundings, examination, etc. Returning to St. Margaret's, January 9, 1893, she appeared perfectly rational, but complained of pain in the region of the uterus, and that her head felt badly. Her mental condition again became much disturbed. She imagined that policemen were coming to take her to a dungeon across the river, that she had done wrong in telling things which she ought not to have told, and that her husband must suffer in consequence.

In this condition she was sent to me February 14, 1893. She was then excited, markedly anæmic, thin and exhausted; did not sleep well; her head felt badly; and in addition to the old delusions, she believed that she was to be buried alive. Within a few weeks her mental condition showed marked improvement, but her physical health improved but slowly, and her convalescence was marked by frequent relapses and by various nervous disturbances.

She returned to her home August 4, 1893, in a normal mental state, but still weak. She has, however, continued to gain, and will probably fully recover her health.

CASE VIII. Mrs. H, in August, 1892, while at a summer resort, without any known cause, except possible exposure to heat, quite suddenly lost all interest in the affairs of life, and began to be much depressed mentally. She felt that she had lost her religious hope, that she could only bring sorrow and disaster to all with whom she came in contact; and she was in constant fear that she would become so bad that she would be sent to an asylum for the insane. In the presence of others she was bright and vivacious, but when alone would spend hours of hopeless misery. She had lost flesh rapidly, and slept badly. She was at once placed upon a generous diet, and fed every two hours. Her mental condition steadily improved. She gained fifteen pounds in three months, when she returned to make a trial of home life, and has since remained as well as ever.

I am, of course, aware that this is a very limited number of cases on which to base any conclusions; but in reviewing them I have been impressed with two things: first, the rapidity with which the mental symptoms disappeared after the commencement of systematic medical treatment; and, secondly, the value of what is known as the restorative plan of treatment in patients with mental disturbance. It should be remembered, however, that with but one exception these were all comparatively recent cases. This is in agreement with the universal opinion of alienists, that the earlier treatment can be commenced the better the prognosis.

These cases were all regarded as suffering from an

impaired nutrition of the brain, and were given bitter tonics to restore the appetite when needed, — syrup of hypophosphites, phosphorus, strychnine, the various preparations of malt, and cod liver oil when possible to induce them to take it. Few hypnotics were needed, but when indicated the plan was to change them frequently, gradually reducing the quantity as the general health improved. My chief reliance, however, has been moderate exercise, out-door life, and the systematic use of a most nutritious diet. In addition to three full meals daily, I order the administration at regular intervals (generally of two hours) of a variety of concentrated liquid nourishment, such as milk, eggnogs, malted-milk, beef-extract, etc. A careful record of the weight was kept; and with scarcely any exception there was an early gain in flesh and an accompanying improvement in the mental condition.

It is difficult, however, to carry out the full details of this plan of treatment at the patient's home, unless an experienced nurse can be had; and even then there are difficulties in the way, as the surroundings are seldom under our management, and the full co-operation of the friends is not always obtainable. For this reason it seems preferable, when possible, to secure for these patients a complete change of surroundings, where all the details of treatment can be carried out under the direct control of the physician in charge.

Medical Progress.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

MORPHOLOGY OF THE MUSCULUS STERNALIS.

Dr. F. G. Parsons[1] reviews very concisely the chief facts observed concerning this interesting anomaly and the chief theories of its significance which have been deduced from them. He then gives new and original reasons for the support of a certain view. His statement of observed facts is so excellent that we give it in his own words. The main ones are the following:

"(1) That it occurs in from three to five per cent. of human subjects, though much more commonly in anencephalous monsters.

"(2) That it occurs in nearly the same proportion in male and female subjects.

"(3) That it is not found as a definite muscle in any of the lower animals.

"(4) That it lies superficial to the pectoralis major.

"(5) That it is very frequently continuous with the sterno-mastoid above.

"(6) That below, it is usually attached to the aponeurosis of the external oblique, or at all events to the sheath of that muscle which is blended with the aponeurosis.

"(7) That it may be uni- or bi-lateral.

"(8) When it is unilateral, it may cross the middle line obliquely. When it is bilateral, the two muscles are frequently connected across the middle line, or they may cross the middle line obliquely, forming a X in front of the middle line.

"(9) That it is usually supplied by one of the anterior thoracic nerves, . . . or by the intercostal nerves.

"(10) That it very occasionally has tendinous intersections.

"(11) That when a well-developed platysma coexists with it, the platysma is always on a plane superficial to it.

"(12) That it frequently pushes the anterior cutaneous branches of the intercostal nerves inwards, so that they form loops around its inner margin."

To this Mr. Parsons might have added that sometimes its fibres mingle with those of the pectoralis major; and that when the sternalis is present the pectoral sometimes shows anomalies by defect.

He then enumerated the following as the chief theories:

"(1) That it is a prolongation upward of the rectus abdominis." We may add that this is quite antiquated.

"(2) That it is a muscle peculiar to man, corresponding to nothing in the lower animals.

"(3) That it is a continuation of the sterno-mastoid above and of the external oblique below.

"(4) That it is a continuation downwards of the sterno-mastoid.

"(5) That it is formed by fibres of the pectoralis major, which have become rotated at right angles to the generality of the fibres.

"(6) That it is a remnant of the panniculus carnosus."

The last view upheld by Sir William Turner and others, is condemned by most, particularly on the ground that the playtsma, which undoubtedly is the analogue of the panniculus, lies superficial to the sternalis. The frequent connection of the sternalis with the sterno-mastoid also stands in the way. Now Mr. Parsons has found that the panniculus of the agouti and of many other rodents divides at the axillary border of the pectoralis major and passes both above and beneath it. He continues: "In man the deep abdominal panniculus has probably become the fascial sheath over the external oblique, and it is quite possible that the deep part of the cervical panniculus which lies over the sterno-mastoid and deep to the platysma (superficial cervical panniculus), may have become incorporated with the sterno-mastoid. If this be granted, nothing is simpler than to regard the sternalis as the remnant of a connection between the deep cervical and the deep abdominal panniculus, seeing that it is attached so often to the sterno-mastoid above and to the external oblique or its sheath below. . . . This theory, moreover, accounts for the co-existence of the platysma with the sternalis, though on a more superficial plane."

Dr. Parsons adds that as he regards the pectoralis major as derived from the panniculus, it matters little whether we regard the sternalis as a part of one or the other. This is a very ingenious view, though resting on a basis that must be doubtful, till several of the points concerning the analogies of the fasciæ and muscles have been definitely settled.

ANTHROPOLOGICAL MEASUREMENTS.

Hasse and Dehner,[2] of Breslau, made observations on rather more than five thousand soldiers with interesting results. We are particularly concerned with the question of the symmetry of the two sides of the body. The legs were of equal length in 32 per cent. and unequal in 68 per cent. In 52 per cent. of the

[1] Journal of Anatomy and Physiology, vol. xxvii, July, 1893.

[2] Arch. für Anat. and Physiol., Anat. Abtheil., 1893.

whole, the left leg was the longer; the right in 16 per cent. The arms were equal only in 17+ per cent., and unequal in 83 per cent.[3] In 75 per cent. of the whole the right arm was the longer, the left in nine per cent. Only one man in one hundred was left-handed and only a single man of this class had the right arm the longer.

THE FORAMEN CÆCUM.[4]

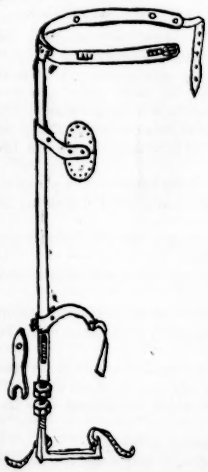
Professor Holl points out that the statements in anatomies concerning this little hole are not all the same. The general impression concerning it is that it is sometimes merely a blind pit, in other cases a communication between the cranial and nasal cavities transmitting a vein. The last impression, according to Holl, is quite a mistake. In the adult it is a closed canal completely filled by a process of dura mater. In the macerated skull of a young person it is truly a canal, but it transmits no vein, for skulls which have not been macerated show that it is closed below by cartilage; the process of the dura mater which passes through it runs for a short distance between the cartilage and the nasal bones. In an embryo of a new-born child this band runs as a small thread to the tip of the nose. The bone which grows round the upper part of this is the nasal spine of the adult frontal bone. This spine is very important; it runs as a pin between the ethmoid, the nasal bones and the median prominence of the frontal. This has, moreover, a pathological interest. If the nasal spine does not develop, this place is closed only by membrane, so that an encephalocele may occur.

THE TRANSVERSE PALATINE FISSURE.[5]

This is the fissure formed by the junction of the horizontal plates of the palate bones with those of the superior maxillæ. It has received no great attention as its variations are of no practical consequence. Professor Stieda has classified the kinds of suture with his well-known accuracy. It is possible that the matter may have some ethnological value. Besides irregular forms which defy classification, he finds three chief dispositions of this fissure. The most usual is when it bends forward with a convexity which is completed at the median line by the opposite suture. It may instead run straight across, or finally it may bend backward. Stieda examined 1,382 skulls which were suited to the purpose, that is to say, in which the hard palate was not injured nor the suture obliterated. More than 1,000 of these were in two collections at Königsberg, but the remaining 300 were in the anthropological institute of Rome. About 200 of the last were skulls of Melanesians and the rest of Italians. Of the Melanesians about 48 per cent. had the anterior convexity and about 40 per cent. had a straight suture. This is very different from the results obtained with the German collections which showed the anterior convexity in from 65 to 68 per cent., and the straight line in from 14 to 19 per cent. The Italian skulls had the forward convexity in 72 per cent., the straight line in 40 per cent. In all races the posterior convexity was less common and irregular forms rarest of all.

THE LYMPHATICS OF THE ANUS.[6]

Dr. Quénu finds that the lymphatics of the anus empty into the glands near the termination of the long saphenous vein, most often somewhat above that level, but not rarely below it. The lymphatics of the anus are connected with those of the rectum along the columns of Morgagni. The course of the rectal lymphatics was studied only on children, which seems unfortunate. The author wished to ascertain whether they emptied only into the glands of the meso-rectum, or whether they had any connection with glands at the sides of the pelvis. He found that the lymphatics of these parts may be divided into three sets: those of the anus already mentioned inferior to the *levator ani*, those just above that muscle running to the lateral glands in the neighborhood of the internal iliac or of its chief branches, and finally, superior ones running to the glands along the superior hæmorroidal artery.



[3] In the original these figures are respectively 18 and 82, but this does not tally with what follows. We have corrected two evident mistakes but an error of one per cent. remained.

New Instruments.

A MODIFICATION OF THE LONG TRACTION SPLINT FOR HIP DISEASE, DESIGNED TO PROVIDE A LIGHT APPARATUS FOR LITTLE CHILDREN.

BY AUGUSTUS THORNDIKE, M.D., BOSTON.

IT not infrequently happens in orthopedic practice that a child three or four years old has to wear a Taylor hip-splint, a high-soled boot, and use crutches. It is almost invariably very slow work teaching such small children to walk thus encumbered. In the out-patient clinic the parent becomes first discouraged, then firmly convinced that it is impossible for such a small baby to walk on crutches; and in some instances the child is taken away from the clinic, and all treatment for a while is abandoned. If not, then after several months of encouragement and advice on the part of the orthopedist, the child gets to use crutches in spite of the parent's unbelief. In the hospital-ward instruction in the use of crutches is more easily and quickly given; but a little child always monopolizes a great deal of the nurse's time before it finally learns to walk. Taking both of these factors into consideration, it seemed to me that much time and trouble might be saved by making the splint out of a lighter material than the square bar of iron or steel generally employed, at least in this city. For this purpose, I have used for the upright of the splint a piece of steel tubing, which is both lighter than iron gas-pipe and stiffer than brass tubing.

Into the upper end of the tube is brazed a forged

piece, flattened out and shaped like the forging on top of the upright of a Taylor splint, which serves to connect it by three iron rivets to the waist-band of the splint. To insure strength, the lower part of the forging should nearly fill the tube for the upper two inches. The waist-band is not different from that of the ordinary traction hip-splint, and provides buckles for the completing belt and two perineal bands. Into the lower end of the steel tube, slides an iron rod; the lower part of this is forged into a light foot-piece, while upon the upper portion, for about six inches, a thread is turned of twelve turns to the inch, which carries two nuts. This rod should slide easily within the tube and at the same time almost fill it. By cutting a slot in the tube of one inch (the lower end of which should be at least two inches from the bottom of the tube) and inserting a small pin through the slot into the rod, the foot-piece is kept from twisting. Two straps riveted to the sides of the foot-piece serve to attach it to buckles on the leg extensions. The thigh-pad and calf-band are secured to the splint by simply wrapping the end of the arm once around the tube and tightening it with a screw. This holds the arm firmly enough for a small child, and enables one to alter the position of the bands with great ease. The upper part of the tube may be made to fit the natural curves of the body, but the lower six inches should be straight to allow the rod to slide within it.

In applying the splint the belt and perineal straps should first be tightened. The straps from the foot-piece should then be buckled firmly into the buckles on the leg extensions, and the webbing strap from the calf-band fastened. When the splint is put on, the pin should be at the top of the slot. By turning the upper of the two nuts with the wrench, any desired amount of extension may be applied; then holding the first nut steady with the wrench, the second nut is screwed firmly down on the first. This locks the two and prevents slipping. Two wrenches are provided for the purpose.

I have only had occasion to apply this form of splint twice during the past eighteen months; but the rapidity with which those little children have learned to get about has led me to think that I have been using too heavy apparatus. My limited experience has already disclosed two facts about this splint: first, that any rivet-hole or screw-hole in the steel tube renders it liable to break; and, secondly, that the "locked" nuts do not hold, but gradually loosen, if the little patient attempts to discard crutches and walk about on the foot-piece and high sole only.

Now that steel tubing is manufactured in this country, the cost of this appliance should not exceed that of other long traction-splints which provide for the adjustment of the amount of extension by the ratchet and windlass.

The Value of Bugs. — A curious case has recently come to trial in Brooklyn. A professional bug-exterminator sued a saloon-keeper for $25 for clearing his premises of insects. The plaintiff declares that he killed 8,000,000 bugs, which is at the rate of 3,200 bugs for a cent. The defendant asserts that the sum agreed upon was $12.50, that the plaintiff previously owed him $11.40, and that in the course of the work of extermination he (the plaintiff) drank up more than the balance.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

Regular meeting, Monday, October 9, 1893, the President, Dr. C. F. Folsom, in the chair.

Dr. George Haven read a paper on

SOME CASES OF LAPAROTOMY.

Dr. J. G. Blake: I have nothing to say about the appendicitis cases. I only desire to congratulate the reader upon getting the malignant disease of the uterus at such an early stage. Usually, when these cases come under treatment the disease has really got beyond control, that is, the glandular tissues and the uterine appendages are so diseased that removal of the uterus itself does not seem to accomplish a great deal. I should like to ask if the surrounding parts were quite free.

Dr. Haven: They were entirely free. The trouble was entirely in the body of the uterus.

Dr. Blake: I think this is the class of cases that justifies a grave operation like removal of the uterus. I have long thought after studying the statistics of radical methods and comparing as far as possible the results with those of milder methods, that the preponderance of evidence was in favor of not incurring the risk of grave operations, but of treating symptoms and keeping the disease in subjection by constant supervision. In considering the results of vaginal hysterectomy for malignant disease, Dr. Chadwick makes the statement that all his cases died within a year; and in the "System of Gynecology," edited by Mann, the statement is made that none of the patients who had undergone the operation of removal of the uterus were living at the end of five years. From my own knowledge, I feel safe in saying that where as much of the disease as can be reached is removed by curettes and caustics and the patient kept under supervision, life is rendered tolerable, free from pain, and prolonged on an average about two years. Unless the doctor is fortunate enough to get the disease in an early stage of development my own opinion is that the milder methods accomplish as much, taking into consideration the risks that follow the radical operation. Most of the cases of malignant disease of the uterus which have come to the City Hospital have come at a late stage, and looking back over a number of years I have never been quite satisfied that the conditions present when the patient came under observation were such as to justify resort to the graver operation.

Dr. J. B. Ayer: The second case I think was extremely interesting. The little girl of six years when I first saw her did not have pain exclusively localized in the region of the appendix. The pain was general. I felt suspicious of this trouble, but could not then make a positive diagnosis. On the second day in consultation with Drs. Haven and Putnam we concluded that there could be no doubt about the diagnosis. The case seemed a desperate one from the outset. The result I think was most brilliant.

I have recently seen another patient who died of appendicitis on the second day, in whom pain did not begin near the appendix, but in the epigastric region. In a few hours, however, it was over the appendix.

Dr. E. H. Bradford: I am glad Dr. Haven has

drawn attention to appendicitis in children, which perhaps is more common than is usually supposed. In a case where I had the opportunity of seeing the autopsy, the patient dying of tubercular meningitis, the appendix was found full of pus. There had been no symptoms directing attention to this and no other abdominal lesion. The appendix was very thin, and a rupture could easily have taken place.

In the case of a child of four, at the Children's Hospital, upon whom Dr. Monks operated, the appendix was found enlarged and thickened in a congenital hernia in the scrotum.

I recall another case in which the operation was done, I think, by Dr. Lovett, on a child of five.

I have seen three other cases in which the symptoms passed away without operation.

I dare say the disease is frequently overlooked in children, operation being thought of in only the severer forms, and in previous years no operation done.

DR. HAVEN stated in answer to questions, that it was the rule that if the appendix could not be freed without undue force, it was better to pack and leave it. The usual fistula closed within a few months. In the present instance, the fistula did not seem to affect the health of the child at all.

DR. HENRY JACKSON: The reports of the two cases in children are interesting on account of the absence in each of the classical symptoms of appendicitis in the adult. I have had one case in a young child which was rather similar. There was no acute abdominal pain in the region of the appendix. The whole abdomen was tense and somewhat tender. The child, who was five or six years old, did not have sufficient pain to cause screaming or even to prevent sleep during the whole night. Examination of the abdomen showed a large area of flatness in the right lower quadrant of the abdomen. Dr. Fitz saw the case in consultation, and we told the family the child could not live unless operated upon. They declined an operation. The child, however, recovered.

DR. HAVEN: I think the position of the appendix in the second case was interesting, it being just below the last rib and firmly bound down with the cæcum. What could be tied off was tied off.

I fully agree with what Dr. Blake said in reference to cases of cancer presenting themselves at a late stage of the disease. I see very few cases that are operable owing to extension of the disease into the pelvis. I think, however, a radical operation is to be preferred to milder methods in cases in which the ligaments or the cellular tissue are not involved. Even the cases relieved by palliative treatment have pain and disagreeable symptoms, and I do not think they do nearly as well as those operated upon radically, if it is possible to operate radically. The duration of life is not the sole consideration; we must also take into account the amount of suffering and discomfort from which they are saved after radical operations.

DR. JOEL E. GOLDTHWAIT presented a paper on

THE TREATMENT OF HALLUX VALGUS.[1]

DR. E. H. BRADFORD; I am very glad to say that the apparatus Dr. Goldthwait has devised is the neatest arrangement that can be made for the purpose, and I hope it will be generally used, for it makes the mechanical treatment possible which has hitherto been difficult. Dr. Goldthwait states very clearly the cause of the deformity. It is impossible to say how common the trouble is; and if one would seek the cause, it is in the shoe. I have taken a certain amount of pains to ascertain the origin of the pointed toe craze. I had supposed it was a modern thing. At the Shoe and Leather Exhibition in Chicago there were on exhibition a large number of shoes of all periods, and the pointed toe seems to date back to the Middle Ages, or indeed before that period. It seems to be the way in which the vagary of human vanity runs; it constitutes the chief cause of the deformity which gives occasion to so much annoyance.

DR. J. G. BLAKE; I happen to be a sufferer from this to some extent, together with loss of the arch, and I shall certainly very quickly avail myself of the benefit following this treatment. Now, however, I want to bear testimony to the immense benefit resulting from the steel plate for flat-foot. I mentioned to Dr. Nichols the pain and fatigue I experienced from walking, and he advised me to wear steel plates. He had my foot measured and plates fitted, and I have had more comfort since I began to wear those plates than I had for many years. The sense of support and strength is something I had not experienced before. I have no doubt I shall be still further benefited by consultation with Dr. Goldthwait.

DR. J. B. BRAINERD: In the last year I have had four or five cases of this distressing trouble which have been invariably associated with flat-foot. All of them have been greatly relieved, so far as distressing symptoms were concerned, by wearing the plates mentioned by Dr. Goldthwait. In only two has the deformity been removed, however. I shall be very glad to apply these steel springs, which I think will be just the thing needed to secure proper position for the great toe.

As to the pain being relieved from wearing the foot plates; that is perfectly reasonable, because with the two deformities and the patient walking on the inner side of the foot altogether, almost all the pressure comes upon the head of the first metatarsal bone, and if the arch is corrected, the patient walks with the foot straight instead of being abducted. That would relieve the pain, but would not, of course, correct the toe deformity.

DR. J. G. BLAKE made an oral communication, describing a case of

GASTRIC ULCER.

This case is peculiar and has reference to the painful and unexpected death of a young woman in this community. The patient was twenty-four years of age. I had known her since childhood. At no time had she complained of any gastric trouble more than, perhaps, slight tendency to nausea when she varied from certain lines of diet. About ten days ago she accidentally swallowed a piece of crust of toast. She said that great pain followed, extending from the beginning of the œsophagus down into the stomach, and she felt it all over the stomach, but more severely towards the back. She was put under treatment with restricted diet. After about a week she seemed to have recovered. Unexpectedly she was taken with hæmorrhage and vomited almost a pint of blood. I saw her soon after and administered remedies appropriate for that condition. After several hours there was a recurrence of hæmorrhage, smaller in amount, and later still another hæmorrhage. Dr. Fitz saw her in consultation. He gave rather a favorable prognosis.

[1] See page 533 of the Journal.

She was put upon rectal alimentation and absolute rest given to the stomach. It was impressed on the patient's father and husband, that there were two sources of danger attending gastric ulcer — one, recurring hæmorrhage, which might prove fatal from its amount, and the other, perforation; and while those conditions did not obtain very often, still cases had died suddenly, and they were warned not to be too sanguine. She died about ten hours after that. She made an attempt to vomit and did not vomit much blood, but died with all the signs of exhaustion. I suppose she had a large internal hæmorrhage. The result, wholly unexpected, was one of the things that ought to be borne in mind in connection with the disease. How much the scraping of the œsophagus and gastric mucous membrane by the sharp edge of this crust had to do with it, I do not know. It may not have had anything, but the pain and distressing symptoms dated from that. The case is valuable I think, inasmuch as it conveys a warning not to be too sanguine about the prognosis in cases of gastric ulcer; also of the fact that in many cases of so-called dyspepsia you may have the condition of advanced gastritis or ulceration existing, not suspected, and which at any time, from slight cause, may take on an alarming condition. In hospital practice we know that gastric ulcer is not uncommon. I have had my share of them. I remember one case that terminated fatally from peritonitis, and the existence of the disease was not suspected. On examination there was a perforation.

Dr. H. Jackson: In post-mortem examination it is not very unusual to find evidence of pre-existing ulcer of the stomach. But cases are not recognized clinically as often as they are demonstrated by the existence of the scars. In the course of a good many outpatient clinics, I have examined very carefully the cases which presented themselves with pain in the region of the stomach or with other symptoms suggestive of gastric ulcer, and I have found very few where I could feel sure that such a condition existed. I have examined those cases, especially since a consultation with Dr. Gannett in a case where there was a serious disturbance of the stomach with vomiting in a young girl, hæmatemesis being absent. Dr. Gannett was of the opinion that ulcer of the stomach existed, on account of a small, sharply-defined area of tenderness. My experience is that proof of the disease clinically is seldom obtained, although the records in large hospitals show that many cases are discovered accidentally at autopsy. In the case alluded to, Dr. Gannett advised absolute rest, and she recovered in the course of a few weeks, and has had no recurrence of the trouble. In this case the symptoms suggestive to him of ulcer, were occasional vomiting, but essentially the point of sensitiveness.

Post-Mortem Idrosis. — A writer in the *International Medical Magazine* records the following curious phenomenon in a case of death from angina pectoris. "The face of the corpse seemed to be bathed in perspiration, the moisture reproducing itself after being wiped off, in spite of the presence of rigor mortis and other unmistakable evidences of death. This most extraordinary phenomenon was witnessed by several local physicians who also viewed the body. The funeral was on that account delayed several hours until decomposition had fully set in."

AMERICAN OPHTHALMOGICAL SOCIETY.

Twenty-ninth Annual Meeting at New London, Conn., July 19 and 20, 1893.

(Concluded from No. 21, page 520.)

THURSDAY. — MORNING SESSION.

REMOVAL OF STEEL FROM THE VITREOUS WITH THE ELECTRO-MAGNET,

by Dr. E. E. Holt, Portland, Me.

The writer had previously reported six cases treated by this method. In the present paper he reports three cases. In all, the piece of steel had entered through the anterior chamber, fracturing the lens. The conjunctiva was separated and an incision made through the sclerotic back of the equator of the eye, the knife in each instance striking the foreign body. The electro-magnet was then introduced and the steel removed. The lens was subsequently absorbed and good vision obtained in every case, notwithstanding the fact that in the third case there was pus in the anterior chamber when the case came under observation.

A PERMANENT MAGNET FOR USE IN REMOVING FOREIGN BODIES FROM THE CORNEA

was described by Dr. Walter B. Johnson, Paterson, N. J.

It consists of a bar of steel, cone-pointed and elongated at each end. It is charged by rotating it within the magnetic field of a generator. It will continue in full magnetic strength for a long time. It has served an excellent purpose on several occasions in removing small particles of steel from the cornea, which had perforated and almost entered the anterior chamber.

SUPPRESSION OF THE VISUAL IMAGE,

by Dr. Walter B. Johnson, of Paterson, N. J.

In convergent stratismas, there is present an amblyopic condition affecting the squinting eye. Hypermetropia was considered by Donders and others as the most frequent cause of convergent squint, exciting excessive efforts at accommodation, resulting in convergence, confusion of images and subsequent mental suppression of visual image in one eye, finally terminating in an amblyopic condition. It has been claimed by Schweigger, Alfred, Graefe and others, that amblyopia is not caused by squint, but exists as a primary or congenital condition. This produces convergence in consequence of confusion of images. The variety of amblyopia in question is apparently a purely physiological condition, the fundus being normal. The amblyopia is sometimes overcome by correction of the visual defects, but vision in the amblyopic eye rarely becomes equal to that of the fellow eye.

The following case was reported: T. K., age nineteen, had been cross-eyed since the age of three years. He has never been able to discern any object with left eye. There was hypermetropia in right eye. Vision in left eye for fingers at six inches. On June 13th, enucleation of the right eye was required as the result of accident. June 18th, vision in left eye had increased to fingers at three feet; examination showed a hypermetropia of 1.50 D. Under careful practice and instruction the vision in left eye rapidly improved, so that by July 1st he could read 20.15 with correcting glass and Jæger No. 1 at twelve inches. Examination three years after the loss of the eye showed that the improvement had continued.

In this case, whatever was the change which led to the loss of vision, it was not structural either in the eyeball or the nerve centre, but was in all probability a pure amblyopia which resulted from the long-continued mental visual suppression.

A CASE OF CONGENITAL CYST OF THE ORBIT, WITH ANOPHTHALMUS,

by DR. GEORGE C. HARLAN, Philadelphia.

The patient was a well-developed and healthy child five months old. The left eye and appendages were perfectly normal. A tumor about the size of a small hen's egg filled the right orbit and projected considerably beyond it. The orbit was fully of adult size and the lids distended to more than twice their normal size. The skin was movable and natural in appearance. The cilia were well developed. The lids were separated about two centimetres. The exposed conjunctiva was congested but not much changed. There was no discharge. There was nothing to mark the position of the cornea. There was no movement in the tumor, no pulsation, and it was incompressible. Fluctuation was decided.

As the tumor was growing and the deformity great, it was decided to remove it. Incision through the conjunctiva gave exit to a quantity of clear watery fluid. The cyst was simple, the outer portion being fibrous and tough and the inner delicate, semi-transparent and bluish.

The child died twenty-four hours after operation, apparently from exhaustion following upon shock.

A careful inspection of the orbit was made after death. There was no connection with the intracranial cavity. There was no indication of any aperture. Nothing resembling an eye could be found in the extirpated cyst, though at the bottom of the sac there was an undefined mass of tissue.

A review of the literature was given; and the author concluded that the tumor was probably formed of the embryonic tissues of the eye, and that it was either an exaggerated hydrophthalmus, or a fœtal encysted coloboma, which by its early inception and enormous growth had prevented the evolution of the eye.

RESTORATION OF THE UPPER EYELID BY MEANS OF A FLAP TAKEN FROM THE CHEEK,

by DR. SAMUEL B. ST. JOHN, Hartford, Conn.

The author demonstrated a method which was applicable to cases in which the upper lid had been destroyed by disease or injury, and in which the lid was removed by operation. In making the flap, the incision commences about half an inch in front of the ear and runs forward below the lower lid about half an inch, and continues until the side of the nose is reached. It is then carried downward until the flap is of sufficient width, and then taken backward. The flap is next separated and secured by numerous stitches to the freshened surface above. The gap left is closed by separating the tissues of the cheek below the wound and sliding them upwards.

Two cases were reported in which this plan had been used with success, and photographs of the patients were shown.

EXECUTIVE SESSION.

The following were elected to membership:

Dr. F. E Cheney, Boston; Dr. J. E. Weeks, New York; Dr. Charles H. Thomas, Philadelphia; Dr. George Fiske, Chicago; Dr. Wm. H. Wilmer, Washington, D. C.; Dr. Edward Fridenburg, New York; Dr. H. B. Chandler, Boston; Dr. Wm. Cheatham, Louisville.

Officers for ensuing year:

President, Dr. George C. Harlan, Philadelphia; Vice-President, Dr. O. F. Wadsworth, Boston; Secretary and Treasurer, Dr. Samuel B. St. John, Hartfort, Conn.; Corresponding Secretary, Dr. J. S. Prout, Brooklyn.

The Society adopted a by-law limiting the membership to one hundred and fifty.

Recent Literature.

A Treatise on Nervous and Mental Diseases for Students and Practitioners of Medicine. By LANDON CARTER GRAY, M.D. 8vo, pp. xi, 687. With 168 illustrations. Philadelphia: Lea Brothers & Co. 1893.

Dr. Gray's book has been so long announced that our anticipations have for an equally long time been raised concerning it; this is apt to be fatal to a book, but in this case the anticipations have been more than realized. The work bears the stamp of a vigorous personality, it is distinctly original, and above all, it is thoroughly practical in its character. As an introduction to the work, the author gives an excellent chapter on the anatomy of the nervous system, and a chapter on electro-therapeutics. The latter has all the merits of the sections on the treatment of the different diseases. He instructs the reader in the minutest details, as to the best forms of apparatus and the methods of applying electricity, speaking a little dogmatically, but concisely, wisely, and to the point. We know of no better practical guide for the beginner than this chapter affords; indeed, in few works could he find precisely that information in regard to the little details of the management of electricity which are so important, yet which most of us have to learn through uncomfortable experience.

The author has designedly paid little attention to classification. Here we think that he has made a mistake. His question, to be sure, is pertinent, "Of what earthly consequence is the classification of the different forms of disease?" To the man who is looking for advice as to the treatment of a case of acromegaly, it makes no difference whether he finds it in the tenth chapter or the fortieth, but for the student it is, we believe, a distinct advantage to classify the various affections, to consider Friedreich's ataxia with tabes, for instance, and not nearly three hundred pages away.

To pathology much space has been devoted — indeed, in some instances, it would seem as if too much space had been given to discussions of theories — but, for the most part, the results of the most accurate and recent observations are summed up in an admirable manner. Occasionally, however, exceptions must be taken to the author's conclusions, for instance, in the section on muscular atrophy. Our knowledge as to the pathology of muscular atrophy is far from being complete, but it seems to us a step far backward to group together two of the forms of dystrophy, the spinal type of Duchenne-Aran, and Charcot and

Tooth's peroneal type under one heading, and to treat amyotrophic lateral sclerosis and pseudo-hypertrophy apart from them. Pseudo-hypertrophy, too, is said to be without atrophic symptoms, yet two pages later atrophy is spoken of as frequent. Although borderland cases undoubtedly exist, we can certainly distinguish two separate types, one of spinal, and one of muscular origin, and since the admirable treatise by Erb, which is not referred to, we are not warranted in separating pseudo-hypertrophy from the other forms of muscular dystrophy.

In the effort to condense the work into a convenient space, something, we fear, has been lost in the sections on symptomatology. The chapter on diseases of the peripheral nerves is inadequate. A single page is devoted to the symptoms of multiple neuritis, but no attempt is made to differentiate the different forms; sciatica gets but a few lines, and the different peripheral palsies are hardly spoken of. As a rule, however, the clinical sections are much more adequate.

Especial care has been given to the sections on treatment, and these form one of the most valuable parts of the book. Indeed, we know of no work on the subject of nervous diseases which gives such complete and detailed directions for treatment. The author is far from being a therapeutic nihilist — he is rather an enthusiast — but he is not led away by new fancies. He is so guarded in endorsing new methods of treatment that he makes no mention of the use of the thyroid gland in myxœdema. Nevertheless, in every section the physician will find all the minutiæ of treatment carefully detailed, and, although the author may be an enthusiast, his enthusiasm has the justification of practical success.

The illustrations deserve more than a word of praise. Many of them are original, and the execution is admirable. Bibliographical lists are attached to many of the sections, but these seem often of doubtful value. Important works are cited in the text which find no mention in the bibliography, while in some cases, wholly irrelevant works are inserted.

While other works are perhaps better for the student who is seeking after a general knowledge of diseases of the mind and nervous system, owing to their better classification and fuller symptomatology, we know few works which will give better satisfaction to the practitioner who is seeking aid in the practical management of the individual patient.

A Treatise on the Science and Practice of Midwifery. By W. S. PLAYFAIR, M.D., LL.D., F.R.C.P., Sixth American, from the eighth English, edition, with notes and additions by ROBERT P. HARRIS, A.M., M.D.

The present edition of this well-known treatise, has been so thoroughly revised and rewritten as almost to amount to a new work, yet the chapters which are most thoroughly new, that is, those which treat of subjects in which the advances of recent years have been most marked, are precisely those in which an American would see most to criticise.

The sections which relate to anatomy and physiology, pregnancy, the phenomena and mechanism of labor, and the more familiar complications of labor and the puerperium are full, thorough and carefully rewritten and wholly deserve the success which the book has already attained.

In those which treat of the management of labor the author certainly departs widely from the over-conservative and timid doctrines which have heretofore characterized English obstetrics, yet to an American, his methods and the treatment which he recommends, often seem somewhat antiquated. The same must be said of the section on operative obstetrics, and indeed of much of the treatment that is recommended throughout the book.

The section on operative obstetrics would call for still stronger criticism of the usual English timidity in obstetric operating were it not for the frequent insertions of the American editor. In speaking of a book edited by Dr. Harris, it is, of course, unnecessary to state, that the chapters which treat of the abdominal operations, and of symphyseotomy, are fully abreast of the world's progress, and in every way admirable.

It is curious to an American to see so high an authority condemning the use of traction on the cord, during the third stage of labor, and advocating Crédé's method of expression, almost as a novelty, and in terms which imply that he stands alone in this matter.

Under the treatment of pregnancy before rupture, the author sanctions the use of electricity, and decidedly recommends puncture of the sac, though he concedes that cœliotomy may be useful in the hands of a few operators of wide experience. Certainly few American authors would think this recommendation, in the words of the preface, "A satisfactory guide to the most recent advances in obstetric medicine."

Under septicæmia it is strange that, though the author concedes the septic origin of most cases, he still leans strongly to the belief that a puerperal fever of unknown (or zymotic) origin is still sometimes seen.

His directions for the treatment of sepsis are excellent, though he perhaps errs on the side of over-caution in the local treatment, and does not lay sufficient emphasis on the importance of early diagnosis and treatment.

Of the book as a whole it may be said that it will furnish admirable collateral reading to American medical students whose instruction on treatment is derived from other sources; and that on questions of treatment, the book is enormously in advance of most, if not all, other English text-books.

The Medical News Visiting List for 1894. Philadelphia: Lea Brothers & Co. 1893.

The Medical News Visiting List for 1894 has been thoroughly revised and brought up to date in every respect. The text portion (32 pages) contains the most useful data for the physician and surgeon, including an alphabetical table of diseases, with the most approved remedies, and a table of doses. It also contains sections on examination of urine, artificial respiration, incompatibles, poisons and antidotes, diagnostic table of eruptive fevers and the ligation of arteries. The classified blanks (176 pages) are arranged to hold records of all kinds of professional work, with memoranda and accounts.

The Surgery and Surgical Anatomy of the Ear. By ALBERT H. TUTTLE, M.D., S.B. (Harv.). Pp. 96. (Physicians' Leisure Library.) Detroit: George S. Davis. 1893.

The twenty-eight photogravure illustrations in this book are very good, and valuable for reference; but as much cannot be said of the text, which abounds in mistakes in spelling. The book is principally a *résumé* of otological work, especially of recent date.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 30, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

A TEMPERATE WORD FOR FOOT-BALL.

A SOMEWHAT intemperate denunciation of the game of foot-ball has manifested itself recently in the editorial columns of medical and daily newspapers. The object aimed at, in so far as there is an object or a suggestion apart from sensational writing, seems to be the abolition of the game. Now, if there is one thing that is quite certain, it is that the game of foot-ball will continue to hold a prominent place among out-door sports, and that it will preserve for some years to come much of its present form. Those who know anything about the game, and those who know much about young men and youths, will demand quietly, firmly, persistently — without fuss and without exaggeration — that the game be regulated and that the players behave themselves; and the game will be regulated and the players will behave themselves. There is no very great difficulty and no inherent impossibility in this. In proof thereof, witness the last annual match between the university elevens of Harvard and Yale at Springfield. Certainly, there never was more eager interest and feeling, whether among the actors or spectators, and yet there was no unfairness, there was no brutality, there were no accidents which could be regarded as in any degree serious. It was perfectly well understood that any player who allowed his enthusiasm to get the better of his discretion would be promptly and impartially laid aside.

The open-air sports in which university teams compete with other university or college teams, are a direct and indirect stimulus to all round physical development and well being, to self-denial, self-control, to sober and temperate living among a *very large number* of the members of the college or the university — not simply among the immediate members of the college team itself. This statement can be amply substantiated by details from the different classes, either at Cambridge or at New Haven.

There is, it is true, a period of some weeks in the autumn when the time of the members of a university foot-ball team is in much demand for other exercises than those connected with "learning," but there is one thing that their critics should know if they do not, and should remember if they have forgotten — namely, that a student who is on probation in any of his studies can have no place on a college team; moreover, it is considered a discredit to a man who is needed and would otherwise be placed, to allow himself to be thus disqualified. This obtains at Cambridge, and we believe, also, at New Haven. From this point of view the out-door sports have been a distinct stimulus to study.

During the last four years a good many matches have been played at Cambridge and elsewhere by Harvard teams. The following are the casualties reported by surgical authority: four fractures of the metacarpal bones, one fracture of the fibula, two dislocations of the elbow, one dislocation of the humerus, one probable fracture of a rib. Such injuries when received by men in training are recovered from in half the time necessary for recovery in other subjects.

The questions of betting and of gate-money have no more to do with foot-ball than with other games or sports. New York furnishes an immense attendance at high prices, and is a favorite place for college contests. It is not a good place in which to let loose a lot of excited young men. Harvard has recognized this fact and has acted accordingly. To blame foot-ball and demand its abolition, because some imprudent students are disorderly, and other too prudent students speculate in tickets, is a confusion of causes as of remedies.

We do not hesitate to say that there is less idleness, less dissipation, less brutality, less meanness and trickery, and a better physical condition among college students with foot-ball than without it, with the out-door games than if their place were taken by compulsory calisthenics and gymnastics.

ENTERIC FEVER IN THE TEES VALLEY.[1]

THE Tees Valley is a district on the east coast of England, in the counties of Durham and Yorkshire, and contains about a half-million inhabitants.

The story contained in this exceedingly interesting and thorough report is the often repeated one of an epidemic of typhoid fever due to pollution of the domestic water-supply. In his introduction to the report, Dr. Thorne Thorne, the chief medical officer, says:

"One factor alone is found to be common to the places thus suffering exceptionally from enteric fever, and this is the use of the water pumped from the River Tees. This river is found to be at all times subject to conditions of the grossest fouling by reason of the fact that human excreta and other filth are knowingly and deliberately conveyed to it. Opportunities for the access of the specific material of enteric fever to the river had been constantly recurring; and, immediately

[1] By Dr. F. W. Barry. Supplement to the Twenty-first Annual Report of the Local Government Board, 1891-92, pp. 150. London, 1893.

antecedent to the epidemic outbursts, sudden floods washed vast masses of the filth which had been accumulating on the banks of the river, down the stream, up to, and past, the points of in-take from which the water was being pumped, and, after filtration through sand and gravel, delivered to certain populations. These populations it was who suffered from the two exceptional prevalences of enteric fever. Seldom, if ever, has a case of the fouling of water intended for human consumption, so gross or so persistently maintained, come within the cognizance of the medical department; and seldom, if ever, has the proof of the relation of the use of water so befouled to wholesale occurrence of enteric fever been more obvious and patent."

The details of the report are of interest also, as bearing upon the question of the viability of the typhoid poison in running water, and the problem of the value of filter-beds as measures of protection and means of purifying polluted waters. At some of the water-works in the Tees Valley, depositing-tanks and filter-beds were in use. At Darlington, in the case of the older filter-beds, the water passes through six feet and six inches of filtering material, — three feet and six inches of gravel, varying in size from apples at the bottom to shot at the top, and above the gravel three feet of sand. In the newer filters the water passes through five feet and six inches of material, — three feet of gravel, two feet and six inches of sand. The rate of filtration is from three to four inches per hour, or about forty-five gallons per twenty-four hours per superficial foot of filter. The surface of each of these filters is supposed to be cleansed once in six weeks, and the whole sand in each filter washed on an average once in three years. Apparently, in time of flood these dispositions offered insufficient protection.

This, like Dr. Barry's previous report upon the prevalence of small-pox in Sheffield in 1887–88, gives evidence of the greatest thoroughness and care in its preparation, and is very fully illustrated with tables, diagrams and charts.

MEDICAL NOTES.

A Very Small Epidemic. — Considerable comment has been made upon the declaration of the health commissioner of Chicago, that small-pox is now epidemic in that city. The number of cases now reported is only eighteen.

Yellow Fever. — Cases of yellow fever still continue to occur at Brunswick, Ga., in spite of the frost at night. They average about two each day, and are chiefly among the white population.

Mr. Gladstone's Physician. — Dr. William H. Broadbent has been chosen physician to Mr. Gladstone, in place of Sir Andrew Clark.

The Maybrick Case Again. — There has been a renewed interest in England in the case of Mrs. Maybrick, who was convicted and is now in prison for poisoning her husband, owing to the statement of a Birmingham chemical firm, that shortly before the death of Mr. Maybrick they analyzed a quantity of German glycerine offered for sale to them, and finding it to contain arsenic, refused to purchase. Recently they have learned that it was sold to parties in the midland counties, and so may have been dispensed to Mr. Maybrick.

Prize of the American Neurological Association. — The American Neurological Association offers a prize of $200 for the best essay on any subject connected with Neurological Science. This competition is open to physicians who are legal residents of States in North and South America. Essays must be sent to the Secretary of the Association, Dr. Græme M. Hammond, on or before the first day of May, 1894. Each essay shall be accompanied by a sealed envelope containing the name and address of the author, and bearing on the outside a motto, which shall also be inscribed upon the essay. Essays shall be type-written, in either the English or French languages, and with the pages securely fastened. The Council of the Association reserves the right to reject any or all essays judged unworthy of the award. Each essay must exhibit original research, and none will be accepted that has previously been published.

An Important Immigration Decision. — Superintendent Stump, in reply to the request of the Cunard Steamship Company to be represented at the hearing in the case of a steerage passenger returned to them under the immigration law, has ruled that, "The right of appeal under the acts of Congress, of 1891 and 1893, is limited to the immigrant himself, or some one in his behalf and representing him in the one case and to one of the inspectors constituting the board of special inquiry in the other, and it is the opinion of this bureau that no other persons are proper parties to the record, or are entitled to participate in the trial or hearing of said cases. The judgment rendered affects only the immigrant personally, touching his right to land, and although incidentally it may be attended by consequences by which the steamship companies and others may be affected pecuniarily, they are not proper parties to the proceedings, and have no such standing in court, as to enable them to participate in the original trial or ask for a re-hearing or pray for an appeal."

The Use of Reading in Medicine. — In his introductory lecture on "The Principle and Practice of Medicine," at St. Bartholomew's Hospital, Dr. Norman Moore, after speaking of the wide range of reading which is open to the physician and the scanty time for study, summed up the value of medical reading as follows: "There is scarcely any medical book, good or bad, which may not be looked through to some useful purpose, if read in the light of the observations of the reader; but there are a few great authors who illuminate the mind of their readers and make them see clearly what they had often looked at, but never before fully understood. These are worth reading often. Heberden, in England, and Trousseau, in France, are of this rare merit. After its primary

object of making a man ready to observe, the true use of reading in medicine is to make him think. The difference between perfect and imperfect knowledge is not so much in the facts known as in the way they are treated by the mind. Perfect knowledge is that which has been thought over; imperfect knowledge that which has only been remembered. This is particularly noticeable in medicine where a few observations, well thought over, will make a man far more useful than the mental retention of abstracts of hundreds of books."

BOSTON AND NEW ENGLAND.

CLEARING OF BOSTON DOCKS. — The work of cleaning and dredging out the accumulated filth in the docks along Atlantic Avenue in Boston, which was directed by the Board of Health, has been finished. The deep layer of rotting fish waste has been for a long time a menance to the public health, and the Board of Health has issued an order forbidding the fish dealers to empty their refuse into the docks.

A CONTAGIOUS HOSPITAL FOR WALTHAM. — After a delay of nearly two years since the Board of Health of Waltham seriously urged the erection of a suitable hospital for contagious diseases, work has been begun on the new building. The immediate reason for beginning the work is the existence of an unusually large number of cases of diphtheria.

DIPHTHERIA IN SOUTH BRAINTREE. — The Pond Street school in South Braintree has been closed on account of the prevalence of diphtheria in the district. Three fatal cases have occurred already among the pupils of one class-room.

DARTMOUTH MEDICAL COLLEGE. — The graduating exercises of the Medical Department of Dartmouth College took place Tuesday evening, November 21st, a class of twenty-eight receiving degrees. The Medical Faculty have just passed the following vote: "That at the end of one full year of the study of medicine and one course of lectures in this school, an examination *will be required* in descriptive anatomy, physiology and chemistry. That at the end of *two* full years of the study of medicine in this school, an examination will be required in descriptive and regional anatomy and further examinations in physiology and chemistry. The examinations so passed, if satisfactory, shall stand as final."

NEW YORK.

THE SATURDAY AND SUNDAY HOSPITAL ASSOCIATION held a meeting at St. Luke's Hospital on November 20th, when a special committee which had been appointed for the purpose some time previous, reported progress in the matter of organizing similar associations in Chicago, St. Louis, and other large cities. At this meeting it was proposed that on Thanksgiving Day contribution boxes should be placed at the entrance of the grounds where the great Yale-Princeton foot-ball game is to be played.

STREET-CAR ACCIDENTS. — The introduction of he electric and cable system of surface cars ha been attended with an increased loss of life. The latest victim of the trolley cars is a policeman in Brooklyn. The previous week a seven-year-old child was decapitated, and it is stated that at least forty-nine fatal accidents have been caused by the Brooklyn trolley lines during the last twelve months. On November 24th, Dr. Paul Hoffman, assistant superintendent of the city public schools, was thrown under a cable car, and only by a miracle escaped death. As it was, four of his ribs were broken, and he was otherwise severely injured.

PRESBYTERIAN HOSPITAL DEFICIT. — The twenty-fifth annual meeting of the Board of Managers of the Presbyterian Hospital was held November 18th. The reports showed that during the past year 1,876 more patients were treated than in the previous year, and that there are now 46 pupils in the training school for nurses attached to the hospital. While the expenditures for the year amounted to $147,875, the receipts were only $58,063; so that there is a deficit of $89,-812.

CONSUMPTION OF WATER. — The report of the commissioner of public works for the third quarter of 1893, shows that the city now consumes 180,000,000 gallons of water daily, and that during the quarter, (the rain-fall having been small), nearly half of the daily supply was drawn from the water stored in the great reservoirs.

REORGANIZED AMBULANCE CORPS. — An order has been issued by the Adjutant-General of the State, abolishing the old Ambulance Corps of the National Guard, which contained about four men from each company of militia, and substituting therefor a smaller and better trained hospital corps.

THE NEW MATERNITY HOSPITAL. — On November 12th, Archbishop Corrigan dedicated the new Maternity Hospital of the Sisters of Misericordia on East 86th Street, with elaborate religious ceremonies, after which there was a public reception in the wards. The hospital is a five-story brick structure, with stone trimmings, and is 138 feet long and 73 feet in width. The cost of the new wing was $92,000, and it can accommodate 150 patients.

UNUSUALLY LOW MORTALITY. — The remarkable record of the week ending November 11th, when the number of deaths was only 641, representing an annual death-rate of 17.46 per thousand of the estimated population, the smallest ever reported, was beaten by that of the week ending November 18th, when the number of deaths was but 612, representing an annual death-rate of 16.66. The average mortality for the corresponding weeks of the past five years was 703 deaths, representing an annual death-rate of 19.14; and the fact is now assured, that the year 1893, as a whole, will show the lowest death-rate since 1883. During the week referred to, three cases of death from influenza were reported; and there were 490 cases of contagious diseases, with 87 deaths, against 419 cases and 78 deaths in the week ending November 11th

There was an increase of 42 cases of measles, 19 cases of scarlet fever, 9 cases of diphtheria and five cases of small-pox. To offset this, there was a decrease in the deaths from phthisis, pneumonia and some other diseases.

Miscellany.

THE RELATION OF THE BACTERIUM COMMUNE COLI TO APPENDICITIS.

Dr. George R. Fowler, of Brooklyn, makes a preliminary report to the New York *Medical Journal*, upon the relation between the bacterium commune coli and appendicitis, a relation which he considers one of cause and effect. His belief is based upon the observations of eight cases operated upon for appendicitis. Cultures were made at once from the seat of disease and from the appendix.

"Of the entire series of eight cases, seven gave pure cultures of the bacterium commune coli.

"In one case the bacillus pyogenes fetidis was obtained, in addition to the bacterium commune coli (examination made by Dr. E. H. Wilson, pathologist to St. Mary's Hospital).

"In four cases encysted sero-fibrinous deposits (encysted intraperitoneal suppurative peritonitis) were present.

"In two cases appendical abscess existed.

"In one case general sero-purulent peritonitis existed.

"In one case no pus or serum was found. A periappendicitis and serous parietal appendicitis existed only; the mucous membrane lining the appendix was normal. No fæcal matter was found in the interior of the tube. The cultures were made from a patch of lymph on the peritoneal surface of an adjoining portion of the cæcum, to which the tip of the appendix had become adherent. This culture gave pure bacterium commune coli. Attempts to procure the microorganisms from the sections of the wall of the appendix were unsuccessful, although more than a hundred sections were made and examined by Professor Van Cott and Dr. Wilson."

THE SAMUEL D. GROSS PRIZE.

The Quinquennial Prize of One Thousand Dollars under the will of the late Samuel D. Gross, M.D., will be awarded by the Philadelphia Academy of Surgery, January 1, 1895.

The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the successful competitor, who receives the prize, shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut Street, Philadelphia, before January 1, 1895.

Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The Committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The Committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

JAMBUL IN DIABETES.

Graeser has reported to the Therapeutic Association of the lower Rhine the results of his study of jambul as a remedy for diabetes. The eugenia jambulana, a tree sixty to eighty feet high, belonging to the family myrtaceae, is indigenous to all the East Indies. For a long time the seeds and bark have been used in decoction by the natives for diabetes. The fresh juice of the leaves is astringent and has some value in dysentery. The experiments of Graeser were conducted upon dogs rendered artificially diabetic by Phloridzin. Both the powdered seeds and an extract from the fruit and bark were used. The reduction in the sugar elimination was marked in all cases. Any unpleasant effects from the drug were rare. In cases of diabetes mellitus in men, the administration of jambul in doses of thirty grammes a day did not give uniform results, though in each case the symptoms were much relieved. The amount of urine in all cases was diminished, in one case from ten litres to four per diem. The hunger and thirst and headache ceased and the patients gained in weight. The variable effects depended upon the differences in strength of the drugs used. Seeds from jambul of British India were less potent than those from the Java plant. Extracts made from old or dried seeds were not to be relied upon. The active principle has not yet been determined.

AN EPIDEMIC OF PRIAPISM.

Dr. Meynier, a French army surgeon, has recently published a curious bit of medical experience. A company of troops *en route*, having halted for some time at El Hacaiba, the men were nearly all seized with priapism and prolonged and painful erections. Considering that an absence for some time from a garrison town might be the cause, the surgeon ordered light diet and flaxseed tea. The condition, however, became steadily worse. The erections continued throughout the company, and the men began to complain of great lassitude and dryness in the throat. Finally many had marked hæmaturia. Careful investigation disclosed the real cause of the trouble. During their leisure the men had been hunting frogs at a neighboring stream. The poplar and willow trees along the banks were found to be thickly covered with coleoptera of the family of cantharides, *meloe*. Chilled in the early morning they fell by thousands into the water where they were gladly and greedily devoured by the frogs — which later gave similar pleasure to the soldiers. The taste of the flesh was in no way injured, but its effect upon the genito-urinary system of

the divers was disastrous. The removal of frogs' legs from the bill of fare put an end to the curious epidemic in a few days.

A PROLONGED FAST.

THERE is reported from Russia a case of unusually long fasting.[1] A young girl of seventeen was overtaken by night near the village of Ruzino in Moscow on the 24th of last November. She took refuge under a small outbuilding covered with straw. During the night it snowed violently, and in the morning the girl was unable to force her way from under the snow. The first day she ate five bits of bread she had with her, after which she had no food but the snow. Fifty-one days later she was discovered buried under three feet and a half of snow. On being taken to the hospital on January 14th, she was in a state of extreme exhaustion and unable to move a limb, though entirely conscious. There was a general cutaneous anasarca. The mucous membranes were excessively pale, and there was no trace of panniculus adiposus. The muscles were much atrophied. The respiration was 26; the pulse 84, small and feeble; the temperature 38° C. The cardiac sounds, though weak, were clear, and there was an anæmic murmur in the cervical vessels. The urine was concentrated, but contained no sugar or albumen. For the next two days she remained semi-conscious and somnolent, but rapidly recovered, and at the end of a week was able to take ordinary hospital diet.

SIR ANDREW CLARK.

ALTHOUGH the death of Sir Andrew Clark has robbed the medical profession of one of its ablest and most honored members, it has served to bring to general notice the details of a life which must always serve as an inspiration and encouragement to all who know of its marvellous industry and power.

Andrew Clark was the only child of a highly educated physician bearing the same name, and was born in Aberdeen on October 28, 1826. He lost his mother at birth and his father while still a little child. He was educated by his uncles, but passed a lonely youth, serving as apprentice to a druggist. He studied medicine in Aberdeen and Edinburgh where he was a brilliant scholar in all branches of his work. His services as assistant to Dr. Bennett in the pathological work of the Royal Infirmary, and later as assistant demonstrator of anatomy under Dr. Knox were of lasting advantage to him. Brilliant, highly trained and eager to devote himself to the scientific study of pathology his career was now seriously menaced, as signs of rapidly advancing pulmonary disease appeared with hæmoptysis. To gain outdoor life he joined the navy and after a few voyages was appointed pathologist to the Naval Hospital at Haslar, where he served for four years, a contemporary worker with Mr. Huxley. In 1853 he went to London and gained the appointment as Conservator of the Museum at the London Hospital. At that time he intended not to practise but to give his attention to pathology, — "to write a pathological work and construct an atlas of pathological specimens and then to die," as he said. He devoted himself with zeal to the work of re-examining with the microscope the large collection of specimens in his care, often spending a week over a single one. The following year he took his degree of M.D., and became a Member of the Royal College of Physicians. He was then elected an assistant physician to the hospital, and began the private practice of medicine. His health was so exceedingly poor that he was not expected to live long, and he had no family or influence to start him in his profession. His own indomitable will and energy, his determination "to die in harness," and his great ability, were all he had to start with. His work in the out-patient department was wonderfully brilliant, his diagnosis being thorough and accurate in the minutest details, yet made with great rapidity. He was at the hospital all day, and often detained his patients till late in the evening. Almost all were made to bring their urine for examination, and every now and then one had to produce his fæces also. His zeal in minute investigation literally knew no bounds. In addition to this work he served as pathologist and lecturer on physiology. In 1858 he was chosen a Fellow of the Royal College of Physicians, and in 1866 full physician to the London Hospital. The cholera epidemic in East London that year was the starting-point of Dr. Clark's great fame. The London Hospital received cholera patients, and Dr. Clark was conspicuous for his devotion to the sick, "working almost day and night in the wards or post-mortem room." It was at this time he became acquainted with Mr. Gladstone, to whom he soon became medical adviser and a most intimate friend. Up to this time his practice had been only moderate and chiefly among men of letters and science, but when he moved to Cavendish-Square his reputation and association with Mr. Gladstone led to an enormous increase in the number of his patients, and he soon became the foremost physician in London. His office practice, beginning at eight A. M., often lasted without interruption till two or three P. M. All his correspondence, which was very large, was written (often after midnight) with full directions in his own hand, a task he was able to fulfil only by "his powers of rapid writing and unfaltering powers of clear expression, his letters having scarcely a single correction or erasure." For twenty years he served as physician to the hospital at a great sacrifice of time and strength. He was led to do this by his unbounded enthusiasm for his work and a "strong conviction that to give up hospital service was to lose the habit of exact research," which could not be carried out in private practice.

His life was one of constant enthusiastic overtaxing of his strength, but was rewarded by an unbroken series of honors. He was successively the Croonian, Lumleian and Lettsomian Lecturer at the Royal College of Physicians, and a Councillor, Examiner in Medicine and Censor. In 1888 he was made President of the College, holding the office till his death. "Those who did not know him well, or had not been brought into contact with him publicly, had no idea of his great qualifications for this office. His dignity of bearing, his masterly power of conducting the affairs of a large meeting, his fluency and propriety of speech, fitted him in a peculiar manner for presiding over the college. Whether in the presidental chair, or as the representative of the college on any public ceremonial or social occasion, he always felt and displayed the dignity and responsibilities of his position, and no sacrifice was too great to enable him properly to discharge the duties of

[1] Lyon Medical, No. 44, 1893.

his office, although the time required each day was a serious tax upon his busy life." "There has been since the time of Sir Thomas Watson," wrote a distinguished Fellow a week or so before Sir Andrew's death, "no president who has discharged the duties of the office with such ability and dignity."

The great secret of his success as a private practitioner was his careful attention to small details; and his "remarkable faculty of listening patiently to all that had the privilege of finding access to him, and he hardly ever evinced any symptom of impatience or hurry. He not only listened, but remembered. . . . He never slurred a point in any case and never passed over a detail which suggested itself to him as being capable of being elaborated for the benefit of his patient. When in the fullest practice he would often spend half an hour over the complete investigation of a puzzling symptom, while his waiting-rooms were full to overflowing." His enthusiastic encouragement of his patients was another factor. He believed in fighting disease, and he inspired those who suffered from it with some of his own courage and hope.

The crowded occupations of his life left him little time for social duties; but his company and conversation were charming and attractive. His naturally critical and controversial mind often led him into discussions which nearly always took the direction of theology and speculative philosophy. The only relaxation he indulged in was reading, which he was able to indulge in whilst riding in his carriage or on railway journeys. Recreation in the true sense he hardly understood.

One of his colleagues says of him in the *British Medical Journal:* "Next to his warm-heartedness, the faculty which distinguished Clark was his limitless energy. I never saw him seem tired. He may have looked so occasionally, but he never allowed his bearing to reveal it. The impression which he generally managed to convey was that the engagement in hand, whether a committee or a consultation, was the very one to which he had been looking forward all day with expectant pleasure. He considered himself a very punctual man, but in reality was not so. He took too much interest in what he was about to be always careful of the passing minutes. In all that concerned money he was liberal, and his unostentatious charities were, I feel sure, very large."

Of his relations to his professional friends the *Lancet* says: "By the members of his own profession in every degree he will be remembered for his kindness and courtesy. Not only as a consulting physician was he able to enter into the difficulties of the general practitioner with unusual intuitive sympathy, but his valuable and overloaded time was always at the service of his colleagues in his capacity as a private physician, and, although he would not have admitted the accusation, his purse was as generously offered as his time. His early training in a hard school had left him full of gratitude for his success, and desirous to display it by generous attention to the claims of those whose work had met with less ample reward."

"There have been greater pathologists than Sir Andrew Clark. There have even been greater therapeutists. Perhaps there have been greater diagnosticians. But there have been few greater physicians, few who have made a deeper impression on the public mind and who have done more to raise the influence and to assert the claims of the medical profession."

METEOROLOGICAL RECORD,

For the week ending November 18, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: –

Deaths reported 2,676: under five years of age 967; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 421, acute lung diseases 420, consumption 315, diphtheria and croup 200, typhoid fever 67, diarrhœal diseases 51, scarlet fever 33, cerebro-spinal meningitis 22, measles 20, whooping-cough 16, erysipelas 8, small-pox 1.

From scarlet fever Pittsburg 7, Chicago 6, New York, Brooklyn, Boston and Cambridge 3 each, Milwaukee 2, Philadelphia, Cleveland, Nashville and New Bedford 1 each. From cerebro-spinal meningitis Chicago 5, New York and Worcester 3 each, Washington, Cleveland and Pittsfield 2 each, Philadelphia, Brooklyn, Milwaukee and Cambridge and Lynn 1 each. From measles New York 11, Brooklyn 4, Chicago 3, Milwaukee and Northampton 1 each. From whooping-cough New York 4, Chicago and Worcester 3 each, Brooklyn, Pittsburg and Cam-

bridge 2 each. From erysipelas Chicago 4, Boston 2, New York and Brooklyn 1 each. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending November 11th, the death-rate was 21.5. Deaths reported 4,254: diphtheria 127, whooping-cough 99, measles 78, fever 73, scarlet fever 66, diarrhœa 50, small-pox (Birmingham 4, Bristol and Bradford 3 each London and West Ham 2 each, Hull 1) 15.

The death-rates ranged from 11.4 in Plymouth to 28.5 in Wolverhampton; Birmingham 27.1, Bradford 20.5, Croydon 13.4, Halifax 15.9, Hull 24.5, Leeds 18.8, Leicester 17.2, Liverpool 23.0, London 21.4, Manchester 21.2, Newcastle-on-Tyne 24.6, Nottingham 22.0, Sheffield 22.6, West Ham 23.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 18, 1893, TO NOVEMBER 24, 1893.

Leave of absence for one month on surgeon's certificate of disability, with permission to go beyond the limits of the department, is granted FIRST-LIEUT. MADISON M. BREWER, assistant surgeon, U. S. A.

The leave of absence granted MAJOR CURTIS E. MUNN, surgeon, U. S. A., is extended two months.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 25, 1893.

M. W. BARNUM, assistant surgeon, from "Richmond" and to the "Kearsarge."

J. W. ROSS, surgeon, from Pensacola Hospital, proceed home and wait orders.

L. B. BALDWIN, surgeon, from the "Michigan" and to the Pensacola Hospital.

J. S. SAYRE, passed assistant surgeon, to the "Michigan."

A. C. CABELL, passed assistant surgeon, from the "Kearsarge" and leave for three months.

G. P. LUMSDEN, passed assistant surgeon, from the iron clads, Richmond, Va., and to the "Kearsarge."

F. A. HESSLER, passed assistant surgeon, from the "Vermont" and to the iron clads, Richmond, Va.

JAMES F. LEYS, assistant surgeon, from the laboratory, Brooklyn, N. Y., and to the "Vermont."

M. R. PIGOTT, assistant surgeon, from the "Kearsarge" and to the "Richmond."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FOUR WEEKS ENDING NOVEMBER 18, 1893.

PURVIANCE, GEORGE, surgeon. To report at Bureau, for temporary duty. November 7, 1893. To inspect Reedy Island Quarantine. November 14, 1893.

CARTER, H. R., surgeon. To proceed to Jessup, Ga., for temporary duty. November 10, 1893.

BANKS. C. E., passed assistant surgeon. To rejoin station, Portland, Me. November 3, 1893.

BROOKS, S. D., passed assistant surgeon. To inspect service at Ashtabula, O., and then to rejoin station at Cleveland, O. November 13, 1893.

MCINTOSH, W. P., passed assistant surgeon. Granted leave of absence for twenty-three days. November 17, 1893.

MAGRUDER, G. M., passed assistant surgeon. Granted leave of absence for thirty days. November 1, 1893. To proceed to New Orleans for duty. November 15, 1893.

GOODWIN, H. T., passed assistant surgeon. Leave of absence extended thirty days. October 24, 1893.

COBB, J. O., passed assistant surgeon. Leave of absence extended twenty days. November 14, 1893.

GUITERAS, G. M., passed assistant surgeon. Granted leave of absence for thirty days. November 14, 1893.

PERRY, J. C., passed assistant surgeon. To rejoin station, Vineyard Haven, Mass. November 3, 1893.

STEWART, W. J. S., assistant surgeon. To proceed to Reedy Island and Delaware Breakwater Quarantine Station, for temporary duty.

STRAYER, EDGAR, assistant surgeon. To rejoin station, Boston, Mass. November 3, 1893.

CENSORS' EXAMINATION.

The Censors of the Suffolk District Medical Society, officiating for the Society at large, will meet to examine candidates for admission to the Massachusetts Medical Society at 19 Boylston Place, on Thursday, December 21, 1893, at 2 P. M.

Candidates should make personal application to the Secretary and present their medical diploma, or its equivalent, at least three days before the examination.

For further particulars, apply from 2 to 3 P. M., to

JAMES J. MINOT, M.D.,
188 Marlborough Street. *Secretary.*

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held at 19 Boylston Place, on Monday, December 4th, at 8 o'clock.

Dr. W. E. Fay will report a "Case of Endocarditis." Discussion by Drs. J. J. Minot, W. F. Temple and F. Coggeshall.

Dr. E. J. Forster will report a "Case of Unique Laceration of the Cervix."

Election of associate members.

JOHN C. MUNRO, M.D., *Secretary.*

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Surgical Section of the Suffolk District Medical Society will hold its regular monthly meeting at 19 Boylston Place, on Wednesday evening, December 6, 1893, at 8 o'clock.

Appendicitis will be the subject for discussion. Dr. M. H. Richardson will open this discussion with remarks based upon one hundred and eighty-one cases. Drs. H. H. A. Beach, J. W. Elliot, Alfred Worcester, of Waltham, will be present. It is hoped that many who have had experience in the management of this disease will contribute something to the discussion.

Material illustrative of any subject in surgical pathology is of interest to the section.

CHARLES L. SCUDDER, M.D., *Secretary*, 1 Marlborough St.

APPOINTMENT.

ARTHUR P. CHADBOURNE, M.D., has been appointed physician to Out-patients at the Carney Hospital.

RESIGNATION.

W. THORNTON PARKER, M.D., of Groveland, Mass., has resigned the Professorship of Climatology in the College of Physicians and Surgeons of Boston.

RECENT DEATHS.

JOHN M. KEATING, M.D., LL.D., formerly of Philadelphia, and well known as the editor of the "Cyclopædia of the Diseases of Children," died at Colorado Springs, November 17th. He was the founder of the "International Clinics," and one of the editors of the *Climatologist*.

DR. CHARLES WARRINGTON EARLE, whose death was noted last week, enlisted in the Federal Army at the age of sixteen. Before reaching his eighteenth birthday he was promoted to second lieutenant, and in this capacity commanded his company at the battle of Chicamauga, where out of forty-five men in the company, thirty-five were either killed or wounded. Official reports of the battle made special mention of his bravery. On retreat of the army into Chattanooga, Lieutenant Earle was captured and sent to Libby Prison. He was one of the men who escaped through the famous tunnel and after a week of wandering through the Virginia woods, reached the Union lines near Williamsburg. Returning to his command, he was promoted to first lieutenant. After the war he commenced the study of medicine and settled in Chicago.

HENRY BRONSON, A.M., M.D., died at New Haven, Conn., November 26th, aged eighty-nine years. He graduated from the Yale Medical School in 1827. He was the author of a "History of Waterbury," his native town, and a number of pamphlets on political economy. Several years ago he gave $83,000 to Yale University, $20,000 to the General Hospital of New Haven and $10,000 to the Waterbury Hospital.

REDUCTION OF CERVICAL DISLOCATION: A SUCCESSFUL CASE.[1]

BY G. L. WALTON, M.D.,
Physician to Neurological Department, Massachusetts General Hospital; Clinical Instructor in Neurology, Harvard University.

THE frequency of cervical dislocation without fatal result, is a subject to which I have already called attention in various articles,[2] the number of cases coming under my observation showing that the lesion is not one of great rarity, although probably frequently overlooked. The discomfort of this disability, even where no paralysis or special pain is present, can hardly be overestimated, and the disfigurement is by no means trivial. Relief of the condition is certainly a desideratum, and such cases as the one I have to report seem to show that such relief is within easy reach when the relations of the parts are thoroughly understood.

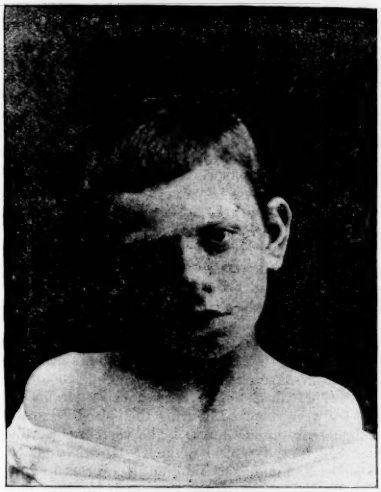

FIG. 1. Before operation.

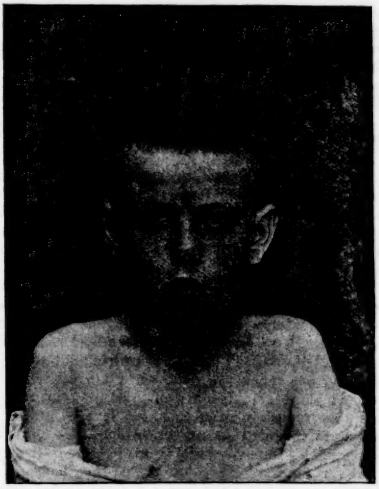

FIG. 2. After operation.

CASE. R. H., a boy ten years of age, fell from a shed about a week before his application to the hospital. He came to the Surgical Out-Patient Department of the Massachusetts General Hospital, in the service of Dr. Mixter, who recognized the trouble at once, and who kindly asked me to see the case.

The boy was fairly developed and well nourished. The head was bent towards the right shoulder, the face turned to the left, and the chin somewhat elevated, the position being that of torticollis from spasm of the sterno-cleido-mastoid on the right. This muscle was, however, lax, while the muscles on the left side of the neck were put upon the stretch. He could not voluntarily straighten the head, although it could be forced around so that the face pointed forward, but immediately relapsed when left to itself. There was a hollow over the spinous process of the fourth or fifth cervical vertebra. Examination of the chest was negative, the respiration was normal (21), the pulse 71, the temperature 98.5°. The gait was normal. There was no paralysis of motion or sensation in either extremity, and no other abnormality, except the displacement of the neck. There was no special complaint of pain, except on lying down (practically impossible), and no special swelling or bogginess of the tissues. The diagnostic features of typical unilateral dislocation were therefore present: namely, immobility and displacement, with the head in the position of torticollis, with laxity of the sterno-cleido-mastoid on the side which would produce such deformity, together with a stretching of the muscles on the other side of the neck.

We decided upon immediate operation, and the patient was admitted to the house for this purpose, in the service of Dr. Beach. Dr. Beach decided, at my suggestion, to attempt reduction by retro-lateral flexion and rotation without extension.

The patient was etherized, the vertebræ first unlocked by bending the head diagonally backwards and towards the left, then rotated into place. No force was required. Reduction was immediate and complete. The hollow over the spinous process disappeared. There was no click heard. He was sent to the ward, recovery from ether being good. The next day, all motions of the head were perfect, and no pain was complained of on lying down. The patient was not allowed, however, to raise the head from the pillow. On the fifth day after operation the boy was

Boston Medical and Surgical Journal, May 8, 1890.
International Clinics, 1892, 2d series, ii, p. 207.

apparently well, and was allowed to have his clothes. Going into the yard without permission, he ran out of the back gate. He was heard of at intervals after this time, remaining well as far as the head was concerned, although he had an attack of diphtheria in the course of the summer. The second photograph, taken about three months after the operation (the earliest opportunity), shows perfect position of the head.

This case represents the complete form of unilateral dislocation, the right articular process of one vertebra slipping forwards and falling down upon the pedicle of the vertebra below — that is, into the intervertebral notch, this accident being rendered easy by the comparatively horizontal position of the articular processes in the cervical region. The position of the vertebræ is seen in the cut (Fig. 3).

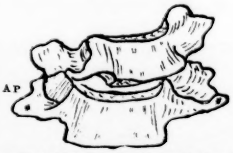

FIG. 3. Anterior view of vertebræ in complete unilateral dislocation, as seen in Fig. 1. A P, articular process of upper vertebra displaced forwards.

Völker considers rotation the essential factor in the displacement, differing from those who regard abduction as also important. Such dislocation is practically impossible in the dorsal or lumbar region without fracture. Fracture of this process also sometimes occurs in the cervical region, together with displacement — a fact which should be taken into consideration before recommending operation. This complication is, however, fortunately rare. The combination was present in one case, however, which was seen by Dr. Richardson, Dr. Hildreth and myself, in which the position of the head was much the same as in the case here reported; but the probability of fracture rendered attempt at reduction dangerous, for fear of producing injury to the cord or nerves, which were hitherto intact. This immunity will be made clear if two cervical vertebræ are placed in the position indicated, it being perceived that the lumen for the spinal cord is little if at all invaded.

Coming to the question of the proper method for reduction, if one attempts to separate the two vertebræ, which have been placed in the position indicated, by direct extension, it will be seen that the vertebræ must be very widely separated at every point in order that the displaced articular process may be elevated. In fact, the separation is so great that it would seem almost incredible that reduction had ever been accomplished in this way were such cases not on record. It is not impossible that in some of the successful cases reported as done by extension, abduction and rotation were added to extension, these three elements constituting practically the plan advocated in the "American Text-Book of Surgery" (1892). The extension may probably, however, be advantageously done away with; especially if retro-lateral flexion be substituted for abduction, the latter movement tending, perhaps, in some cases, to interfere with reduction by bringing more closely into apposition the two articular processes already impinging; whereas the backward movement is practically certain to unlock the displaced upper process. Since advocating this movement and the discontinuance of extension in previous contributions,[3] I find, on further study of the literature, that Richet[4] and Hueter[5] advocated similar plans early in the sixties, Richet[6] proposing abduction and rotation, though not without extension, and Hueter discarding extension. Völker[7] discussed the subject in 1876, considering extension and rotation equally efficacious with abduction and rotation. Hueter's plan seems to have been disregarded in practice, and since his time, as before, extension has been generally, in fact almost invariably, relied on as an essential part of the reduction. I find no reference to Hueter's suggestion in the "International Encyclopædia of Surgery" (1884), where extension is recommended as an essential part of reduction. Stimson[8] regards Hueter's plan favorably in his work on dislocations.

The essential elements in the plan here advocated are, (1) dispensing entirely with extension; (2) using only retro-lateral flexion and rotation. The plan is not, therefore, entirely novel, but is really a reversion to Hueter's methods, with a modification of the direction of the initial movement from simple abduction to retro-lateral flexion.

The extension generally practised seems to me not simply superfluous, but to detract from the best result, in that it tends to draw up the lower, along with the upper segment, and hence only to interfere with the lever movement which really accomplishes the unlocking.

It might be supposed that the tension of the muscles would have also to be taken into consideration in the operation. Apart from the fact, however, that etherization should always be employed in the operation, which would render the muscles lax, experiments on the cadaver show that the muscles may be practically disregarded, the ligaments alone serving to hold the vertebræ firmly in the new position. Such experiments (previously reported) were conducted by Dr. Richardson and myself in the dissecting-room of the Harvard Medical School. In a series of bodies all muscles were removed, leaving the spinal column with its ligaments alone intact. The vertebræ were then displaced in the typical manner. It was found that no moderate amount of traction in a direct line would raise the displaced articular process in the least degree. It was found, however, easy to unlock the displaced articular process by retro-lateral flexion, that is, by bending the head obliquely backwards and to the side — the side opposite to that of the displaced process — that is, in the typical (complete) case, to the side opposite to that in which the head is bent. For this manœuvre it was found that an inappreciable amount of force was required, and comparatively little elevation. Rotation into position completes the reduction. This was the method adopted by Dr. Beach in the case above reported, and with perfect success.

Cases sometimes occur in which the position is not one of the complete variety. As an instance, I will

[3] Boston Medical and Surgical Journal, September 15, 1892, p. 265. Journal of Nervous and Mental Diseases, September, 1892.

[4] By Richet's original report it seems that strong extension was practised by an assistant; while he, by putting his own hands over those of the assistant, performed the abduction and rotation, adding at the same time something to the extension. This seems to have been overlooked by Hueter, who made an abstract of Richet's article, and who gave him (Richet) the credit, which was rather due to himself, of abandoning extension.

cite the case (already published), of which the photograph is here given, of a boy who fell upon the ice while skating backwards. Displacement with immobility occurred, followed by paralysis of the shoulder and considerable pain in the neck. When seen at the hospital some months later, the condition was that represented in the picture. It will be seen that the head is bent to the left, and that the muscles on the right are put upon the stretch. The position of the head is, however, not that of torticollis, in that the chin is not rotated to the left, nor elevated. The obvious inference in such a case is either that the articular process on the left has slipped backwards, or that the articular process on the right has slipped forwards, but has not fallen into the intervertebral notch. Manipulation of the vertebræ on the skeleton shows that the former dislocation would be an extremely improbable one, at least, unaccompanied by fracture,[9] and

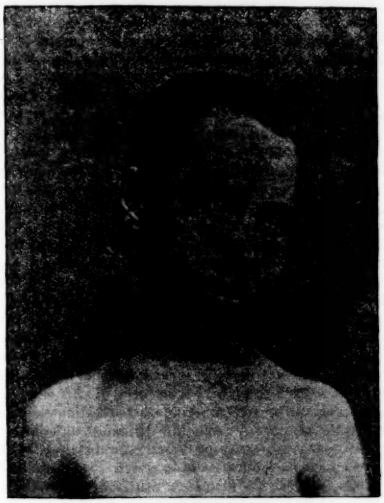

FIG. 4. Incomplete form of dislocation.

that, even if it were possible, the head would not be bent to the left, but, if anything, rather to the right. Displacement of the right articular process in the manner indicated would, however, explain perfectly the position of the head; as this process, if arrested in the course of riding over the articular process below, would be higher than the corresponding process on the left (Fig. 5), and thus cant the head to the left, while turning the face in the same direction. To reduce the dislocation in this case the head should certainly have been bent backwards and to the left, then rotated. It is not, therefore, safe to blindly follow the rule of bending the head, either in the direction opposite to, or towards that in which it is already bent.[10] Paralysis in this case (due probably to stretching of nerve roots), which included the supra- and infra-spinatus and the deltoid, gave us a clew to the height of the displacement. There was also an irregularity in the spinous processes at about the height from the third to the fourth vertebra. It might be supposed that such displacement would always be easily recognized in these cases. This is, however, not the fact. Examination of the spinous processes should always be made, but in many cases will be found unsatisfactory, especially where there is a swelling of the tissues, such as sometimes occurs in comparatively fresh cases.

Bilateral dislocation, both forwards and backwards, is comparatively rare. I have seen one example of the former and have a picture (given me by Dr. Richardson) of the latter. In the former case the head was displaced forwards, and the face pointed upwards; in the latter, the chin was bent towards the chest. Direct extension in such cases has required extreme force and has not always proved successful. It would seem reasonable, therefore, as Heuter formerly suggested, that the attempt be made to first reduce one articular process, then the other, in the method indicated for unilateral dislocation, extension here also probably hindering rather than assisting.

FIG. 5. Anterior view of displaced vertebræ in form of dislocation seen in Fig. 4. A P, articular process caught before dropping into intervertebral notch.

This whole subject appears to have received little attention in comparison with its importance; partly, perhaps, because such accidents are erroneously considered extremely rare. In Lidell's elaborate article[11] on the subject the different forms are described with great accuracy, and twenty-nine cases of unilateral dislocations are quoted from Ashhurst's tables. I have already reported sixteen cases of dislocation without fatal result, since which I have seen two more typical cases and several others in which this diagnosis was taken under consideration, but in which the displacement was so slight as to render the diagnosis uncertain. Most of these cases were unilateral. This would seem to indicate that the lesion is not one of great rarity. The subject is renewed here for the purpose of calling attention to the importance of being on the lookout for this condition as well as of renewing the discussion regarding the proper method of reduction, and establishing the success of the method advocated. Operative interference has already proved successful in a large number of cases, as already stated, generally, by direct and forcible extension combined with manipulation of the displaced parts. Dr. Burrell

[9] Blasius, quoted by Stimson, only found one case of backward unilateral dislocation, and in this case fracture occurred also of the lamina and body of the vertebra below.

[10] Stimson regards this form as the more common, alluding to the complete form as follows: "Not only may the abduction of the upper segment of the column, which is necessary to the production of the dislocation, be almost entirely corrected by the sinking back of the articular process of the upper vertebra into the notch of the lower one." In this description of the proper method of reduction to which I have alluded, this form is also apparently taken as the basis, for he says the articular process should be freed by still further abducting the head and upper segment of the column (away from the side of the dislocation).

[11] International Encyclopædia of Surgery, vol. iv, p. 709.

informs me, however, that he has performed the reduction without extension, and I dare say others have done so without reporting the cases.

The number of cases of spontaneous reduction observed is striking, in contrast with the cases of operative interference, where extreme force has been necessary. Dr. Beach has forwarded me a communication regarding a case, hitherto unpublished, occurring in his practice, which will serve as an excellent example of spontaneous reduction. The communication is as follows:

BOSTON, October 10, 1893.

MY DEAR DR. WALTON: With this I forward the notes of a case which occurred in my private work, and may be added to the hospital case if you would like to have it.

In June, 1889, a child between six and seven years of age was brought to me with the deformity characteristic of dislocation in the cervical region of the vertebræ. She had fallen from a hammock a few days before that, and, either in falling or striking, produced the luxation.

There was no contusion or tenderness to indicate the location of a blow, nor could she give any clear idea of being struck in the fall. Upon examination of the spines of the cervical vertebræ, the line from the second to the fifth was concave, the convexity towards the pharynx. An inspection of the larynx disclosed a convexity corresponding to the body of the third vertebra. For the first few days after the injury the muscles of the neck were rigid, and there was lameness on both sides of the neck, not well defined. Very little motion was possible. Rotation began first, and afterwards flexion. With the exception of some difficulty in eating there was no impairment of any function.

At the time of her visit to me, she had lost a certain amount of muscular rigidity and could flex and rotate the head to a limited degree. In view of her improvement, I advised against any extension under ether, and requested that a plaster cast be made to preserve a record of the deformity. Before this could be done, however, a spontaneous reduction took place on the second night after my examination, when, after being much fatigued by her journey, she slept very soundly. On the following morning the cervical vertebræ were in perfect position and she had free motion of the head in every direction.

Yours sincerely,
H. H. A. BEACH.

There was considerable controversy in former times as to whether pure dislocation of the vertebral column was possible even in the cervical region. This point has, however, become so fully established as to require no discussion here. It is certainly true that pure dislocation in the dorsal and lumbar regions is practically impossible; in the cervical, however, it constitutes a large proportion of the cases. Lidell's estimate that dislocations of the cervical vertebræ constitute one-half the cases of vertebral injury met in civil practice, is probably not an over-estimation. Bryant [12] treats this subject as being of comparatively little importance to the practising surgeon. Still, as Lidell has pointed out, the establishment of this fact and the diagnosis of dislocation from fracture, or the combination, is of great importance when we come to consider the question of operation. On this point, namely, the advisability of operation, there has been in the past more or less difference of opinion. Boyer and Dupuytren, for example, object to attempts at operation as dangerous. Erichsen considers the attempt only justifiable where the danger is imminent. Porta, Bryant, Ashhurst, Lidell and others, on the other hand, favor operation. Lidell states that there is a hope that the fatality will be considerably diminished by improved methods. It would seem that successful cases of reduction have been already sufficiently numerous to warrant the attempt, with care, even under the methods commonly employed. Successful cases have been reported, for example, by Gray,[13] Wood,[14] Völker,[15] Hickerman,[16] Schuk,[17] Schranth,[18] Stout,[19] Aubert,[20] Van Walther,[21] Guerin,[22] and others. Ashhurst, in his list of twenty-nine cases of unilateral cervical dislocation, reports sixteen in which attempts at reduction were made, all but one being successful. It seems probable that this is a rather large proportion, many unsuccessful cases having probably not been reported. Among unsuccessful cases followed by death may be mentioned those reported by Gaitskill,[23] Spencer,[24] and Petit Radel.[25] There have been unsuccessful operations followed by spontaneous recovery.

To recur to Völker's views: this writer has reduced a case of complete unilateral dislocation by extension and rotation (the reduction requiring, however, several attempts for its completion), and argues that this method is equally logical and easy with that which he has credited to Richet — an opinion which seems generally to have prevailed since that time.

With regard to direction of abduction, when practised, there seems to have been some obscurity of expression. Völker quotes Hueter as recommending to bend the head towards the shoulder towards which it is already bent, then to rotate; but rightly comments that in cases of complete dislocation this would be exactly the wrong direction. He substitutes, therefore, the suggestion of bending the head to the side where no projection (Hervorragung) is noted; then rotating. It is not impossible that the obscurity of these directions have been in part at fault for the non-adoption of the method. These arbitrary rules are difficult to remember; but if one attempts to carry any given rule into effect, I should suggest the following: Perform retro-lateral flexion toward the side toward which the face is turned by the dislocation, then rotate back to place. The force of this rule will be appreciated by remembering that rotation must always take place away from the displaced side, except in the case (which may be practically disregarded) of displacement backwards. It is also well to remember in diagnosis, that the face is turned from the displaced process, no matter which way the head is bent.

In some cases, it is true, there may have been so little rotation in the dislocation as to render the diagnosis difficult between dislocation and inflammatory process. Gentle attempts at reduction would, however, as Völker states, be always in order in such cases, to effect the cure, and at the same time to establish the diagnosis.

The ease with which spontaneous reduction takes place in sleep was commented on by Völker as due to relaxation of the muscular strain kept up in the waking hours to prevent pain, such reduction being easily

conceivable when it is realized that the part of the articular process which bars the way to reduction is only about six millimetres in height, perhaps less.

The advisability of using ether in all attempts at reduction is too apparent to require mention.

With regard to the method usually advised and followed, Lidell says (loc cit.) p. 723:

"Had I this case now to treat, I should, as soon as it became clear that the man would not recover under an expectant line of treatment, that is, on the second morning after the accident, relax his muscles completely by administering an anæsthetic, and then by carefully made *extension and rotation, etc.*,[26] try to restore the dislocated bone to its normal position."

He quotes Ashhurst (p. 729) as saying: "In the treatment of dislocation of the cervical region, the mortality has been nearly four times greater when constitutional or general treatment has been relied on exclusively, than when attempts have been made to reduce the dislocation by *extension, rotation, etc.*"[26] Lidell continues: "It seems to me that the inference is fairly warranted from the foregoing considerations that *extension*[26] (combined, of course, with rotation or pressure, as required) should be employed in every case of spinal dislocation or of spinal fracture with dislocation where the spinal functions are disturbed.

Looking more closely into the order of procedure, we find that one plan seems to have been to first rotate in the direction in which the head is already turned, then to extend and rotate the head back to place (Maxson,[27] Wyeth[28]); another method has consisted of extension followed by rotation (Rathburn,[29] Gray,[30] Perisot, Berthold,[31] Lucas[32]); another, suspension of the head and rotation of the body (Morton[33]); another, as extension and manipulation (Van Walther). In bilateral dislocation steady extension, followed by direct replacement without rotation, has been adopted (Ayers[34]); with slight rotary movement (Stout); extension with rocking movement, and finger in the pharynx (Carter[35]).

With regard to the degree of force used in extension, this seems to have been in most cases very considerable: Suspension of the head between the hands (by Morton); strong extension (by Wyeth); a considerable amount of force — "all, I believe, I was capable of exerting" (by Carter); chin and occiput held by the hands of the operator covered by those of another, strong traction being employed with counter-extension by folded sheets around the shoulders, a third physician placing the hands under those of the other two, to aid replacement (Ayers); "steady pulling, gradually increasing" (Thon[36]); three pull the head and one the shoulders with the whole weight (Schranth); place the knees on the shoulders, drawing the head, then turning it into position (Erichsen); a hand on the forehead and on the occiput covered by those of an assistant, counter-extension being firmly maintained (Gray).

Even the degree of force indicated has not always proved successful, as in the case of Warren, in which subsequent spontaneous reduction pointed the way to direction rather than force as the key to the situation.

It is certainly in the line of advance (notably illustrated by Bigelow's brilliant exposition of hip-joint reduction) in other dislocations to do away with this excessive force, and to follow backwards as nearly as possible the movements made in dislocation — an object which we are here aided in accomplishing by the use of the fulcrum.

The question naturally presents itself: After how long a time shall we advise operation? Gray's case was successful after four months. The spontaneous reduction in Warren's case, already alluded to, took place after nearly as long a period. Guerin reduced a case after seven months. We should err on the side of caution when any question of fracture is present, or where great force is to be used, even in simple dislocation; but when we consider how little force is necessary by the method advocated, as shown by Beach's case, there seems little or no risk in attempting reduction after a considerably longer period than four months has elapsed, though the exact length of that period it would seem premature to determine without further experience. Attempts should be abandoned if the displacement is not easily reduced.

SALINES IN APPENDICITIS.[1]

BY S. C. GORDON, M.D., PORTLAND, ME.

DR. M. H. RICHARDSON, in his article published in the JOURNAL of September 28th, objects very strongly to the use of salines in appendicitis, especially in the early stages; and inasmuch as this is the time when in my opinion they are the most required and will do the most good, I cannot allow some of his positions to pass without comment, particularly as I am one who has "advocated" the prompt and free use of this method of treatment.

In the first place, I think Dr. Richardson does not fully state the case when he says: "The theoretical action of cathartics in peritonitis, as given by various men, consists in an absorption and removal by intestinal drainage of the toxic products of certain micro-organisms which, multiplying in or near the peritoneal cavity, endanger life." Now while this is true, it does not express the whole truth. I am just old-fashioned enough to believe that general bleeding oftentimes does an immense deal of good in the sthenic form of inflammation, not by removing "toxic products" alone, but diminishing the volume of blood in the general circulation, thus unloading the distended vessels in the part inflamed, and facilitating absorption of the liquid exudate, before any purulent degeneration takes place in it. I believe and know from "very considerable experience" that leeches will almost invariably stop the inflammatory process in orchitis and many other local inflammations, for the same reason. It is not simply the removal of "toxic products," but in the case of appendicitis it is more the removal of exudate while in a liquid state, in order to prevent the "toxic" elements from the intestines poisoning it and thus producing pus.

When we are called to the case there is a beginning or well-advanced peritonitis, caused by septic matter

[1] A reply to Dr. Richardson's article of September 28, 1893.

that has escaped from the appendix (in the cases where perforation has occurred), all the blood-vessels in the vicinity are enormously distended, and exudate is being poured out in the intervascular spaces. The *prompt* and *free* use of salines unloads these distended vessels, and promotes absorption of the exudate, before it is converted into pus. By thus promptly relieving the congested vessels, and removing pressure, pain and fever are both relieved, and in nine cases in ten, in my "considerable experience" the case is practically ended for that time. Other and similar attacks may follow soon or late, unless operation for removal of the diseased organ is made in the interval, which I always advise.

Again, Dr. Richardson says: "I do not object to carrying out this theory after the appendix has been securely tied, or after it is clear that there is no danger of rapid extravasation, but in the first forty-eight hours of appendicitis, I look upon the administration of salines as extremely dangerous, and as a not infrequent cause of general peritonitis and death. The reasons for this lie in the pathological conditions that exist in a very considerable percentage of cases. If in a given case there is a perforation in an appendix of large lumen, salines by liquefying the fæces and increasing peristalsis, *will cause an immediate and almost invariably fatal extravasation.*"

My answer to this is: First, the septic material has already escaped from the appendix and produced the peritonitis, and removing the "shell" which is left does not remove the *cause*, for that has already "gotten in its work" and done all the harm it can. It is the *condition* we are called upon to treat, and not the "tenement" that once held the toxic element. *Removing the former habitat of the cause does not remove the cause or the effect*, but it does add traumatism to an already serious matter.

Again, in my "very considerable experience," I have never seen a case, with one exception, where any fæcal matter has existed in the "lumen" of the appendix, no matter how "large" the lumen. The effect of inflammation is to close the end nearest to the cæcum, so that no material escapes from the bowel. Salines do not, therefore, cause "extravasation" from the intestine. In the single exception alluded to, there was simply the *color* of fæcal matter, and not any substance, that had escaped, and the proximal end was closed, so that no more could escape.

Dr. Richardson says in a subsequent paragraph, "There is the same objection to the use of salines in gunshot wounds of the intestines, in perforation of typhoid fever, or in perforating ulcers of the intestinal tract generally." I agree that there is a most decided objection to the use of salines in the pathological conditions named, but I fail to see wherein the analogy lies between these conditions and those usually found in appendicitis. In the latter there is a perforation through the appendix only, which allows some septic material to escape, while the opening to the bowel is practically shut up. While in the "gunshot wounds, etc.," there is a direct opening into the bowel itself. While the "same objection" may apply in the latter condition it fails to apply in the former, simply from the fact that the conditions fail to be the same. In "catarrhal appendicitis without perforation" I agree fully with Dr. Richardson that it is the "mildest of diseases" (of the kind), *if you always know it when you see it.* But even that is attended with a certain amount of peritonitis: and salines can do no harm, but can, and do accomplish much good by terminating the case by rapid resolution, thus preserving the integrity of the tissues, so that perforation is much less liable to occur, and "general spreading peritonitis" is prevented. I am fully in accord with Dr. Richardson when he says that these cases of "general spreading peritonitis, far from being curable by salines, are, in my opinion and experience, beyond relief even by the most radical surgical measures, except in very rare instances." I know of several instances, however. I do believe also if the rule should be established in the profession, that at the *very earliest symptoms* of appendicitis salines should be promptly and effectually used, a large number of these cases could be prevented.

When we consider the percentage of natural cures reported, we should hesitate long before operating in the acute stage. Ranvers reports 2,000 cases in the Prussian army with 96 per cent. of cures without operation; Charité Hospital, Berlin, 54 cases with three deaths; Nothnagel's Clinic, Vienna, 65 cases and three deaths, etc. But I do believe strongly in operation after a well-marked attack is convalescent. There is always danger of relapses, and the danger of operation in the interval is, in my opinion, very small — one or two per cent. possibly.

Since June 14, 1892, I have operated nine times in the interval of attacks (none less than two, and one eight attacks). Seven of the nine I treated through the acute stage by salines. During that time I have also treated four others without operating afterwards. All recovered without any serious symptoms following the operation. No one of the four has yet had relapse. Some of these cases I did not see until pus had formed (as the operation afterward showed), and yet I preferred to risk medical rather than surgical treatment until convalescence was established. I think the result proved the wisdom of my course. Results are, after all, what we work for; and while statistics are often fallacious, yet we are governed by them in a measure in our own line of work.

I am not prepared to say that I should refuse to operate in the acute stage, where there is clearly an abscess to be drained, or a "general spreading suppurating peritonitis"; but I shall in the future be governed by my "very considerable experience," and treat all cases in the *early stages* by salines.

THE SYMPTOMS OF SENILITY IN PARALYSIS AGITANS.[1]

BY THEODORE DILLER, M.D.,
Visiting Physician to the Insane Department of St. Francis Hospital, Pittsburg, Pa.

THE recent investigations of Dana[2] and Ketscher,[3] throw a flood of light on the morbid changes which produce the symptom-complex known as paralysis agitans. These changes, confined chiefly to the cord, consist in dilatation of the blood-vessels, infiltration of round cells with marked degeneration and pigmentation of the nerve cells. Ketscher found miliary aneurisms and hæmorrhages throughout the cord. Both these authorities unite in saying that the primary change occurs in

[1] Read before the Pittsburg Academy of Medicine, December 4, 1893.
[2] Journal of Nervous and Mental Diseases, May 1, 1893, pp. 359, 360.
[3] Neurolg. Centbl., No. 5, 1893 (quoted in Journal of Nervous and Mental Diseases).

the blood-vessels, and that the nerve changes are secondary. Indeed, the results of their studies are so concordant throughout, that it would seem that we could (as Dana remarks) take paralysis agitans from the list of functional diseases and place it in that of organic diseases.

Ketscher further examined the nervous systems of ten old people who had never suffered from shaking palsy, and found almost identical changes with those he had discovered in paralysis agitans, save that they were less pronounced. He concludes that shaking palsy is nothing more than a pronounced senility occurring prematurely.

Two men, one forty, the other forty-five years old, and one woman, aged fifty, suffering from paralysis agitans, have come under my care recently. In all three of them I noted the unmistakable signs of senility, and desire to record a clinical symptom which may have some weight in supporting the deduction which Ketscher makes from his pathological investigations of the disease. Moreover, the symptom, from a clinical standpoint alone, is, I believe, of considerable diagnostic significance. All three of my patients spoke of having rather suddenly become aged. They had lost their vim, vigor and enterprise. This symptom of aging had been noticed and remarked upon by friends of these patients. It was both objective and subjective.

In two of my cases, the disease is yet in its early stages, the tremor being confined to a single hand. Both presented the "bread crumbling" position of the hand; in one the *facies* were rather suggestive. But the attitude, voice and symptom of festination were absent. It is in cases such as these that this early symptom of aging will be of diagnostic value. The fully developed disease is so characteristic that it may be most easily recognized even apart from the symptom of senility.

None of the recent text-books speak of this sudden aging as an early symptom of the disease. Only the piping voice and the general appearances of senility in the fully formed disease are spoken of.

How constantly this symptom of sudden aging may be observed in the early stages of paralysis agitans will, of course, require many more observations than the few I have made to determine. I trust they will be forthcoming.

Clinical Department.

A CASE OF DYSPHAGIA WITH DILATATION OF THE ŒSOPHAGUS, AND PNEUMATOSIS.[1]

BY GUSTAV LIEBMAN, M.D.

Miss S. S., fifteen years of age, had been always well until the catamenia set in two years ago, when she flowed excessively during eight days; after a pause of three weeks the menorrhagia commenced once more and lasted another week. There have been no signs of a menstrual flow since. While having had some dyspeptic symptoms before that time, no difficulty in deglutition was known to the young patient; but this made its appearance coincidently with the cessation of the metrorrhagic flow. As in most of these cases the patient at first met with difficulty in swallowing solids; soon she had the same trouble with semi-solids; and after the lapse of a few months she was only able to swallow fluids, and with great difficulty at that. A few weeks after the appearance of the dysphagia our patient acquired the habit of sucking air into the œsophagus, in order, I think, to force the liquid food down into the stomach. The air would enter with a rumbling noise; and this very rumbling, which she located, as she does still, over the whole length of the sternum, was, as it is still, a source of great distress and no end of complaint. The act of swallowing became more and more difficult; she sucked greater quantities of air, until the whole abdomen would swell up like a balloon, producing a distressing feeling of bloating and oppression. This sense of oppression would last until some of the gas was expelled through the cardia or by rectum. The liquids having hardly reached the stomach — or what the patient thought to be the stomach — vomiting would set in; and of a cupful of malted milk but a very small portion would be retained. The child was treated for some time in the Massachusetts General Hospital, where she improved somewhat under a diet of peptonized milk taken per os, and milk and eggs given through the feeding-tube; but she grew worse after having been at home but a few days.

The clinical picture has remained unchanged ever since with the exception of a short period of improvement, to be mentioned later on. The patient lost flesh to the point of emaciation, and was most of the time unable to leave her bed. Sleep was poor; the bowels constipated; and the vomiting occurred no matter whether the patient *drank* her liquids or had them put into her stomach by means of the tube. This was the condition when I first saw the patient, October 30, 1892. The following *status presens* appeared then:

A young girl, fifteen years of age, of anxious expression, intelligent, four feet and seven inches in length, emaciated. The integuments are dry and sallow, not elastic. The urine is of 1,015 specific gravity; no albumen; no sugar. The heart, lungs and bronchial tubes are healthy. The gastric region and abdomen are enormously distended — drum-like; and the stomach and colon sounds not to be differentiated upon percussion. Meteorism extends to the symphisis pubis on the one hand, and to eight right and left intercostal spaces on the other. Liver dulness is abolished, but discernible further up in the middle axillary line, between eighth and ninth ribs. There is vomiting after the taking of any kind of food. Of the three cupfuls of food (consisting of milk and egg) put in the stomach through the tube, one cupful stays. There is at present a continuous swallowing of air, even when no food is taken. When fluids are taken there is considerable effort to press them down, but there is no pain. Instead of the first deglutition murmur (*Durchspritzgeräusch*) there is a pharyngeal sound transmitted along the whole œsophagus. After a few seconds there is a second sound, though this cannot be heard at all times.

I ordered the patient to drink a glass of water; she succeeded in taking from forty to fifty cubic centimetres. This was regurgitated in less than five minutes; and upon introducing a stomach-tube to a distance of sixty centimetres, but a few drachms of water escaped through it. There was no obstacle to the entering of the tube through the cardiac orifice. Washing out the stomach followed this procedure; washings clear and limpid. Patient dwelt with a great deal of volubility

[1] Read before the Suffolk District Medical Society, October 18, 1893.

upon her suffering from the "rumbling," rolling gases in her throat and along the œsophagus. Ordered daily irrigations of stomach, and bromide of strontium.

November 2d. Patient swallowed some tea and milk, also some beef-tea (bovox), and vomited about all some five minutes afterwards. This specimen was not changed at all in appearance. Reaction was neutral; there was neither peptone, propeptone, dextrine nor sugar.

Three days afterward I obtained a specimen through the tube, the examination of which showed the following:

Reaction, acid.
Acidity = 30%, that is, it takes 30 c.cm. of normal one-tenth soda solution to neutralize 100 c.cm. of gastric juice.
Hydrochloric acid, —

November 8th. Direct faradism by Dr. Gertrude Van Pelt.

December 18th. Has had no irrigations for over a month, but two internal faradizations twice a week. Some little improvement. Acting upon my earnest solicitation, patient succeeded in stopping the air-sucking; and in order to confirm this more fully, feeding through the *tube* only was ordered.

December 23d. Patient feeling better in every respect. Abdomen softer and small; stools freer. Sleeps sounder. Vomiting has stopped.

February 2d. Still better. Tympanites in gastric region gone, also in abdomen, but still present over left false ribs. Stomach contents, acid; but hydrochloric acid still lacking.

March 10th. Things do not look so well; more meteorism and some vomiting; although patient is able to sit up occasionally. Ordered her to resume direct faradism, that had of late been neglected. So far I had been loath to blow up the stomach with air, deeming it a cruel procedure under the circumstances; but I did it to-day, the distension being still very much less than two months ago. Lower border of stomach was found two finger-breadths below umbilicus. I also blew up the lower part of the œsophagus; while doing so, I found increased tympanites on left front and side, but indistinctly so on back (both sides of vertebræ).

April 6th. Prognosis unfavorable, although the swallowing seems to be easier. Direct faradism insisted on.

CONCLUSIONS.

We have then to deal with

(*a*) A very distressing case of dysphagia.

(*b*) A fusiform dilatation, to a slight degree, of the œsophagus.

(*c*) Pneumatosis — an aggravated distention of the stomach with air (drum disease).

As regards the dysphagia, it would appear that its first occurrence was synchronous with the two first and only efforts of nature at menstruation, and that the great loss of blood might have had considerable to do with it.

My reasons for supposing a fusiform dilatation of the œsophagus are:

(1) The vomiting or regurgitation of unchanged liquid food, of neutral reaction, if *swallowed* by the patient, and not put down into the stomach with the feeding-tube.

(2) The great distance to which the stomach-tube had to be introduced — almost its entire length — to reach the cardia and the fluids contained beyond. While the distance from the incisors to the cardia in *adults* is estimated at forty centimetres, that in the case of our child-patient is far in excess of that figure. This strange fact can only be explained by the suggestion of a distention of the œsophagus and the consequent formation of a semicircle by the tube in gliding over the distended wall. That the dilatation is of the spindle-shaped variety I infer from the fact that there is no accumulation of fluids in the lower œsophagus to be met and discharged through the searching-tube, as would be the case in the sacculated variety; and from the fact that I was able to blow a considerable amount of air into the œsophagus before the patient made complaint about it, and that the resonance in both the back and front increased thereby — in front I must admit much more so than in back on both sides of the vertebræ.

From the text-books we learn very little about those dysphagias not depending on *anatomical* stenosis. As their probable causes, may be mentioned:

(1) Spastic contractions of the œsophagus (œsophagism) due to hysteria.

(2) Paralysis of œsophagus (Ziemssen), or fatty degeneration of its muscular layer (Bartholow).

(3) A lack of reflex relaxation (opening) of the cardia during the act of deglutition (Meltzer, Einhorn).

(4) Spastic contraction of the cardia.

Œsophagism I eliminate because there is absolutely no obstacle to the insertion of an instrument within the œsophagus, and because the general mental habitus of the patient is not that of an hysterical person. There is much volubility of tongue, to be sure; but what a sufferer the poor girl is! Moreover, there is neither hyperæsthesia, paræsthesia nor hemianæsthesia. Paralysis we must exclude, as no infectious disease like diphtheria had preceded the dysphagia. Nor is there anything like a bulbar affection of the larynx or pharynx. A fatty degeneration of the muscular layers is not impossible, but cannot be proved. The theory of a spastic contraction of the cardia would best explain the origin of the pneumatosis, inasmuch as the spasm of the cardia (and eventually the pylorus) would naturally cause retention of gas within the stomach. But we must exclude also this explanation, because there is no resistance to the stomach-tube within the cardia, and because of the ease with which the act of vomiting takes place.

There would then remain, as the only possible explanation of the dysphagia and the resulting dilatation, a lack in the reflex relaxation of the cardia during the act of swallowing. Einhorn says: "Meltzer has shown that with every act of swallowing the cardia opens by way of reflex-action. Supposing that the centre or the circuit of this reflex-action is in any way disturbed so that the cardia does not relax during swallowing, there will necessarily result a slight difficulty in transferring the food from the œsophagus into the stomach."

That, in our case, the great loss of blood at such a tender age might have affected the nerve centres in general, and the one presiding over the reflex opening of the cardia in particular, is a probability with which, as a causal factor of the dysphagia, we have to reckon. The pneumatosis (the filling and distention of the stomach with gas) is without doubt due to the

sucking of air on the part of the patient. This proposition is borne out by the improvement following the use of direct faradization, the abstention from swallowing air, and the feeding of the young girl with the feeding-tube only. To this mode of feeding, doing away with deglutition, the largest share of the temporary improvement was due. Still some of the good result may be ascribed to the tonic effect of the intragastric current upon the vagus as well as to its moral influence exerted upon the will-power of our patient.

May 5, 1893. Although deglutition is still much improved (forty c. c. of milk swallowed by patient and vomited five minutes later were changed in appearance, curdled and of acid reaction, a proof that the milk had reached the stomach) and although the pneumatosis is much less conspicuous, the patient is worse and extremely emaciated. There is bronchial breathing and delayed expiration, but no cough or expectoration.

July 11th and 12th. Great pain in left front, making the administration of one-twentieth of a grain of morphine necessary.

July 15th. Death.

DISCUSSION.

DR. VAN PELT: I had the pleasure of seeing this very remarkable case. I never saw anything like it before. In a few moments as I watched it, the stomach became so distended with air as to look like an enormous tumor. One could easily hear the air rushing in.

DR. F. C. SHATTUCK: If I am not mistaken, the patient whose remarkable case Dr. Liebman reports was under my care twice at the Massachusetts General Hospital. The first time was for only a few days after a change of service. Some weeks later she re-entered and I did my best to help her. There was then no vomiting and the constant complaint was that she could not swallow, although she swallowed air in large amounts and the largest-sized stomach-tube encountered no resistance. She was an undeveloped girl, and weighed only fifty-six pounds. Under feeding through the stomach-tube and by the rectum she gained seven or eight pounds in a few weeks and improved decidedly in appearance. She then began to vomit, and I could do nothing further with her by moral or other treatment. I regarded her as hysterical. Last winter I saw her at her home at her father's request. She was in a pitiable condition, emaciated to the last degree, with the lips drawn tightly over the teeth, and a belly distended to the last degree with air. The case seems to me to be one of those rare instances of fatal hysteria, the dilatation of the stomach and œsophagus being purely secondary to over-distension from the air which she swallowed.

REMOVAL OF FOUR INCHES OF THE RECTUM FOR CANCER: ANASTOMOSIS BY MEANS OF THE MURPHY BUTTON.[1]

BY H. O. MARCY, M.D.

W. S., aged forty-six, merchant. In good health until the early part of the summer of 1893. First noticed a slight tenesmus and pain at stool, with a little bloody mucus, some time in June. Was first seen by me in July. Quite two inches above the anal aperture, upon the anterior wall of the rectum, was a well-defined mass of infiltrated tissue, of irregular ovate shape, an inch or more in its longer diameter, the upper border of which was reached by the finger with considerable difficulty. The diagnosis appeared all too evident, but its location rendered surgical interference seemingly unwarranted.

[1] Reported at the Surgical Section of the Suffolk District Medical Society, November 1, 1893.

Upon my return to the city in the early part of September, I found that the growth had been so rapid that the entire circumference of the rectum was invaded, and much suffering was experienced on account of the stenosis. Blood in considerable quantity was daily lost; and it seemed a plain duty at once to advise colotomy. He accordingly entered the hospital on the 12th of September, left inguinal colotomy being performed the same day. He was discharged the 26th, much improved, free from pain, but still losing daily a considerable quantity of blood.

Notwithstanding various measures were tried to control the hæmorrhage, it gradually increased to such an extent that danger to life from this cause alone seemed immediate and imminent. He was readmitted to the hospital on the 17th of October and a modified Kraske operation was undertaken for the removal of the diseased portion of the rectum. To this end an incision was made posteriorly, commencing about an inch from the anal outlet and carried upward on the median line upon the sacrum. The coccyx and two-fifths of the sacrum were removed, allowing room to dissect the rectum from its attachment, dividing posteriorly the meso-rectum and entering at once into the peritoneal cavity. In this way sufficient length of the bowel was brought down for easy manipulation. The rectum was now divided two inches above the anus, and the constricting diseased portion split open upon its posterior border, for the double purpose of ascertaining the limitation of the disease, and to aid thereby the careful separation of the bowel from its anterior attachments, which to the base of the bladder were everywhere pronounced. The rectum was then divided above the growth, the disease having invaded about four inches of the bowel. Quite a number of vessels were divided in the section, but they were easily secured. During the summer, I had profited by the experiences and instruction of Dr. Murphy, of Chicago, in the use of his anastomosis button. These were reinforced by my own experimental studies upon animals. I had been indebted to Dr. H. O. Walker, of Detroit, only a few days previous to the operation, for the suggestion that the button might be used advantageously in the restoration of the continuity of the rectum, although it had never been applied for this purpose. The ends of the larger-sized button were adjusted in the divided extremities of the bowel and compressed. Owing to the thickness of the rectal wall (the muscular coat of the upper portion being markedly hypertrophied) I reinforced the parts with a continuous suture. I closed, also, the opening into the peritoneum of the pelvic floor with a continuous suture, in order to prevent the prolapse of the small intestine which had appeared in the wound, as well as to cut off the peritoneal cavity from possible subsequent infection. The posterior wall of the bowel was re-attached to the divided tissues, and a large part of the wound was closed by several lines of buried sutures. An iodoform-gauze drain was inserted and the dressing applied.

Convalescence was rapid and uneventful, the temperature scarcely reaching 100°. The button was removed the twelfth day with a little difficulty, not having freed itself quite entirely from its attachment; but its removal was hastened, because pressure of the button upon the neck of the bladder caused discomfort and some difficulty in urination. There is a fistulous opening posteriorly at the site of the union of the

bowel connected with the yet unclosed wound. The only ill effect noticed from the necessarily free opening of the sacral canal has been a marked hyperæsthesia of the cutaneous surfaces for a considerable distance above and upon either side of the wound. The patient has improved rapidly in his general condition and in restoration of color, and has been sitting up and walking about his room for a week. He was discharged from the hospital November 5th, the twentieth day after the operation.

It will be interesting to note the subsequent history of the patient, the cicatricial closure of the wound with the patency of the bowel maintained, and the possible return of the disease. So far as I am able to determine, the disease was limited to the intestine, and no enlarged glands were found.

A POSSIBLE CASE OF MATERNAL IMPRESSION.

BY JOHN LOVETT MORSE, M.D.

WILLIE M., three and one-half years of age, was born at full term after a normal labor. About the middle of her pregnancy, his mother was very much shocked at seeing a relative who, unbeknown to her, had had both legs amputated after an accident. All her other children have been well formed and there is no history of such malformation in the family. The constrictions involve bones as well as superficial structures. The use of the limbs is, however, perfectly normal. The case seems suggestive, at least, of maternal impression.

A BAD FAMILY RECORD.

BY O. T. HOWE, M.D., LAWRENCE, MASS.

A YOUNG lady, sixteen years of age, came to me recently for hæmorrhage from the lungs, and gave the following family history:

Her grandfather, Mr. D., died when middle-aged of phthisis. He left six children. Mary Eliza died when three years of age, Alice and Katie when twenty, and Mark (her father) when thirty-two, all of consumption. Another daughter, Margaret, is now sick with the same disease. The grandfather had one brother, who died when middle-aged (cause not known), and left eleven children. Of these, five have already died from, or are now in, consumption, and one is subject to hæmoptysis. Of these twelve cases I have known personally quite a number. They were fine, healthy subjects and one (Mark) an athlete. Almost all these cases developed after the children had left home, and when they were not exposed to any contact with the disease.

Medical Progress.

RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, JR., M.D.

PACHYDERMIA OF THE LARYNX.

McBRIDE[1] gives a very good description of this rather rare condition, so rare that until the illness of the Emperor Frederick of Germany it attracted little attention. At that time Virchow described symmetrical elongated swellings of oval shape, found in the region of the vocal processes. In association with these swellings the epithelium of the vocal cords is generally found thickened, and sometimes a very marked development of epithelium is found in the interarytenoid region. Later, Frænkel described the swellings on the vocal processes, often showing in their centre a pit or hollow, and often of a whitish-rose or red color. The microscope shows great thickening of the epithelium, horny changes in the outer cells and multiplication of papillæ. Sometimes the swelling appears upon one vocal process only, and a corresponding pit or depression is seen on the opposite cord. Another position in which pachydermia may occur is in the interarytenoid space, the position which, as is well known, is frequently the seat of incipient tubercular infiltration. Several cases have now been collected from different authorities, describing these tumors in both of these situations. Many of those in the latter position occurred in tubercular subjects, and should consequently be classified as phthisical pachydermia, as distinguished from idiopathic pachydermia. The difference in diagnosis between these two conditions is thus made by McBride: In the idiopathic variety the swelling rises gradually without any very definite margin so far as shape goes, although the color is distinctly defined, being of a whitish-gray with just a tinge of pink. The outline is smooth or finely granular, with sometimes a furrow or cliff. In the interarytenoid

[1] Edinburgh Medical Journal, April, 1893.

tumor of phthisis, on the other hand, the swelling is distinctly a tumor with more or less defined margin. The color is usually pink or red and the outline may be smooth or coarsely papillary. The posterior wall of the larynx seems to enjoy special immunity from neoplasms, consequently any distinct swelling in this position is rightly considered as suspicious of tuberculosis. The microscopic structure of benign pachydermia is almost identical with that due to phthisis; the latter is by far the most common. The author reports five cases, two situated in the interarytenoid space, two upon the vocal processes, and one upon the anterior third of both cords.

THE FREQUENCY OF TUBERCULAR AFFECTIONS OF THE LARYNX.

Although containing but little that is new, the conclusions of Kidd[2] being based upon the post-mortem material of the London Hospital, are interesting and instructive. The hospital records show that tubercular disease of the larynx is found in at least fifty per cent. of all patients dying of chronic pulmonary tuberculosis. On the other hand, in only about twenty per cent. is the presence of laryngeal tuberculosis found during life. This discrepancy in the clinical and pathological statistics depends mostly upon the fact that the larynx is frequently not affected until late. Both sexes are equally liable to the disease, and the greatest number of cases is found among young adults. There is good reason for believing that in the immense majority of cases the larynx is infected by the pulmonary sputum, but a few cases of undoubted primary tuberculosis of the larynx have been reported. The lesion may be either an infiltration or an ulceration; the infiltration may be either diffuse or circumscribed. The former is by far the commoner, consisting of aggregations of miliary tubercle, or of widespread cellular growths. In exceptional cases masses of considerable size project into the cavity of the larynx. On the vocal cords ulceration is the most constant lesion, although this condition is generally preceded by a localized infiltration. In some cases there is found a circumscribed or diffused infiltration of the cords, which assume a semi-transparent, fleshy, thickened appearance. In advanced stages the cord may become completely effaced by ulceration. On the posterior wall of the larynx submucous infiltration and swelling is very common, though ulceration generally co-exists. The thickening of these parts may attain to great dimensions. Next in order of frequency come lesions of the epiglottis, consisting commonly of shallow, multiple, roundish ulcers, or of diffuse tubercular infiltration. Ulceration generally attacks first the laryngeal surface. Extensive destruction of the epiglottis, sometimes erroneously considered to be pathognomic of syphilis, is occasionally the result of tuberculosis. The ventricular bands are less liable to affection, the other parts of the larynx even more rarely. The author found the vocal cords affected in sixty-eight per cent. of the cases of laryngeal tuberculosis; the posterior wall in sixty-one per cent., the epiglottis in twenty-seven per cent., and the ventricular bands in twenty five per cent. Of the cartilages the arytenoids are particularly prone to become affected by extension of the process of the parts around them, though the other cartilages occasionally become necrosed. Some degree of repair is by no means infrequent in the floor and edges of the ulcers, but healing is rarely more than partial or temporary. An actively secreting and extending ulcer may spontaneously transform into a granulating pinkish surface. In the rare cases of spontaneous healing the amount of cicatrization is slight.

[2] Medical Press, February 1st.

DIPHTHERIA AND OTHER MEMBRANOUS AFFECTIONS OF THE THROAT.

During the past year much practical advance has been made in the early recognition of diphtheria by ascertaining the presence of the Klebs-Lœffler bacillus in the throat. In some cities the local boards of health have already completed arrangements by which cultures from suspected cases may be made for purposes of diagnosis. The practical application of this work, especially at the Boston City Hospital, forms the subject of an interesting and concise paper by Dr. F. H. Williams.[3]

The Klebs-Lœffler bacillus is often found with other organisms, chiefly various forms of cocci. These latter may be found in the throat without the bacillus, and associated with appearances that often cannot be distinguished from those accompanying the bacillus except by the aid of a microscope. These cases are often designated as pseudo-diphtheria. In connection with other infectious diseases, notably scarlet fever, measles and typhoid fever, membranous throats are found. Of these some are associated with the bacillus of diphtheria, others are not. The proportion of fatal cases in which the Klebs-Lœffler bacillus is found, is much greater than in cases in which it is not found. In some cases the bacillus was found without, or before, the appearance of a false membrane, a fact which adds to the importance of early bacteriological examination. Cultures are not always infallible for some reason, such as the presence of a small amount of corrosive sublimate in which the bacillus will not grow when planted and therefore must be sought in the original specimen. But with all the sources of error, we now have at our disposal a method of diagnosis better than anything we have ever had before.

In the discussion of Dr. Williams's paper, Dr. W. T. Councilman describes the pathological anatomy of diphtheria and other pseudo-membranous inflammations of the throat. In conclusion, he says that of late considerable attention has been given to the pseudo-diphtheritic or diphtheroid affections of the throat, that is, other inflammations of the throat in which the appearances similate a pseudo membrane. Too frequently a sort of white deposit and discoloration in the pharynx is regarded as a membrane. The membrane found in the membranous inflammation is perfectly distinct anatomically, it is always tense and firm, and is made up of fibrin and degenerated cells. In the diphtheroid inflammations we may have masses of detritus consisting of cast-off epithelium, mucous and masses of bacteria collected on the surface of the mucous membrane and frequently extending into the follicles. This can be easily told from the membrane because on touching it with the needle, the needle sinks into it and it can be removed, not as a membrane, but as a more or less granular mass. Sometimes these deposits are accompanied by considerable swelling, irritation and other evidences of inflammation, and when removed, there may be, here and there, a very slight fibrinous inflammation beneath them. It is not

[3] Read before the Massachusetts Medical Journal, June 14, 1893.

uncommon to have a high fever and considerable constitutional disturbance in these cases, but the condition runs its course in a few days and is attended with little danger.

HAY FEVER.

Under the title of "Periodical Hyperæsthetic Rhinitis," including hay fever, rose cold, rag-weed fever and similar disorders, Sajous [4] gives his recent conclusions concerning the etiology and treatment of this disease, which differ in some respects from those previously given by the same author. The symptoms he believes to be the sudden cessation of the inhibitory functions of the nerve-centres, presiding over the physiological processes of the upper respiratory track. The most marked symptom of this nervous disturbance is hyperæsthesia, and there is a liability of the nasal mucous membrane to become unduly influenced by certain irritants, which irritants differ in different subjects. For a more detailed account of the nervous conditions and the appearance of asthma, we must refer to the original article. As regards the different results obtained from local treatment and cauterization of the nasal mucous membrane, they are ascribed to the great variations existing in the systemic and local conditions, capable of giving rise to the central adynamia. Of all local applications he prefers glacial acetic acid, and has obtained much better and more lasting effects than by the use of the galvano-cautery. The mucous membrane at varying times, after local treatment has been applied to it, tends to return to its former hyperæsthetic condition, and consequently renewed cauterizations, in connection with treatment directed to the central nervous adynamia, are the most satisfactory methods of treating the conditions, with hope of ultimately restoring both to their normal functions. In this way, also, the element of habit, a not unimportant feature of these cases, is eliminated. He condemns the advice given by some authors, to avoid local measures after the annual paroxysm has begun. Many cases are benefited by beginning within the month preceding the attack, or even during the attack. Some cases are permanently cured, some more, some less benefited. As palliative treatment, he suggests contracting the nasal mucous membrane by a solution of cocaine, applied by the physician, once every other day, and maintaining the effect by means of a ten-per-cent. solution of menthol in almond oil, preferably to mineral oils, and by the internal use of atropia, one two-hundredth of a grain every four hours the first day, then every six hours.

THE SURGERY OF THE FRONTAL SINUSES.

Collier [5] describes empyema of these cavities and an operation for opening them. Distension causes the walls to yield in their weakest spot, which is generally through the roof of the orbit, more rarely anteriorly. Where the opening into the nasal cavity is not occluded, pus may make its escape periodically through the nostril. The etiology is often undefined and cannot be associated with any corresponding disease in the nose. Headache at the root of the nose is a common symptom, often more annoying from its persistency than from its intensity. It is often more marked in the recumbent position and on waking from sleep. Dull and rainy weather often increases the headache, also bending forward and stooping, but high altitudes and dry atmosphere decreases it. The diagnosis is often difficult, unless pus is found issuing from the opening of the passage into the nose. To open the frontal sinus, except where there is bulging in the orbit, the author shaves the eyebrows and opens in the exact spot of the middle line on a level with the upper margin of the orbit. An incision is made commencing at the root of the nose, and carried upward about two inches. A hole, three-quarters of an inch in diameter, is trephined, care being taken not to lacerate the lining membrane of the sinus. Some difficulty is found in removing the button as a whole, on account of the bony ridge dividing the sinuses. The diseased sinus is then opened by a scalpel and scissors, any secretion or polypus removed, and an opening is made into the nose, a drainage-tube inserted and maintained in position. The pericranial aponeurosis as well as the skin is separately and accurately sutured. By this method the author obtains healing of the wound by first intention, an insignificant scar and an avoidance of the danger of a fistula. In cases characterized by protrusion and lateral displacement of the eyeball, an incision parallel to the eyebrow at the most prominent part of the swelling, is made, and in this case also, communication of the nose is established.

THE INFLUENCE OF WEATHER ON TONSILLITIS.

Lennox Browne [6] in criticising some recent opinions on this subject, concludes from his hospital records that the epidemic wave of acute tonsillitis is greatest when the first rainfalls, after a lengthened period of dry weather, being but slight, are sufficient to stimulate to activity the dry and comparatively inert organic matter, and it only passes away with the thorough flushing of the sewers after heavier rain. Although dust plays a part in the production of throat diseases, long-continued drought and heat only become seriously noxious factors on occurrence of a change.

THE FREQUENCY OF LYMPHOID HYPERTROPHIES IN CHILDREN.

This subject has, up to this time, not received the amount of attention which its importance deserves. An attempt, on a small scale, to ascertain the condition of the upper air-passages in the throats of children who were supposed to be healthy has been made by Vinton,[7] who finds that out of 550 children, in the New York public schools, only 20 per cent. can be classed as normal; 60 per cent. had more or less adenoid vegetation; 20 per cent. enlarged tonsils, and 12 per cent. had both combined. Fuller statistics of this kind will be valuable in determining the advisability of operating for these hypertrophies in the absence of any symptoms due to their presence.

NASAL POLYPUS.

Marmaduke Sheild [8] describes the common gelatinous polypus of the nose and its proper treatment. While containing nothing new, the paper states clearly the modern method of treating this disease, which is often not sufficiently understood by the general practitioner. The polypi are mostly composed of loose connective-tissue distended with mucin and covered with ciliated epithelium. They are also most always multiple, and swell up in damp weather. In the majority of cases they spring from the mucous membrane, covering the

outer wall of the nose, either over the middle turbinate or the mucous membrane of the outer wall under it, rarely from one of the accessory cavities. For their diagnosis and treatment, a speculum and a good light are required. It is important to remove all of the growths, which is best done by means of a cold-wire snare, previously bathing the parts with cocaine. It is important to detect and destroy the very small growths, for it is the continued growth of these which leads to such rapid reproduction of the disease. After they have been removed, the mucous membrane, in the situations of the former growths, should be destroyed with a cautery or caustic.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

C. L. SCUDDER, M.D., SECRETARY.

REGULAR Meeting, Wednesday, November 1, 1893, DR. ABNER POST in the chair.

DR. GEORGE L. WALTON read a paper on

REDUCTION OF CERVICAL DISLOCATION: A SUCCESSFUL CASE.[1]

DR. H. H. A. BEACH: Dr. Walton has certainly given the subject a most careful investigation. I wish to express my indebtedness to him also for suggesting the method of reduction to which a successful result is due. I do not think that one can appreciate the ease with which such a reduction can be accomplished without seeing it. There is as much difference between the method employed and the ordinary way by extension and counter-extension, which I have commonly used and seen employed in the treatment of spinal cases, as there is between the old way of reducing hip-joint dislocation by the pulleys and that by flexion and rotation. Dr. Walton has cleared up the haze and uncertainty enveloping the directions for reduction prescribed in standard text-books, by his explanation of the mechanism of the articulation and by demonstrating conclusively how and for what purpose the force employed should be applied. An interesting point suggested by my experience in the treatment of this case is the importance of the ligamenta-sub-flava as an obstruction to reduction. Under the complete relaxation afforded by ether, the deformity persisted; eliminating, so far as one case could supply evidence, the muscles as a factor in maintaining the deformity of dislocation. This estimate of the muscles as an opposing force in reduction is strengthened by Dr. Walton's experiments with Dr. Richardson on the cadaver, the muscles having been removed from the neck before producing dislocation.

If the muscles are excluded as the factor in maintaining dislocation, what is there to explain the condition? Only the ligaments are left, as Dr. Walton has stated. Of these it seems to me that we may eliminate those that connect the skull with the atlas, the atlas with the axis, and the latter with the third vertebra, in view of the fact that fractures or dislocations there are inevitably followed by rapidly fatal results. The supra-spinous, the inter-spinous and the inter-transverse ligaments may be excluded, as being imperfectly or barely represented in the cervical portion of the vertebral column, leaving only the anterior common ligament and the posterior common ligament as directly connecting the bodies, and the capsular ligament surrounding the articular processes, the latter permitting the greatest amount of mobility and need not be considered in the matter of reduction. Last of all let us recall the origin and insertion of the ligamenta-subflava, a strong and tough structure composed of yellow elastic tissue, connecting the laminæ of the vertebra above with its fellow, below, and extending from the root of the articulating process of each side to the point where the laminæ converge to form the spinous process. It is rational in the consideration of luxation to admit the importance of so powerful a ligament, which by its close attachment to the roots of the articulating processes holds them firmly together. I must confess that no other explanation so satisfactorily accounts for the firmly locked vertebræ in their misplaced position, even after the patient is etherized; or for the elastic resistance experienced by the operator during the tension necessary for lifting the superior articulating process enough to permit its rotation to the normal position.

In short, the method provides a carefully planned manœuvre, executed without doing violence to the ligamentous structure, and well calculated to lift the articulating process of a dislocated vertebra by leverage about one-third of an inch, after a considerable resistance is perceptible, and by a slight rotation, remedy a dangerous lesion. Even with fracture I should think that if it were done carefully there would be no impropriety in an attempt at reduction.

DR. M. H. RICHARDSON: The work that Dr. Walton has done in this subject is, I think, of great value. Even if this method was tried early in the sixties none of us have been familiar enough with it to apply the principles. Cases of dislocation of the neck are certainly not infrequent. They are certainly as frequent as dislocations of the hip. The results are quite as serious as dislocations of the hip, even where the cord is not pressed upon. In the experiments which were made at the Medical School, as I remember them, I was convinced that the trouble with the former methods of extension and counter-extension was in traction upon the wrong ligament. In the old method of traction on the hip with extension and counter-extension, you pulled on the ligament and had to rupture it. I think the same thing is true in these unilateral dislocations, and for that matter in bilateral dislocations. Certain ligaments were put upon the stretch, and that is one reason why in dislocations there is impaired mobility. The ligament is put upon the stretch, and to reduce it by extension or counter-extension you must tear that ligament in two, whereas if you understand exactly the way in which the bones are locked together, by this manipulation the ligament is relaxed which keeps the bone in position, and the thing is lifted into place with the greatest ease. I believe also that the muscles have a good deal to do in keeping this dislocation unreduced. When the muscles have all been removed, as in the dissecting-room, it is very hard to keep that dislocation unreduced of itself. Of course, the force which produces the dislocation tears the ligaments which bind the bones together in normal position, and to reduce that dislocation these ligaments do not stand in the way. That is the reason why by proper manipulation, by going through reversely the same course by which

[1] See page 553 of the Journal.

the bones got out of place these ligaments do not stand in the way. Even under ether there is always a contraction of the muscles which keep the bones in that dislocated position; and I believe that whatever force is necessary is in overcoming that muscular contraction, and not in any opposition offered by the ligamentous structures. I have seen the method of counter-extension tried. I think that must be Dr. Warren's case that Dr. Walton referred to. I was not aware of any spontaneous reduction. Two or three of us were at one end of this man, and two or three at the other. We pulled as hard as we could, and it produced no effect whatever. This man was discharged, and sent to Tewksbury to die. I think he had pressure on the cord. I saw him some months or years afterwards running an elevator in Jordan & Marsh's. I do not think there was any reduction of the dislocation. He held his head in the same peculiar position afterwards as before. It certainly seems to be our duty in cases of dislocation without pressure on the cord, and in fact even with pressure on the cord, to go through these manipulations. If any one has a clear understanding of the lesion, I do not believe there is danger of doing harm. If you do not understand the condition of the two bones, you will be increasing the amount of displacement and encroaching upon the spinal canal sufficiently to press the cord. I feel very much indebted personally to Dr. Walton for his paper.

DR. G. L. WALTON: The suggestion of Dr. Beach's I think is a very valuable one regarding the ligamenta-sub-flava, and explains what seems rather difficult to explain without bringing into consideration a ligament which is elastic. It is a point that had not occurred to me at all. Dr. Beach and Dr. Richardson have given me a great deal of credit, but both have aided me much in reference to the anatomy of the parts and their relations, and I have to thank Dr. Beach for allowing me to publish this case. I think a great deal of credit is due to the surgeon who has the courage to attempt the reduction of these dislocations. In reference to the case Dr. Richardson has alluded to, I suppose this is the one which Dr. Warren asked me to see and from which my study of this subject dated. This man's head was bent backwards so that the face was pointed upwards, both articular processes having slipped forward. There was such pressure on the cord that he had a spastic gait, clonus, and exaggerated reflexes and numbness up to the chest. He got steadily worse and was finally unable to get about. He was sent to the Convalescents' Home, I think. While there they were giving him a warm bath and pouring cold water down his back at the same time. He experienced a shock like an electric shock and the bones slipped into place, excepting that the head was held somewhat stiffly afterwards; but it was not in the original position. He certainly could not have recovered the use of his limbs unless there had been a reduction.

DR. RICHARDSON: We are not speaking of the same case. The man to whom I alluded did not hold his head up as Dr. Walton has described.

DR. BEACH: I am not quite sure that Dr. Walton referred to Ashhurst's table of twenty-nine cases, which furnish an additional argument for a trial in any case. There were twenty-nine cases altogether, twenty-one of which were successful. Extension was employed in fifteen of the successful cases. Of the eight fatal cases one only had extension.

DR. WALTON: I mentioned the cases, but did not mention that fact.

DR. FRED B. LUND read a paper entitled

A STUDY OF TENDON SUTURE: A FEW CASES OF INTEREST.

DR. RICHARDSON: This subject seems to be one of the greatest interest to surgeons generally and to the general practitioner. I think some of the members may remember the celebrated suit for malpractice many years ago, in which a physician near Lowell was sued for malpractice for not sewing together the tendons. That was long before the antiseptic days and before any tendon suturing could have been performed with much chance of success, an operation depending so much upon aseptic methods. In this case it was contended by those physicians who were willing to testify against their brother practitioner that the tendons ought to have been sutured. All the tendons in the wrist were cut. In the accident-room the house-surgeons are constantly called upon to make this suture, and, as Dr. Lund says, there is no more important thing. Men come in with clean-cut wounds; are practically disabled; the usefulness of the hand is very much impaired. I had considerable experience in tendon suture at first when we were called upon to see these hands; and one of the most successful of the early cases was one that occurred when Dr. Edward Reynolds was house-officer. The woman was leaning on the handle of a bread-knife, the hand slipped and the tendons of the palm were cut off. I sutured the flexors (superficial and deep) of the palm of two fingers and a half. The result was very gratifying. The repair of tendons where is loss of substance is interesting. In all secondary sutures the contractions of the flexor bellies or the muscular bellies cause a wide separation, and in some instances the tendon is destroyed by the accident. A day or two ago, I had a case in which a young man had one of the flexors cut, with the median nerve and one or two muscles. I split the tendon and turned down. The great difficulty in that was caused by the same cause that we have of difficulty in suturing, that is, that the parallel fibres of the tendon are very easily separated, and you cannot get any longitudinal pull except by some such method as described, but this made a very satisfactory lengthening of the tendon, although no force could be applied at the point where the reflection was made. I have always used silk and I suppose that is one of the best methods of suturing. I have had considerable experience with this, and there is nothing so satisfactory as a clean tendon suture, and I do not know of any subject of more practical importance than this. Take this young man, who was practically disabled without a tendon suture; the physician where this happened merely brought the wound together, and the whole palm and the wrist was a mass of cicatricial tissue, and in the midst of the cicatrix were the ends of the median nerve. I referred this case to Dr. Walton for study. He advised immediate liberation of the nerve, and we made suture of the nerve and of the tendon. I feel very much encouraged in the prognosis from what Dr. Lund has said. I should not expect any return of sensation for a long time. I think that every one ought to be familiar with these methods of suture, especially in general practice in manufacturing towns.

In the case just mentioned there is motion in the fingers, but I think it is done by the interossei. An-

other thing that occurred to me is that a good deal of the motion in the hand in the successful cases must be aided very materially by the great development of the interossei. You can get very good extension of the interossei, of course aided by the lumbricales. The operation referred to was done only Saturday.

DR. H. O. MARCY: It is a pleasure to listen to such an exhaustive and carefully-written paper upon a subject of much importance. The coaptation of the divided, separated ends of a tendon is often difficult, because the transfixing suture tends to split the parallel fibres held together only by the cement substance, and will permit of very little tension. I have advised the following method as possessing advantages over any which has come to my knowledge: The divided ends having been brought into view, with a fine tendon suture — for this purpose much to be preferred to silk or catgut — fix the side of the retracted tendon with a loop knot, at a little distance from its division. Then insert the needle into the opposite end of the tendon at right angles to its long axis, and when the ends of the tendon have been approximated, fixing the suture by a half-reef knot. This is repeated one or more times as may be deemed desirable. A continuous fixation suture thus applied with a fine, round needle, minimizes the damage to the tendon, holds it securely in its grasp; and when impossible to make complete coaptation, it serves as a ladder to bridge the gap with material of identical histological structure. It remains also unchanged for a much longer time than catgut.

CANCER OF THE UTERUS.

DR. M. H. RICHARDSON: This uterus I removed yesterday from a comparatively young woman for marked cervical disease. She had been suffering for some months with the usual symptoms of cancer. Early this summer I curetted and cauterized the mass with great care, preparatory to an extirpation of the uterus. She was so much improved by this operation that she returned home, and did not present herself for the more radical operation until two days ago. There was an extensive ulceration of the cervix, with thickening. No metastases could be discovered.

The patient was prepared for a combined abdominal and vaginal hysterectomy. After making the vaginal cut, the uterus was found to be so movable that I finished the operation by that route. The whole operation took ten minutes. The broad ligaments were easily, and apparently securely, tied. Great care was taken not to infect the abdominal cavity, and the parts were irrigated and cleansed most thoroughly after the operation. She rallied from the ether well.

During the afternoon and evening she showed signs of internal hæmorrhage. The pulse gradually rose to 120. In my absence, Dr. Scudder was called. Before he got there the pulse had risen to 160, and there was a subnormal temperature. He removed the packing and found a continuous ooze from the left side. The lower abdomen was freed of blood clot and fresh packing put in high up above the wound into the abdomen. No vessel of any size could be found and no ligature could be applied.[2]

This — the chief danger in a hysterectomy by the vaginal route — has never happened before in my experience. At the close of the operation the wound was perfectly dry, the ligatures were tight, and the case looked as promising as any that I have ever had. In a few hours, in spite of all the care that had been taken, the patient passed from a condition of comparative safety to one of the utmost danger.

In the past four weeks I have removed the uterus, for various causes, six times. In every case I selected the abdominal route. All the cases were septic — either from ulcerating cancer or from a sloughing fibroid. The dissection was carried on — the patient being in the Trendelenberg posture — with the greatest ease. The floor of the pelvis was covered, after the removal of the uterus, by sewing the peritoneum together with a continuous Lembert stitch. All recovered without complications.

It seems to me that, on the whole, the abdominal route is preferable in most cases of hysterectomy.

This specimen shows the great limitations of this procedure in cancer. The disease has been removed by a very narrow margin — a margin that would seem utterly inadequate in cancer of the lip or cancer of the breast. In spite of the advanced stage of this disease, there was no evidence of infiltration in the broad ligaments.

DR. MARCY exhibited a cancerous uterus of extraordinary size removed by vaginal hysterectomy. The specimen possessed additional interest because of the enlargement of the right Fallopian tube, which was distended with a dark-colored fluid, and where it presented in the wound resembled a loop of small intestine. The removal had been effected with the unopened tube still attached to the uterus.

TUMOR OF THE PAROTID.

DR. RICHARDSON: This specimen shows macroscopically the characteristic appearances of the more common parotid tumor — myxochondroma. Clinically, the case presented features of great interest. The patient, Mrs. T., a woman fifty-four years of age, had had for about two years a swelling in the left parotid region. There had been no pain, except an occasional pressure symptom in parts remote from the tumor. The general health had been very good. The tumor presented itself below the left ear, at the lower angle of the parotid. From this point it extended inwards, half filling the pharynx. She was sent to me with the diagnosis of cancer, and the case was supposed to be inoperable. The irregularity and hardness of the mass suggested strongly to my mind a cartilaginous tumor; but the more I examined it, the more uncertain seemed both the diagnosis and the possibility of its removal.

This morning, under ether, I cut down upon the mass, and found it — to all appearances — an enchondroma. It was distinctly encapsulated, and extended behind the angle of the jaw well into the pharynx, pressing upon the tonsil. It was attached superiorly to the pterygoid plates of the sphenoid; posteriorly it pressed upon the styloid process. The mass was enucleated without difficulty, and with very little hæmorrhage. Great care was taken not to injure the facial nerve, though I had told her that, on the chances, it would be impossible to avoid total facial paralysis. The facial nerve was exposed during this operation, and held one side, and apparently is uninjured. The tumor itself was friable, and came to pieces in its enucleation. In parts it is distinctly cartilaginous; other portions suggest a myxomatous condition.

Dr. Councilman, on seeing the tumor, without knowing its origin or history, at once pronounced it a

[2] The patient has made an excellent recovery (four weeks after the operation), and is about to be discharged from the hospital.

myxochondroma of the parotid. This opinion has been verified by microscopic examination.

DR. MARCY: Dr. Richardson's cases are of much interest. I would like to ask him, or any member of the Society, the explanation of the very high temperature which occurred in a case recently operated upon. An enormous pus-tube was everywhere adherent — to bladder, intestine and pelvic walls. It probably contained nearly a quart of very offensive pus, and unfortunately broke on removal. The utmost care was exercised in cleansing the pelvic basin, and a packing of iodoform gauze was applied. Soon after being placed in bed the temperature was 102°+, and it rose steadily to 108°+ before her death, which occurred in thirty hours. The pulse was small and frequent; little pain; mind clear and active to the last. The autopsy, as might have been expected, showed no evidence of peritonitis. Time for septic poisoning by germ development was wanting. Why the remarkable elevation of temperature?

Dr. Marcy also reported a case of

REMOVAL OF FOUR INCHES OF THE RECTUM FOR CANCER: ANASTOMOSIS BY MEANS OF THE MURPHY BUTTON.[2]

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

STATED MEETING, November 21, 1893, CHARLES E. QUIMBY, M.D., chairman.

DISCUSSION ON THERAPEUTIC INSTABILITY, ILLUSTRATED BY PNEUMONIA AND TYPHOID FEVER, WITH SPECIAL REFERENCE TO DIETETICS AND SPECIFICS, CARDIAC AND GENERAL STIMULANTS, AND ANTIPYRETICS.

The discussion was opened by DR. WM. L. STOWELL, who read a paper entitled,

STATEMENTS IN LEADING WORKS ON MEDICINE OF THE PAST TWENTY-FIVE YEARS.

DR. WM. H. DRAPER said he did not think the changes in treatment described in the paper just read were really as great as one at first sight might suppose. If we were to crystallize the various opinions expressed by the different authors referred to, we should find that while the means employed were numerous, the principles involved were very few. Instability was, perhaps, rather an opprobious term; yet it would certainly have been very unfortunate if there had been stability in the matter of therapeutics, since instability represented progress.

As regards pneumonia and typhoid fever, it was doubtless within the recollection of many of those present that pneumonia was considered a purely inflammatory disease; so that the older practitioners treated it by bleeding, purging and sweating. In the same way typhoid fever was looked upon as an affection in which the intestinal lesion was really the important and essential feature, and it was therefore treated with remedies intended to exorcise the disease from this part. The great revolution in therapeutics which had come about within his recollection, was based on a study of the pathology of the disorders in question. This determined the fact that both pneumonia and typhoid were essential fevers of limited duration which ran their course in a definite period. Therefore, they were now treated symptomatically. While it was true that we could not abort or "cure" them, their whole treatment was revolutionized. He did not mean to say that during all this time many so-called specifics had not been brought forward and tried. The great revolution in the treatment, however, was due to the knowledge that had been acquired of the natural history of these diseases, rather than to any essential specific method of dealing with them. He believed that they were treated much more successfully than was the case thirty years ago, simply for the reason that they were now allowed to run their course without any damaging interference on the part of the medical attendant.

He did not think that in our time we should meet with any specific for either pneumonia or typhoid fever. The researches of scientific men in regard to the germ theory up to the present time did not offer any such hope. If we even did succeed in finding a specific treatment, it would doubtless be based on bacteriology, but thus far no agent for destroying the disease germs had been discovered which would not also destroy the life of the patient if employed in such a way as to accomplish the former result.

In regard to the matter of dietetics, no special changes had come about within the last four years. The revolution in this field had taken place before his time, in the days of Graus and Stokes. When the former expressed the desire that the words "He fed fevers" should be inscribed upon his tomb-stone, he struck a note which at once resounded throughout the civilized world, and everywhere met with a warm response. It seemed to him, however, that for a number of years after the time of these great men the pendulum had swung too far in the other direction. Murchison was, therefore, correct in stating that fever patients were, as a rule, overfed. In our desire to sustain the strength, we frequently give more nourishment than could be assimilated. The introduction of milk as a food in fevers was a great improvement on the old beef-tea diet. As Flint said, beef-tea was perfectly worthless, except to supply the system with fluid. It was a well-ascertained fact that albumen was not well digested by fever patients. It was not best, therefore, that we should give them albuminoids to any extent. He felt sure that every one present had at times observed difficulty in the digestion of milk, on account of the albumen which it contained. In the febrile condition it was utterly useless to attempt to give any amount of albuminous food. Fatty matters, cream and the sugar of milk, with sufficient water, were much more satisfactory. One of the greatest improvements that had been made of late years had been the establishment of milk laboratories in New York and Boston, for which we were indebted to Dr. Rotch, of the latter city. From these could be obtained for infants and invalids milk with a diminished percentage of albuminoids, the preparation of the milk being varied in different cans according to the prescription of the physician. During the continuance of the fever we could not expect to nourish the albuminous tissues.

Dr. Draper went on to say that there was another point in regard to which his experience did not show any very great variability. When he entered Bellevue Hospital, enormous quantities of alcohol was given to fever patients, although one, at least, of the attending physicians, the late Professor McCready, did

[2] See page 561 of the Journal.

not sanction this practice, always protesting that it was "a great waste of good whiskey." At this time it was very common to administer from a pint to a pint and a half of this stimulant in the twenty-four hours to those suffering from typhoid and typhus fever, particularly the latter. As with the matter of feeding, so he believed that there was over-stimulation in those days. Murchison laid down some very good rules in regard to the use of alcohol in fevers, but he did not think they were any better than those of Stokes, which he had always found admirable in practice. So long as alcohol diminished the frequency and improved the force of the pulse, so long as it rendered the tongue less parched and dry, so long as it diminished subsultus and delirium, there could be no question that it was doing the patient good. But when it seemed to increase the frequency of the pulse, to render the tongue dry, and to increase cerebral excitement, it was causing mischief. This mischief was explained by the fact that an excessive quantity of stimulus was being given; the alcohol circulating in the blood as alcohol, and not being consumed. There was always an active controversy going on as to whether alcohol was a food or merely a stimulant; but when we found that a patient was taking a pint of whiskey in the twenty-four hours, and yet no odor of it whatever was perceptible in his breath, it certainly looked to him as if the alcohol must be consumed, or at all events gotten rid of very quickly by the system. It was either split up and consumed, or else was eliminated by the kidneys and skin with such rapidity that it did not intoxicate the individual.

DR. A. A. SMITH said that he wanted to have more hope than his friend, Dr. Draper, in regard to the successful treatment of pneumonia and typhoid fever. He had passed from the time in his very early practice when he learned that there was those who believed that the course of these diseases could be shortened. Now we knew that this was impossible. At the same time, he believed that the time would come when we would be able to shorten them, though not by destroying the germs giving rise to them. Recent investigations founded on Koch's discovery of tuberculin, (although the latter, used in the way in which it was had proved a dismal failure,) seemed to indicate this. His memory or experience did not go back as far as Dr. Draper's; but of all the remedies which were in use when he commenced to practise, twenty-two years ago, alcohol was the one, *par excellence*, which had held its own. At the time to which he referred, it was given unstintedly from the beginning to the end, and its administration was largely a question of how much of it the patient could hold. At Bellevue Hospital, as at the period mentioned by Dr. Draper, alcohol was used as the standard treatment. More recently there had been a change in this respect, and he would venture to say that, while it was perhaps given in as many cases at the present time, it was prescribed in much smaller quantities than formerly. From his personal observation, therefore, he would place it first among tonics and stimulants.

The second place in this respect he would give to opium, and particularly in the treatment of pneumonia. He placed it among tonics and stimulants because he believed that was where it truly belonged. If it were an agent acting alone upon the heart, it could hardly be classed among them; but if we regarded it from the standpoint of its action on both the nervous system and the heart, opium would be found to hold an important place as a tonic and stimulant. Especially was it valuable in pneumonia if there was much pleurisy present, with considerable pain and a great deal of disturbance of the nervous system, and if the cough was troublesome. It gave the patient an opportunity to oxygenate his blood. It should not, however, be used in too large quantities or for too long a time.

As to quinine, when he was an interne at Bellevue Hospital he was instructed by the visiting physician to give, as a rule, from sixty to eighty grains a day to patients suffering from pneumonia, and was taught that it acted as a heart tonic and nervous stimulant, sustaining the patient, reducing temperature a time, and shortening the disease. In many cases he believed that these large quantities of quinine did shorten the disease, though it was only by shortening the patient's life. Of course, a large number of the patients recovered, but he had no doubt that it was in spite of, and not on account of, the good effect of the remedy. He would venture to say that no one at the present time would think of giving eighty grains of quinine a day in a case of lobar pneumonia to-day. In small doses, however, (say from six to eight grains a day,) it was an efficient tonic and stimulant, and still held a useful place in our armamentarium.

Ammonia. — Twenty-two years ago the preparations of ammonia occupied a prominent place in the treatment of pneumonia. Following the lead of Richardson, who claimed that they lessened the coagulability of the blood, our medical men gave carbonate and muriate of ammonia freely to every patient. Whether they did good or not, he was impressed with the fact that these agents almost invariably produced disturbances in digestion. At the present day they were not used nearly so much as formerly. There was one preparation of ammonia, however, which was not open to the same objection, and which often acted very well, namely, the aromatic spirits.

Digitalis. — Digitalis was not so much used as formerly. It held its place well for a number of years, and then lost ground. At the present time, however, it seemed to be again gaining in favor. Personally, he employed it more than he did twelve years ago, but not to as great an extent as he did twenty years ago. As to convallaria, it had flashed out brilliantly for a short time; but its day had gone by. Strophanthus was not equal to digitalis as a tonic and stimulant, but was still used by many practitioners. There was a doubt in a good many minds, however, whether either strophanthus or digitalis was ever called for in typhoid fever or pneumonia.

Strychnia. — This was one of the best, if not *the* best, heart and nerve tonic on our list of drugs. Twenty years ago it was scarcely used at all; but it now occupied a very prominent position. Along with strychnia there was another agent which deservedly held a very high place. Glonoin had of late grown in favor in the treatment of pneumonia. There was much diversity of opinion in regard to it, and it was exciting a considerable amount of discussion; but it seemed to him destined to hold its place.

Baths. — It was only within a few years that baths had become so popular in this city and country, and he thought that they properly came under the classification of tonics and stimulants. He was glad to agree with those who were enthusiastic as to their efficacy, and believed that where they were employed the ordi-

nary tonics and stimulants were not nearly so much called for as otherwise.

The ethers and camphor had not held their own at all, although ether might occasionally be used with good effect in an emergency. If oxygen was classed among the tonics and stimulants, it was only because it acted in the capacity of these in an indirect way. Twenty years ago it was much employed. Then it fell into disuse, and now again was gaining in favor.

DR. ALFRED L. LOOMIS was to have treated of the subject of Antipyretics, but was prevented by illness from attending the meeting.

DR. GEORGE L. PEABODY spoke on the

ACCEPTED TEACHINGS OF TO-DAY.

In regard to pneumonia, he said he thought that we had entirely a matter of intelligent, expectant and symptomatic treatment. There was no routine treatment that could be applied to any considerable number of cases, because the cases varied so greatly in character. For the treatment of the cough in some patients, inhalation of chloroform in small quantities was found beneficial. Five or six drops were enough for this purpose, in a wide-necked bottle covered with cotton. By this means the reflex irritability of the pharynx was not infrequently relieved. Inhalations of the hot vapor of water were also valuable in alleviating cough and loosening and promoting the discharge of matters from the upper air-passages. While some patients were greatly annoyed by coughing, others obtained relief only by this means.

Pain often called for treatment. In the minds of many practitioners, however, there was a bitter prejudice against the use of opium and its alkaloids in pneumonia. This, no doubt, had its basis in the old idea that these agents depress the respiratory centres and were therefore contraindicated. He knew of one very prominent physician, of large hospital and private experience, who was especially outspoken in opposition to the use of opium in any form and would not prescribe even the one-sixteenth of a grain of the drug in a cough mixture. Personally, however, he believed that we were amply justified in giving one-sixth of a grain of morphia subcutaneously, as circumstances required, provided the patient was carefully watched. Occasionally, the pleuritic pain was readily relieved by external applications of heat or cold. Both heat and cold seemed to act equally well in this respect, and this was, no doubt, because they both produced very much the same effect locally.

For the relief of insomnia we frequently had to resort to the use of hypnotics, and here he preferred the use of such agents as sulphonal to opiates.

Dyspnœa, if not due to involvement of a very large amount of lung tissue, but to venous congestion, could often be successfully relieved by the temporary withdrawal of blood from the parts by means of ligatures placed upon both the upper and lower extremities. These could be allowed to remain with perfect safety for from an hour to an hour and a half. Of course, if the urgent symptoms were due to very extreme involvement of lung parenchyma, such ligatures were of little or no value. Under these circumstances came in the efficacy of oxygen; but except such a condition were present, he did not think the use of this agent was called for.

Stimulants alone were often of great service. Among these caffeine ranked high, but it was important that we should have a reliable preparation of the drug. Most of the citrates of caffeine sold were worthless, and he therefore advised that caffeine itself should be used. It was true that caffeine was insoluble in water, but it was readily soluble with citric acid, and under the circumstances it was best for the physician to make his own solution.

In croupous pneumonia, hyperpyrexia should be treated exactly as in typhoid fever, namely, by means of cold baths after the Brandt method. With a temperature of from 103° to 105° it was perfectly satisfactory to put the patient in a bath of 65° every three hours, if necessary, and frictions to the body could be more thoroughly applied in pneumonia than in typhoid fever, for the reason that in the former it was not necessary to spare the abdomen. Sponging was of much less value. The use of antipyretic drugs he believed to be absolutely unjustifiable in pneumonia, that is, if given for the purpose of reducing the temperature. It was true that in a strong, robust patient such agents as phenacetine might occasionally be used with advantage; but they should never be given in antipyretic doses. In this disease it was important that the heart should be sustained in every possible way, and it should be urged that the patient be kept constantly in a recumbent position.

The food should be simple and nutritious, and nothing was better than some form of milk, predigested or fermented. As regards stimulants, alcohol was better than anything else. Digitalis, while inferior to alcohol, was still a serviceable agent, and it was a matter of some importance to know that we now had a perfectly reliable preparation of that drug in digitalin. The dosimetric method of medication, recently introduced from France, was now used to some extent in our hospitals. It was the practice to administer one one-hundred-twentieth of a grain of aconitin, one sixty-fourth of a grain of digitalin, and one one-hundred-thirtieth of a gram of arseniate of strychnia every hour, as long as the pulse remained above 100. When he commenced the use of this treatment he felt convinced that his pneumonia patients were materially benefited by the remedies employed, but more recently he had been so frequently disappointed in the results obtained, that he did not now employ the dosimetric system as much as before.

As to drugs in the treatment of typhoid fever, the modern teaching was practically this, the fewer the better. The systematic cold bath, as prescribed by Brandt, he believed to be rapidly superseding all other methods of treatment, and in his opinion it was worth more than all the other means employed in the last twenty years. He wished to say, however, that he did not think the matter of intestinal antisepsis as yet a finished chapter, but still hoped that something would come of it. Of course, we could not expect to destroy the germs in the intestines and elsewhere, but whether it might not be possible to antagonize the septic alkaloids resulting from them was still an open question. Some time ago he had treated quite an extensive series of typhoid fever cases by means of beta-naphthol and resorcin, and the results seemed so satisfactory that he was inclined to believe that an important advance had been made; but when he came to compare his results with those of other physicians who had not employed either of these agents, he found that they were equally satisfactory, and he was therefore forced to the conclusion that the success noted was due, not

to the remedies employed, but to the comparatively mild character of the disease prevailing at that time.

DR. SIMON BARUCH said that the stability of a remedy must be judged by the length of time in which it had been in use. He found that some of the remedies which had been most highly commended by the speakers this evening were mentioned by Hippocrates. These were the hygienic remedies, dietetics and baths. In fact, they were the only ones thus commended which were to be found in the writings of Hippocrates.

Recent Literature.

The Meaning and the Method of Life: A Search for Religion in Biology. By GEORGE M. GOULD, M.D. New York: G. P. Putnam's Sons. 1893.

"One of the saddest things in man is his willingness to be ignorant and incurious of the mystery that he is, and by which he is surrounded. . . . All things are divisible into living and lifeless things. To identify matter and the living intelligence shown in every cell and organism by any system of theology or materialism is to do violence to logic."

These extracts from the introduction suggest the lines of thought into which Dr. Gould leads the reader. Dr. Gould is a thorough physiologist, too thorough, we suspect, to be readily followed by non-medical philosophers; and he is certainly too thorough a metaphysician to be easily followed by most medical men. In spite of this the book is fascinating, and will be especially so to those whose religious belief, or whose atheism does not force them to disagree with the reasoning from the start. The key-note of the method and meaning of life lies in a God who is not omnipotent, whose manifestation appears in life, and whose implement is the living cell. Belief in an omnipotent and absolutely good God leaves, to many minds, much unexplained in science and in religion. Dr. Gould's Biologos, or God working through the cell, shows unbounded goodness and love and beauty. He encourages every thing good and combats every thing bad. Badness, when it occurs, is contrary to his wish, but beyond his control. He has no power over matter except indirectly through his living structures.

It is impossible for us to enter deeper into the book without being urged on still farther. We recommend it to our readers with the belief that they will find much in it worthy of thought.

Hand-Book of Public Health and Demography. By EDWARD F. WILLOUGHBY, M.D. London and New York: Macmillan & Co. 1893.

Solomon's often-quoted aphorism, "Of making many books there is no end," applies with unusual aptness to the numerous works upon public hygiene which have been published within the past two years. This recent work by Dr. Willoughy, is one of the better books of its class, and in its main points constitutes a trustworthy and valuable hand-book. The author's classification is as follows: The health of man, embracing dietetrics, clothing and personal hygiene, habits, exercise and rest; the health of the house, including air, warmth, light, ventilation and general sanitary arrangements; the health of the city, including water-supply, disposal of refuse and excreta, river pollution, and disposal of the dead; the health of the people, treating of preventable diseases, school hygiene and health of the workshops; demography; meteorology. An appendix is added, containing a digest of English health laws, with the metric system and other useful tables.

The author's classification is worthy of careful study, and suggests the fact that the present system in use by English-speaking physicians generally, has outgrown its usefulness and should be revised to conform to the progressive teachings of medical science.

The chapter upon demography is especially clear and concise, and will be found very helpful.

Treatment of Sterility in the Woman. By DR. DE SINETY. Translated by E. P. HURD, M.D. Detroit: George S. Davis. 1893.

This number of the "Physicians' Leisure Library" gives to the profession De Sinety's well-known treatise on sterility. It is a very satisfactory presentation of the subject, and gives all the well-recognized causes of sterility and their treatment. In spite of the numerous causes which are undoubtedly operative in this condition, the fact remains that there are many cases where no cause can be found. There is no question that in time we shall know more about these obscure cases, and it was hoped that Dr. Sinety might throw some light upon them, but he fails to do so.

The book is interesting and instructive reading.

Zur Lehre Vom Luftwechsel. Von DR. GUSTAF WOLFFHÜGEL, Professor and Director des hygienischen Instituts an der Universität Göttingen. Munich, 1893.

Professor Wolffhügel very justly dedicates this monograph of seventy-five pages to Pettenkofer, upon the occasion of the latter's recent jubilee, and takes occasion to say in the opening chapter that Pettenkofer's work upon ventilation, for many years out of print, leaves but little to be said upon the subject.

The principal chapters are devoted to the problem and the object of ventilation, the examination of the air of inhabited apartments and the calculation of the air-supply. The book is especially rich in its quotations from the best modern authorities upon ventilation.

Outlines of Practical Hygiene, adapted to American Conditions. By C. GILMAN CURRIER, M.D. Pp. 468. New York: E. B. Treat. 1893.

In this excellent treatise the author states that his "dominating principle has been to maintain a judicial attitude in every detail, allowing no scope for vagaries. Accepted truths alone are incorporated in its chapters." The book is devoted to the principles of public, and of personal, hygiene, and the author shows himself to be thoroughly conversant with foreign as well as American literature upon the subject.

The illustrations are mostly new and well selected, and the book may be commended as a safe and ready hand-book for the health-officer, the general practitioner and for all persons who desire concise and well-expressed information upon this subject.

A Manual of Diseases of the Ear. By GEORGE P. FIELD, M.R.C.S. Fourth edition. Philadelphia: Lea Brothers & Co. 1893.

Mr. Field's fourth and enlarged edition comprises three hundred and seventy-one pages; nineteen colored plates, chiefly views of the external auditory canal and of the membrana tympani and middle ear, as seen through a speculum; sixty-seven wood-cuts in the

text; and a double index of authors and of subjects. The book is intended as a reference hand-book for the practitioner, and devotes but forty-one pages to the consideration of the anatomy and physiology of the ear, the remaining chapters being in the form of clinical lectures, with quotations of illustrative cases occurring in the author's practice. To the subject of osseous tumors of the external auditory canal, a chapter of twenty-seven pages is devoted, with a tabulated record of operative results; and twenty pages are given to diseases of the auricle. The chapters on acute and chronic non-suppurative disease of the middle ear include sixty-six pages, and those on suppurative disease and its results, eighty-one pages. The mention of operative procedures in this connection, especially of the mastoid operation, except as they occur in the report of cases, are very short. The chapter on the value of pain as a symptom of ear disease, is both readable and suggestive. The remaining chapters, on diseases of the internal ear, include a *résumé* of the author's observations on the use of pilocarpine.

The Mastoid Operation. By SAMUEL ELLSWORTH ALLEN, M.D. Cincinnati: Robert Clarke & Co. 1892.

This book of one hundred and eleven pages is an excellent review of the subject of mastoid operations as defined by Schwartze, to whom the author gives this credit in his preface. The first part, comprising twenty-nine pages, is historical, beginning with the first recorded operation by Johannes Riolanus in 1649, and terminating with the latest contribution of Stacke in his method of opening the mastoid antrum. The anatomical portion, comprising twenty-five pages, is illustrated by five good plates of section of the temporal bone and is clear and direct in its descriptive text. The remainder of the book gives the pathology of the subject very briefly, and the method of operation, as taught by Schwartze, more at length; and this is followed by a description of the operation of Stacke. The work is to be commended for the spirit in which it was undertaken and for its value as a careful record of observations.

Text-book of Normal Histology. By GEORGE A. PIERSOL, M.D., Professor of Anatomy in the University of Pennsylvania. 8vo, pp. xviii, 439. Philadelphia: J. B. Lippincott Co. 1893.

This beautifully printed and illustrated volume deserves a cordial welcome, as a very valuable compendium of histology, which is so well done, except in regard to the accounts of the course of the renal tubules and of the uterus, that there is little opportunity for unfavorable comment. It ought at once to take its place as the accepted standard manual of the subject. It is pervaded by that freshness, which is won only by those authors who have a first hand mastery of the subject. The great pains taken by the author is especially evidenced by the numerous and very accurate figures, with which the pages are crowded. These figures preserve well the natural appearance of the preparations, and will, therefore, be far more useful than the crude illustrations, which have marred many of the best English text-books, to perplex and discourage students and others. In an appendix there is given a judiciously selected collection of the most useful methods.

We can thoroughly recommend Dr. Piersol's treatise and hope it will have a large sale.

An Elementary Text-Book of Biology. By J. R. AINSWORTH DAVIS. Two volumes, 12mo. Part I, Vegetable Morphology and Physiology, one volume, pp. 287. Part II, Animal Morphology and Physiology, pp. 405. London: Charles Griffin & Co., Lim't. 1893.

This excellent work describes, with a view to laboratory study, a series of typical plants and animals, following the method of practical instruction which has done so much to elevate biology as an educational discipline. The selection of types is good, the descriptions are clear, and there is a good deal of general information included; so that a student who had worked carefully through the two volumes would possess the foundations of a general knowledge of biology. The illustrations and press-work also deserve praise. It is an objection to the manual that too much space is devoted to the lower types. The work is especially designed for college classes.

Heath's Practical Anatomy; A Manual of Dissections. Eighth edition. Edited by WILLIAM ANDERSON, F.R.C.S. With 329 engravings on wood. Philadelphia: P. Blakiston, Son & Co. 1893.

Mr. William Anderson has given another proof of his merit as an anatomist by his excellent editing of this well-known work. He has improved it by taking out as well as by adding, and yet the physiognomy of the book remains the same. The omission of histology, which was not only antiquated but out of place in such a work, is something to be thankful for. Excellent diagrams have been introduced, and frozen sections are coming into favor. T. D.

Der Bau des Menschen als Zeugniss für seine Vergangenheit. [*The Structure of Man as Witness of his Past.*] Von DR. R. WIEDERSHEIM, Prof. an der Universität Freiburg. Zweite umgearbeitete und stark vermehrte Auflage. Mit 190 Figuren in Text. Freiburg und Leipzig: J. C. B. Mohr. 1893.

This second edition of a remarkable publication is considerably larger than the first, and has many illustrations. Its merits and defects are of the same nature as in the former edition, which was well characterized by a distinguished anatomist as "exhaustive but not critical." Every part of the body is in turn called upon to show its normal structure, its embryology and its variations, its close resemblance and analogies to corresponding parts throughout the animal kingdom. As a monument of anatomical learning the work deserves the highest praise. It is to be strongly commended to every anatomist as a most useful book of reference. Philosophically the work leaves something to be desired. It proves clearly enough the essentially animal nature of man's *body*, but then no one nowadays questions this, and to harp on it too long is

> "Thrice to conquer all one's foes,
> And thrice to slay the slain."

But when it comes to understanding why or how certain anomalies appear in man we are left in the lurch. The author appears to be satisfied to prove that these are normal in certain animals. This is hardly satisfactory if some of these animals are on side lines and can by no possibility have been in the line of descent. It seems more and more necessary to invoke some as yet unknown law to account for what may be called cross-relationships. In other words there are phenomena not to be explained by heredity. T. D.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 7, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE TWENTY-FOURTH ANNUAL REPORT OF THE MASSACHUSETTS STATE BOARD OF HEALTH FOR THE YEAR 1892.

THE successive reports of our State Board of Health mark a progressively increasing interest in matters of public health which is most satisfactory in its results. Weekly returns from sixty per cent. of the population of the State are now received at the State House, reporting causes of death, temperature-variations, etc., for each locality; and seventy-three local boards of health, representing seventy per cent. of the population, report annually cases of illness and deaths, and record all sanitary needs and improvements. In 1892, the ratio of deaths to reported cases was from diphtheria, 29.24; scarlet fever, 4.60; typhoid fever, 22.99. In 1891, the mortality was, respectively, 23.5, 3.34, 19.05, as compared with 23.7, 5.8, 20.8, in England for that year. By recent law, all cases of diseases dangerous to the public health must be reported to the State Board of Health by the local boards within twenty-four hours of their receiving notice of them.

Boston records the lowest mortality from typhoid fever of any large city in this country, 2.9 per 10,000 inhabitants, as compared with 17.4 in 1846, before the introduction of a public water-supply, and an average of 3.2 from 1890 to 1892 inclusive, or .9 less than the average from 1885 to 1889. This low average for the last three years the Boston Board of Health attributes to an improved water-supply and to better hygienic conditions. The Board has with commendable zeal at last established a disinfecting station, fourteen years after its importance was urged by the State Board. Its inspection of cattle for slaughter and for export, and its sanitary control of dairies and cow stables have been perfected during the year.

In Bridgewater, scarlet fever became epidemic, and for a while beyond control, by infection through cases so mild as not to be recognized. In Brookline, the local board was petitioned to abate a local prevalence of intermittent fever.

In general, local epidemics of typhoid fever were attributed to bad drinking-water or imperfect drainage, and many polluted wells were condemned; great complaint is made of methods of disposal of swill and garbage of varying degrees of nastiness, with general commendation of the crematory at Lowell; the need of district sanitary inspectors is emphasized; more thorough vaccination is urged; hospitals for infectious diseases are demanded.

In Waltham, an officer was employed to enforce absence of infected children from school, etc., and in East Bridgewater the local board demanded — what should be subject to general law — compensation to men kept from their work, in order to compel quarantine and care of their infected families.

There was an epidemic of fifteen cases of small-pox, with two deaths, in New Bedford, in June; and throughout the year there were four other cases in other towns. Three small outbreaks of typhus fever, from immigrants, were readily controlled. The interstate notification of diseases dangerous to the public health has given prompt information throughout the country of their appearance in any locality.

The 587 exceedingly interesting pages of the Report on Water-supply and Sewerage, under the provisions of Chapter 375 of the Acts of the Legislature of 1888, comprise 71 pages of most valuable advice to cities and towns on water-supply, sewerage and sewage disposal, and pollution of streams, with articles on examination of water-supplies, examination of rivers, summary of water-supply statistics; three papers by Prof. Thos. M. Drown, Chemist of the Board, "On Interpretation of Water Analysis." "On the Amount of Dissolved Oxygen in the Water of Ponds and Reservoirs at Different Depths in Winter, under the Ice," and "On the Mineral Contents of Some Natural Waters in Massachusetts"; two papers by Gary N. Calkins, Assistant Biologist, "A Study of Odors observed in the Drinking-Water of Massachusetts," and "Seasonal Distribution of Microscopic Organisms in Surface-Waters"; "Experiments upon the Purification of Sewage at the Lawrence Experiment Station," by Allen Hazen, Chemist in Charge; "Experiments at the Lawrence Experiment Station upon the Purification of Water by Sand Filtration," by George W. Fuller, Biologist at the Station; "Some Physical Properties of Sands and Gravels, with Special Reference to Their Use in Filtration," by Allen Hazen, Chemist in Charge; "Sewage Disposal of Cities and Towns in Massachusetts by Intermittent Filtration."

The Board concludes, from investigations of artificial ice, that artificial processes of freezing concentrate the impurities of the water in the inner core or the portion last frozen; that the impurities are least if distilled water is used; that the number of bacteria in artificial ice is insignificant, under the prevailing methods of manufacture; and that the amount of zinc found in ice is insufficient to cause injury from its use.

Under the law for food and drug inspection, 5,712 samples of food, including 3,271 of milk, were exam-

ined, of which 1,913 (of which 1,514 were milk) were found adulterated or below the standard. Of 487 samples of drugs, 312 were found of good quality. There were 136 complaints made in court, 123 convictions, and fines imposed of $3,661.70.

Five [1] detailed investigations of epidemics of typhoid fever, with the well-known thorough and scientific methods of Professor Sedgwick, the Biologist of the Board, constitute most interesting contributions to the study of that disease.

Professor Sedgwick's original bacteriological investigations, which proved so conclusive as well as novel, are already familiar to the readers of the JOURNAL.[2] In greater detail and with an excellent series of illustrations, they form the basis of the first paper. In the last, Professor Sedgwick attributes the three outbreaks to secondary infection from one person to another through uncleanly habits.

PREVENTION OF TUBERCULOSIS.

AT a meeting of the Board of Health of the City of New York held November 29th, Dr. Herman M. Biggs, Chief Inspector of Pathology, Bacteriology and Disinfection, made an important report on tuberculosis. It was supplementary to a previous report in regard to the disease submitted by him four years ago in conjunction with Drs. Prudden and H. P. Loomis; as a result of which the Board issued a circular of information and instruction for public distribution. In his present communication Dr. Biggs says: "The time, it seems to me, has arrived when it becomes the duty of all sanitary authorities to assume a more aggressive attitude towards this, the most widely purulent and fatal disease to which the human race is subject, and I desire to present to the Board certain suggestions as to definite means which should at once be taken to prevent and restrict tuberculosis." Before offering these suggestions, he points out the fact that for a number of years the deaths from tuberculosis in New York have amounted to more than five thousand annually, and makes some general observations on the nature of the disease; among which are the following:

It has been shown that many millions of tubercle bacilli may be discharged, under certain conditions, by one person suffering from pulmonary tuberculosis in the course of twenty-four hours. As tuberculosis can only result from the action of these germs, it follows that when the disease is acquired it must result from receiving into the body the living germs that have come from some other human being or animal affected with the disease. While the meat and milk of tubercular cattle may be important sources of danger, yet the disease is acquired as a rule through its communication direct from man to man; the usual mode of infection being the breathing of air in which the living germs are suspended in dust. It follows that tuberculosis, being a communicable, that is, a contagious germ disease, is distinctly preventable. The means which are most certain to prevent its spread are those of scrupulous cleanliness regarding the sputum. These means are largely within the control of the affected individual. It should be constantly kept in mind that it is the sputum, and the sputum alone, which is commonly the important agent in its transmission. It is furthermore to be remembered that consumption is not always, or even generally, as was formerly supposed, a fatal disease; but that in a very large proportion of cases, if recognized early, it is a distinctly curable affection. An individual who is well on the road to recovery may, if he does not with the greatest care destroy his sputum, diminish by self-inoculation his chances of recovery.

The recommendations made by Dr. Biggs are as follows:

(1) That there be systematically disseminated among the people by means of circulars, etc., the knowledge that any tubercular person may be a source of actual danger to his associates and his own chances of recovery diminished if the discharges from the lungs are not immediately destroyed or rendered harmless.

(2) That all public institutions, such as asylums, homes, hospitals, dispensaries, etc., be required to transmit to the Board of Health the names and addresses of all persons who are suffering from pulmonary tuberculosis.

(3) That special inspectors be assigned to duty for the investigation of this disease.

(4) That the Board urge upon hospital authorities the importance of separation, so far as possible, in the hospitals of this city, of persons suffering from pulmonary tuberculosis from those affected with other diseases.

(5) That the Department of Charities and Correction of this city be requested to set apart one of the hospitals under its charge, to be known as "The Consumptive Hospital," to be used for the exclusive treatment of this disease.

(6) That the Board undertake the bacteriological examinations of the sputum for diagnosis in every case of pulmonary disease of doubtful character in hospitals or private dwellings or tenement-houses, where the physician in attendance desires that this should be done.

(7) That all physicians practising their profession in this city be requested to notify this Board of all cases of pulmonary tuberculosis coming under their professional care.

In conclusion, Dr. Biggs says: "For the proper performance of the preliminary work, as detailed above, a special corps of medical inspectors and disinfectors

[1] On Epidemics of Typhoid Fever in the Cities of Lowell and Lawrence, with Observations upon its Existence in Other Cities of the Merrimack Valley, especially in Newburyport, by Prof. W. T. Sedgwick. On an Epidemic of Typhoid Fever in the Village of Chicopee Falls, apparently due to Infected Drinking Water, by G. V. McLauthlin, with a Prefatory Note by Prof. W. T. Sedgwick. On an Epidemic of Typhoid Fever in the City of Springfield, apparently due to Infected Milk, by Prof. W. T. Sedgwick and W. H. Chapin, M.D. On an Epidemic of Typhoid Fever in the City of Somerville, apparently due to Infected Milk, by Prof. W. T. Sedgwick. On Epidemics of Typhoid Fever in the Villages of Bondsville, Provincetown and Millville, apparently due to Secondary Infection, by Prof. W. T. Sedgwick.

[2] Vol. cxxiv, 1891, 397-402, 426-430.

should be provided, whose duties should be entirely confined to work connected with the investigation of tuberculosis, and the carrying out of the means to be taken for its prevention. It is my belief that the New York City Board of Health, which has so often achieved such notable success in the management and control of other contagious diseases, should take the lead in this matter, and adopt measures to meet this new and urgent demand upon its resources."

This report was referred to the Sanitary Committee for its consideration.

MEDICAL NOTES.

A New Medical Prize. — The Alumni Association of the College of Physicians and Surgeons of New York, offers a prize of $500 for the best essay embodying the results of original investigations upon any medical subject. Essays must be sent to the Secretary before April 23d, 1894.

Northwestern Ohio Medical Association. — The forty-seventh semi-annual meeting of the Northwestern Ohio Medical Association, will be held at Toledo, Ohio, December 14th and 15th. The banquet will be given on the second day.

Dr. Truedau's House Burned. — The house and splendidly equipped laboratory of Dr. E. L. Truedau, at his sanitarium at Saranac Lake, New York, were destroyed by fire December 4th, during Dr. Truedau's absence in New York, where he is seriously ill.

Professor Tyndall's Death. — The death of Prof. John Tyndall, which occurred at Hazelmere, England, December 4th, is said to have been hastened by an overdose of chloral.

An Anthropological Prize. — A member of the Anthropological Society of Washington, D. C., has offered two prizes — one of $150 and one of $75 — for the best essays on the subject of "The Elements that go to make up the most Useful Citizen of the United States, regardless of Occupation." The essays, to be of 3,000 words, must be sent to the Secretary of the Society by March 1, 1894.

An Honor to Dr. Jacobi. — The chair of pædiatrics in the University of Berlin, made vacant by the resignation of Professor Henoch, was offered to Dr. Abram Jacobi, of New York, who has declined the honor, preferring to remain an American citizen. This is the first time such a distinction has been offered to an American physician.

An Epidemic of Diphtheria in London. — During the last two months there has been a very large number of cases of diphtheria in London and the death-rate has been unusually high. During the week of November 18th there were 103 fatal cases, chiefly among children under five years.

A Street-Car Ambulance. — An electric ambulance car is to be tried upon the street-car system in St. Louis. The idea was suggested by the City Health Commissioner, Dr. George Homan, and as three of the large hospitals and the city dispensary are situated upon the lines of street railways, a smooth running and rapid means of transportation is expected from the new plan.

The International Medical Congress. — The International Medical Congress which was postponed from September 24th, on account of the prevalence of cholera in Italy, will be held at Rome from March 29 to April 5, 1894.

Cancer in England. — The mortality from cancer is increasing in England. In 1850 there was one death in seventy-four due to cancer; in 1860, one in sixty-two; in 1870, one in fifty-four; in 1880, one in forty; and in 1890, one in 28. There is said to be a similar increase in Scotland, Norway, Holland and Prussia, but a decrease in Ireland.

Twelfth International Medical Congress. — The Russian Government has shown much interest in the meeting place for the Twelfth International Medical Congress in 1896. It desires that Moscow be selected as the city, and promises to donate 50,000 roubles towards the expenses of the Congress.

Immigration and the Quarantine Service. — On this subject President Cleveland says in his annual message to Congress: "The Superintendent of Immigration, through the Secretary of the Treasury, reports that during the last fiscal year there arrived at our ports 440,793 immigrants. Of these, 1,063 were not permitted to land under the limits of the law, and 577 were returned to the country from which they came, by reason of their having become public charges. The total arrivals were 141,034 less than for the previous year. The Secretary in his report gives an account of the operation of the Marine-Hospital Service, and of the good work done under its supervision in preventing the entrance and spread of contagious diseases. The admonitions of the last two years touching our public health and the demonstrated danger of the introduction of contagious diseases from foreign ports, has invested the subject of national quarantine with increased interest. A more general and harmonious system than now exists, acting promptly and constantly operating by preventive means to shield our country from the invasion of disease, and at the same time having due regard to the rights and duties of local agencies, would, I believe, add greatly to the safety of our people." Certainly the work accomplished by the medical inspectors of the Marine-Hospital Service sent to the dangerous ports in Europe this last summer deserves any favorable recognition it may receive.

Abuse of Medical Charity in London. — Much discussion has taken place recently in London regarding the abuse of hospital charity by persons not in need of free medical attendance. The interest in the question has been general, both within and outside the medical profession. Mr. Herbert Spencer says that thirty per cent. of the people of London are frequenters of the hospitals and dispensaries, and that most of them are able to pay their doctors.

"THE FROG." — A correspondent of the *Lancet* writes that among the country folk of Lincolnshire, England, there occurs an infantile stomatitis which is rather common and known as "the frog," from the usual treatment, which consists of giving the child a very small frog in a muslin bag to suck.

THE FIRST MOHAMMEDAN WOMAN PHYSICIAN. — The first Mohammedan woman to practise medicine has recently been given a position under the Russian government. Her name is Miss Bibi-Radya-Koudlouiarow.

A PORTUGUESE PHYSICIAN CONVICTED. — The trial of Dr. Urbino Defreitas, one of the most prominent physicians of Oporto, for murder has just been finished. He was charged with poisoning his nephew and trying to poison his two nieces in 1890, in order that he might inherit a fortune to which they were heirs. Despite the divergence of expert opinions, Defreitas was found guilty, and was sentenced to eight years solitary confinement.

SURGERY AND THE DEMI-MONDE. — A small company of particularly select demi-mondaines, says the *Progrès Medical*, has just instituted a "Dîner des Infécondes," under the honorary presidency of a surgeon noted for the readiness with which he performs ovariotomy. This charming company of patients who have been operated upon meets for dinner each month, the surgeon presiding at the table. The novelty of this form of vicarious menstruation is truly Parisian.

A MEDICAL TRAGEDY. — An especially sad example of the dangers to which physicians are exposed is reported from Presbourg in Hungary. A physician after visiting a patient with diphtheria went home to change his clothes before continuing his calls. On entering the house his little son rushed up to him and before the father could prevent it, had jumped upon him and kissed his face. Two days later the child was taken ill and soon died of septic diphtheria. The father's reason gave way under the blow, and he died after a short illness attended by acute delirium, in which he constantly cried out, "I have killed my boy."

BOSTON AND NEW ENGLAND.

TOYS FOR THE BOSTON CITY HOSPITAL. — Owing to the large number of children at the Boston City Hospital, especially in the scarlet fever and diphtheria wards, there is an especial need of toys for the convalescents. Physicians having private patients recovering from these diseases are reminded that the books and toys which otherwise must be destroyed are very welcome at the hospital for use in the wards for infectious diseases.

FOOT-BALL ACCIDENTS. — The young man who dislocated his neck while playing foot-ball at Farmington, Conn., last month, died during the past week. This makes the fourth fatal case of broken neck from foot-ball this season.

A NEW CITY HOSPITAL FOR FITCHBURG. — The city council of Fitchburg, Mass., has voted to negotiate a loan of $100,000 for the establishment of a city hospital. Some time ago Mr. G. S. Burbank left his entire property, valued at about $400,000, to the city as residuary legatee for the founding of a free hospital. His widow, however, has been very anxious to see the work underway, and the trustees of the will have obtained consent to anticipate the legacy and borrow money for the purpose. The land purchased by the city is centrally located, covers about 400 acres, and was bought for $70,000. The rest of the money above the $70,000 will be applied to fitting up the buildings now on the estate, so that they can be used for the hospital. The present hospital accommodations of the city are a few rooms at the poor farm, which cannot be isolated from the rest of the house.

NEW YORK.

THE NEW WEST SIDE GERMAN DISPENSARY BUILDING. — The new home of the West Side German Clinic and Dispensary on West 42d Street was opened to the public on Thanksgiving Day. The institution was started twenty years ago by Drs. Lampert and Teller, and for the past fourteen years has been located on 38th Street. The cost of the new building, the whole of which is occupied by the Dispensary, has been about $50,000. It is not intended exclusively for Germans, but is open to the deserving poor of all nationalities. Special care is taken by the managers to exclude all those who are able to pay for medical treatment, and during the past year over eight hundred such cases have been turned away. The new building is fitted up with the most approved apparatus and appliances in its various departments, and in its construction throughout, special pains have been taken to prevent the lodgment of disease germs.

Miscellany.

LONG-CONTINUED RECTAL ALIMENTATION.

A CASE of successful, long-continued rectal alimentation is reported in the care of Dr. Maragliano,[1] which certainly meets the objection so often raised, that no real nourishment is obtained from rectal feeding. The patient, a woman, had a circumscribed peritonitis from perforated gastric ulcer. For ninety-four days she was kept continuously upon exclusively rectal feeding. In this time the patient lost but 2,700 grammes in weight. The diet consisted of the following enemata:

Lean beef	300 grammes
Pancreas	150 grammes
Mix well, rub up in a mortar, and strain; then add:	
Water, q. s.	
Carbonate of soda	5 grammes
Fresh ox-gall	25 grammes

This suffices for four enemata a day when diluted with a sufficient amount of tepid water.

CLIMATE OF COLORADO.

DR. C. THEODORE WILLIAMS, in an address before the Royal Meteorological Society, summarizes the chief features of the climate of Colorado as follows:

[1] Le Bulletin Médical, No. 86, 1893.

(1) Diminished barometric pressure, owing to altitude. (2) Great atmospheric dryness, especially in winter and autumn. (3) Clearness of atmosphere and absence of fog or cloud. (4) Abundant sunshine all the year round, but especially in winter and autumn. (5) Marked diathermancy of atmosphere, producing an increase in the difference between the temperature in the sun and in the shade, varying with the elevation in the proportion of one degree for every rise of two hundred and thirty-five feet. (6) Considerable air movement, even in the middle of summer, which promotes evaporation and tempers the solar heat. (7) The presence of a large amount of atmospheric electricity.

FRAGMENTATIO CORDIS.

ACCORDING to a report of Oestreich to the Society for Internal Medicine,[1] fragmentation of the heart is much more common than has been supposed, and can be recognized, not only by the microscope, but macroscopically, by a peculiar friability of the muscular substance. If the fragmentation occurs in any part of the heart more than another, it is always in the papillary muscle of the left ventricle. It is not a cadaveric process, but occurs ante-mortem, as shown by experiment upon animals and the examination immediately after death, of the hearts of criminals who had been hung. It may occur alone or with other affections. He considers it an "agony product," a mechanical breaking up of the primary muscular bundles as the result of the final cardiac efforts. Accordingly, it can in no case be considered during life as an actual disease. It was found especially frequent in cases of sudden death and chloroform poisoning. It is more frequent in old persons than in young, and was never seen in children under one year.

SOURBERBIELLE.

A RECENT number of the *Gazette des Hôpitaux* contains an interesting account of the French surgeon Sourberbielle, who was one of the best known of the jurymen who tried Marie Antoinette. He came of a medical family which boasted at least twenty physicians or surgeons. His grandmother's three husbands were all doctors, and his four uncles were practising surgeons. After receiving his preliminary training from one of these uncles, he was a pupil of Larrey and became noted for his skill in lithotomy, and was given by legacy all the instruments of Pascal Baseilhac. On the outbreak of the Revolution, Sourberbielle entered with enthusiasm into all the political turmoil. In 1789 he was made a surgeon-major of the organized "Conquerors of the Bastile."

He was on intimate terms, both professionally and personally, with Marat, Danton and Desmoulins. Later he sat in complacent judgment upon Danton, and condemned him to death with the quiet remark, "There are two men who cannot live together, Robespierre and Danton: the former is more useful to the Republic, therefore it is necessary to guillotine Danton, *c'est simple comme bonjour!*"

For Robespierre he had the greatest affection, and was for a long time his trusted adviser and physician. Unmoved by suffering and indifferent to the gentler emotions, as a rule, he never spoke of Robespierre's anguish without a shudder.

On the trial of Marie Antoinette his ardent republicanism caused him to be selected as one of the jurors. At this time, too, his cold, hard character seemed to show a little bit of humanity. He called the attention of the convention to the damp, unhealthy cell where the queen was confined as being worthy their pity. Still he voted for her death.

After the restoration, Sourberbielle was made surgeon-in-chief to the Parisian gendarmerie. He was made master-in-surgery in 1792, but did not receive his doctorate until 1813. During the Terror he was health-officer to the revolutionary prisons, and had charge of the medical service in the École de Mars. Later he was made surgeon-major to the imperial police and in the national guard.

His great renown, at this time almost European, was for his skill as a lithotomist, especially in the method *du haut appareil*. He considered lithotrity a reproach to surgery, and had constantly large classes of physicians studying under him his operation of cutting. His hand was so steady that at the age of eighty-two he still operated successfully, and to the day of his death, at the age of ninety, he took an active and polemic interest in all surgical questions.

TEMPERATURE IN GENERAL PARALYSIS OF THE INSANE.

THE statements so generally made that there is a great daily variation of temperature in general paretics have recently been put to the test of careful experiment by Drs. Peterson and Langdon, of New York.[1] Twenty-five well-marked cases of general paralysis were selected from the Hudson River State Hospital for the Insane, and in each case careful thermometric observations were made every two hours for one week. In ten of the cases additional observations were made, for the same length of time, every two to four hours, with thermometers in both axillæ, in order to determine the question of axillary asymmetry. There were a few instances of marked oscillation of temperature. The greatest single day's change was 3.8° Fahr., but the average was much less. The lowest average daily variation in the twenty-five cases was .8°, the highest 2.2°. The total average for all the cases was 1.4°. "The smallest average axillary asymmetry was .13°, the greatest .34°, but among single observations there were many instances of exact correspondence. The greatest single change in any case was 2.4°. The mean of greatest single differences was 1.17°."

They conclude from their observations that:

"(1) As regards the average bodily temperature, we find it to correspond to physiological normes. The statements of our predecessors as to hyperpyrexic or subnormal averages cannot be sustained.

"(2) The diurnal oscillations of temperature in paretics also correspond to physiological normes. The statements to be found in literature as to extraordinary daily variations being frequent in these cases are absolutely erroneous.

"(3) Asymmetrical axillary differences are so small that they cannot be considered as abnormal, and certainly not of any diagnostic significance.

[1] Deutsche Med. Woch., No. 39, 1893.

[1] Journal of Nervous and Mental Disease, November, 1893.

"(4) When unusual variations of temperature occur in general paretics, their cause must be sought for in conditions not related to the pathological phenomena of paralytic dementia, but depending upon thermogenic features unrecognized by the physician, or 'masked' by the mental state of the patient. Thus, in one case of our series, an increasing hyperpyrexia was noted during the second week's observations, but the pneumonia causing it was 'masked' until the fifth or sixth day, the patient dying on the sixth day. Again in another case where the highest single daily oscillation was 3.4° and the average daily oscillation for the week 2.2°, the patient suffered from bed-sores which undoubtedly produced some septicæmia. That variations of temperature may take place in connection with the paralytic and convulsive seizures of these cases we do not gainsay, but have made no observations under such circumstances."

LATE EPILEPSY.

THE occurrence of epilepsy for the first time in the middle and late decades of life has generally been considered of rare occurrence; and Wood even goes so far as to say that the disease occurring after the age of thirty-five is always symptomatic and not a true epilepsy. Delanef and Charcot considered that thirty years was the age, after which epilepsy should be called late; and this time has been generally accepted. Mendel, in a paper read this summer before the Congress of German Physicians, takes exceptions to the views hitherto accepted,[1] and claims that late epilepsy is not uncommon, and that so large a number of cases show signs of the disease for the first time after the age of thirty that he does not consider it right to give the name of late epilepsy until a later age. He bases his statement upon his own cases, 904 in number. Kohler, in 1887, collected 1,352 cases of epilepsy, and found that the first manifestation occurred after the age of thirty in 180 cases, or 13.3 per cent. Mendel, in his own cases, all carefully differentiated from the numerous errors of diagnosis, found that 152 cases, or 18.7 per cent. occurred after thirty. The decade from thirty to forty, especially, showed a greater number of cases; Kohler's figures giving 5.8 per cent., and Mendel's 10.9 per cent. of all cases occurring first in that period. After the age of forty there is a marked decrease in the number of cases, and this age he selects as his dividing line. The oldest patient observed was a woman of sixty-three, though cases have been reported of older persons. The greatest care should be taken in young children to eliminate the convulsive seizures of paralysis and idiocy, and in older persons, especially the epileptic attacks of cerebral syphilitic-dementia or general paralysis.

As regards sex, his figures confirmed the observations of Bennett and Gowers, that males are the more frequently affected. In 53 cases occurring after the age of forty, there were 38 men and 15 women.

The question of heredity becomes more difficult to decide the older the patient is, owing to the absence of family or friends. Still, in one-fourth of his cases, Mendel obtained a clear history of inherited disease; and he does not agree with Nothnagel and Seeligmüller, who say that a person inheriting epilepsy who remains free from the disease to the age of twenty will be free in later years. The taint may be entirely latent for sixty years, and then for the first time show itself. The predisposing causes are many, fright being a not uncommon one. In none of his cases "is syphilis given etiological place, for syphilitic epilepsy is to be distinguished from the genuine form, and can be so distinguished clinically, at least, after careful observation."

His conclusions were as follows:

(1) Cases of epilepsy occurring after the age of forty are to be considered as "late."

(2) Late epilepsy occurs absolutely and relatively more often among men than among women.

(3) Hereditary tendency plays an important part even in late epilepsy.

(4) The course of the disease is, as a rule, milder and less progressive than in youth.

(5) The intellect appears to suffer less in late epilepsy, even after long continuance, than in younger patients.

THERAPEUTIC NOTES.

TREATMENT OF DYSPEPSIA IN CHILDREN. — Tordens, in a discussion of the therapeutics of infantile dyspepsia and the subsequent atonic condition of the bowels, makes four divisions of treatment. (1) Elimination[1] of noxious elements by emesis, lavage (both rarely if ever called for) and catharsis. (2) Anti-fermentative medicines. Among these he includes the various combinations of pepsin, resorcin, salicylic acid. In cases of diarrhœa with markedly green stools he recommends lactic acid in small doses. The following combination he also finds useful:

R	Creosoti	2-4 drops.	
	Aquæ destil.	35.00 grammes.	
	Syr. Altheæ	15.00 grammes.	M.
Sig.	A small spoonful every two hours.		

(3) Sedatives, warm baths and light friction. For colicky pains a mixture of aqua chamomilla, subnitrate of bismuth and syrup of anise often gives relief. (4) Tonics and stimulants for the subsequent atony, of great value are

R	Tinct. Cascarillæ	10 drops.	
	Aquæ destil.	50.00 grammes.	
	Syrup	10.00 grammes.	M.
R	Ext. cort. Chinæ.	0.25 grammes.	
	Aquæ destil.	50.00 grammes.	
	Syr. Aurante.	10.00 grammes.	M.
Sig.	To be given in teaspoonful doses.		

QUININE IN MALARIA. — Sézary recommends the following method of administering quinine, where it is to be given over a continued period of time, as to patients living in a malarial district. It is said to cause no gastric disturbance.

Sulphate of quinine	3 grammes.
White wine	1 litre.
Tartaric acid enough to render the solution acid.	

EPISTAXIS.[2] — Several statements having recently been made as to the efficacy of applying ice to the external genitals in cases of epistaxis, Dr. Schrieber, of Moscow, points out[3] that in an old Russian book — published by an anonymous physician in 1827, and bearing the title, "*Rükovodstvo K, Letchenyü Boleznei Prostymi Sredstvami*" ("Hand-book of Treatment of Diseases by Simple Means"), — the application of cold to the external genitals is recommended as the best

[1] Le Bulletin Médical, 1893, No. 28.
[2] St. Louis Medical Journal, October.
[3] Novosti Terapii, Nos. 25 and 26, 1893.

method for controlling a nasal bleeding. "The patient must immerse his or her genitals in cold water, and keep them therein for a short while."

Correspondence.

"HALLUX VALGUS."

BOSTON, November 30, 1893.

MR. EDITOR: — I am much interested in an article bearing the above title, by Dr. Joel E. Goldthwait, which appears in the JOURNAL of this week. The disease in question is one of the most common and one of the most inconvenient which a surgeon is called to treat; and I sincerely trust that the splint which Dr. Goldthwait describes may prove efficacious for its relief. I am, however, free to say that in an experience extending over a large number of cases, I have not succeeded in obtaining complete and permanent relief from the use of any external or mechanical appliance which I have been able to find or invent.

The greater number of the cases which I have seen have been of aggravated and chronic character, and possibly may have passed the stage in which external treatment could afford relief; and most of the patients have later submitted to operation, with the result of relief from the deformity resulting from the abnormal position of the parts composing the joint, and absolute comfort and ease in the perfect use of the foot; with the addition of what was to me a source of some surprise at first, an apparent restoration of the functions of the joint, that is, a freely movable, firm and useful articulation.

The first application in this country, so far as I know, of the operation described by Dr. Goldthwait, was made by Prof. P. H. Hamilton, of New York, who presented a record of eleven cases thus treated. The article appears in the transactions of the Buffalo meeting of the American Medical Association. In this paper Professor Hamilton recommends a subsequent treatment which required two to three weeks for the cure.

In the New York *Medical Record*, July 30, 1880, I published an account of two cases in which an operation somewhat similar to that described by Dr. Goldthwait was performed upon both feet of the same patient with successful results. In all my cases the diseased and distorted head of the bone was entirely removed. Since that time I have had quite a large number of cases of this disease, in one or two of which the inflammation of the soft parts had become so extensive that the skin over the joint had necrosed, and a fistulous opening led from the surface into the cavity of the joint. In this case the entire cavity was filled with granulations, and the recovery materially retarded; but the patient has, nevertheless, in every instance, a useful and mobile joint, from which he has never suffered the slightest inconvenience.

I cannot think that the partial operation described by Dr. Goldthwait would have been either desirable or efficient in any of the cases I have seen. The most marked characteristic of these cases has been the displacement of the head of the first metatarsal bone, with greater or less degrees of distortion in shape, often with arthritic deposits, and sometimes with destructive changes in the joint structures which would not be relieved by the removal of a wedge-shaped portion of the head of the bone. It would seem to me that entire removal of the diseased structures is better surgical practice in this, as in other operative measures. I have never left the wound open, but have closed it with sutures, which in all but one case were removed on the third day, with the result of first intention in healing; and the patient was walking on the fifth day. In no case has there been a recurrence of the bunion, or any indication of trouble in or around the structures of the joint.

Very truly yours,

ALBERT N. BLODGETT, M.D.

STAINING BACTERIA UPON THE SLIDE WITHOUT USING A COVER-GLASS.

BOSTON, November 19, 1893.

MR. EDITOR: — Some of your readers may be interested to know of a method, which I have been using for some time and have found very convenient, of staining bacteria upon the slide without the use of a cover-glass.

By means of a platinum loop a drop of a liquid culture or of the water of condensation from a solid culture is spread upon a clean slide. Or a drop of water may be placed upon the slide first and then spread with a small quantity of the material to be examined. The preparation is held in the fingers and passed three or four times through the flame of a Bunsen burner or alcohol lamp. From a dropping-bottle the carbol-fuchsin or other stain is put on the specimen for a minute and washed off in water. After drying, cedar oil is dropped directly upon the preparation which is now ready to be placed under the immersion lens.

The advantages are: Convenience in handling; no need of forceps nor of Canada balsam; the slides clean readily in alcohol. The method is especially adapted to the rapid examination of plates from a mixed infection. When a specimen is found which it is desirable to preserve, the oil can be blotted off and replaced by balsam and a cover-glass.

Respectfully,

CHARLES NORTON BARNEY,
Harvard Medical School.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOVEMBER 25, 1893.

Deaths reported 2,459: under five years of age 787; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 358, acute lung diseases 408, consumption 266, diphtheria and croup 169, typhoid fever 49, diarrhœal diseases 43, scarlet fever 27, cerebro-spinal meningitis 23, measles 19, whooping-cough 15, malarial fever 7, erysipelas 3, small-pox 3.

From scarlet fever New York and Chicago 6 each, Boston and Cambridge 4 each, Brooklyn 3, Milwaukee 2, Cleveland and Chelsea 1 each. From cerebro-spinal meningitis Brooklyn and Cleveland 4 each, New York and Chicago 3 each, Washington 2, Boston, Worcester, Lowell, Chelsea, Malden, Quincy and Pittsfield 1 each. From measles New York 9, Chicago, Brooklyn and Milwaukee 2 each, Worcester, Fall River, Lowell and Pittsfield 1 each. From whooping-cough Cincinnati 4, New York and Chicago 3 each, Brooklyn 2, Boston, Cleveland and Lynn 1 each. From malarial fever New York 3, Brooklyn 2, Cleveland and Nashville 1 each. From erysipelas New York, Chicago and Brooklyn 1 each. From small-pox New York 2, Chicago 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending November 18th, the death-rate was 24.0. Deaths reported 4,751: acute diseases of the respiratory organs (London) 615, diphtheria 117, whooping-cough 92, measles 85, scarlet fever 77, diarrhœa 62, fever 61, small-pox (Bradford 8, Birmingham 4, Bristol 2, London, West Ham, Leicester, Oldham and Leeds 1 each) 19.

The death-rates ranged from 10.8 in Halifax to 31.4 in Birmingham; Bradford 24.5, Brighton 17.7, Croydon 11.0, Hull 27.2, Leeds 21.2, Leicester 17.2, Liverpool 28.8, London 24.4, Manchester 25.6, Newcastle-on-Tyne 23.0, Nottingham 16.8, Portsmouth 17.1, Sheffield 26.4, Sunderland 20.2.

METEOROLOGICAL RECORD,

For the week ending November 25, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 25, 1893, TO DECEMBER 1, 1893.

FIRST-LIEUT. ALEXANDER N. STARK, assistant surgeon, U. S. A., is relieved from duty at Fort Clark, Texas, and will report in person to the commanding officer, Fort Sam Houston, Texas, for duty at that post.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, December 11, 1893, at 8 o'clock, P. M.

Dr. M. H. Richardson: "Trigeminal Neuralgias Treated by Avulsion of the Second and Third Divisions at their Foramina of Exit from the Skull; with cases." Discussion opened by Dr. G. L. Walton and Dr. S. J. Mixter.

Dr. F. C. Shattuck: "Four Cases of Myxœdema Treated by Thyroid Extract." Discussion opened by Dr. J. J. Putnam.

Members are kindly requested to show interesting cases and pathological specimens.

JOHN T. BOWEN, M.D., *Secretary*.

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday, December 13th, at 8 o'clock, P. M., by Dr. H. P. Bowditch. Subject, "Anthropometry and the Laws of Growth." Physicians are cordially invited.

APPOINTMENTS.

The following appointments have been made to the Faculty of the Dartmouth Medical School: TILGHMAN M. BALLIET, M.D., Professor of Therapeutics; GILMAN D. FROST, M.D., Professor of Anatomy; GEORGE A. LELAND, M.D., Professor of Laryngology.

RECENT DEATH.

SAMUEL MOORE LOGAN, M.D., M.M.S.S., formerly of East Boston, died at Riverside, Cal., recently, aged sixty-five years.

BOOKS AND PAMPHLETS RECEIVED.

The Medical News' Visiting List, 1894. Philadelphia: Lea Brothers & Co. 1893.

Manual of Bacteriology for Practitioners and Students, with Especial Reference to Practical Methods. By Dr. S. L. Schenk, Professor Extraordinary in the University of Vienna. Translated from the German (by the author's permission) with an appendix. By W. R. Dawson, B.A., M.D., Univ. Dublin, Late University Travelling Prizeman in Medicine. With four hundred illustrations, partly colored. London and New York: Longmans, Green & Co. 1893.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XXI.

DISEASES OF THE BONES.

These are just the same as the diseases of the soft parts, only they have different names. What is called ulceration in the soft tissues is called caries in the bone; and what is called mortification in the soft tissues is called necrosis in the bone. The names, however, need not confuse us; but the processes which take place in bone as distinguished from the same processes in the soft tissues are very different on account of the difference of the tissue. The bone is immensely hard. All processes which take place in it are proportionately slow; and the process of ulceration, or the process of suppuration, or inflammation in the bone itself, is a matter of weeks or months; whereas the same process would run its course, in the soft parts, in a few days. Singularly enough, bones, which are quite free from sensitiveness, become excessively painful when inflamed; and this is due, probably, to the fact that their interior is subjected to an immense hydraulic pressure on account of the hardness of the bony structures, where inflammatory processes and exudations are taking place; just as the pain of felon or deep whitlow, which is intense as compared with the pain of a superficial abscess, in a lymphatic gland; just as we know that that must be due to the fact that pus is shut down on the bone under the periosteum; so, in the bone itself, inflammatory processes are very painful, as well as very slow.

The first class of affections of the bones which we naturally would take up would be those which affect the periosteum or membrane which nourishes the bone upon the outside. The periosteum is, in its healthy state, a thin and nearly transparent membrane, made up of a delicate web of connective tissue containing vessels, clinging closely to the bone, fitting it snugly in every direction, having to be dissected up to distinguish it from the bone and affording the superficial bone a large part of its nourishment. The Haversian canals and the inner periosteum also nourish the inside of the bone. The simplest and most common affection of the periosteum is called,

SIMPLE ACUTE PERIOSTITIS.

It usually comes on in consequence of a blow, or frequently by great exposure to cold. It has frequently arisen from the patients plunging into freezing water, or standing for a good while in snow, and then walking about briskly and restoring the circulation too rapidly, or approaching a fire, something of that kind. It often occurs over the tibia. I will take that as a site of the disease easy to demonstrate and talk about.

What are the signs of simple acute periostitis? Always swelling, always a tumor, but small, defined, oval, firm, painful. This is due to the pouring out of serum and the white cells of the blood between the periosteum and the bone. Nothing can resist this hydraulic pressure. The bone does not give way, but the membrane over it does, and it rises out in the form of a sac. This sac raises the fascia and muscle over it and the skin, so that we feel the tumor on the surface, which is due to effusion of serum. It does not fluctuate. It is too tight and hard to fluctuate. There is no discoloration of the skin. A painful, non-pulsating and non-fluctuating tumor over the hard bone; that is the peculiarity of acute periostitis.

It arises also from other diseases. It arises very frequently from syphilis. Then it is of a much more subacute or chronic character. The pain is aching and dull. The formation of the tumor is slow. It never reaches the suppurative stage. It forms an outgrowth upon the bone called a node, beneath the periosteal layer.

The treatment of acute simple periostitis is easy and quite sure to effect a cure if it is attended to promptly. The limb must be kept strictly still in the horizontal position; warm fomentations applied over it are often sufficient. If that is not sufficient a cure may be hastened by a blister, or the strong ethereal tincture of iodine, or compound tincture of iodine, applied. In the mild case, often the result of rest and warmth and subsequent blistering is to cause gradually an absorption of the effused fluid; the periosteum settles down upon the bone and the disease is cured. If, however, the disease is seen at a later stage and has gone too far to be relieved by this simple method of treatment, then the best treatment is an incision, which should be made down to the bone until we are sure that the knife scrapes on the bone itself. That is curative at once. Inflammation subsides; the pain goes away; bloody serum and thickened flakes come out through the opening in the periosteum. Possibly suppuration takes place, but not always. If the part is stuffed with antiseptic gauze, probably it will not suppurate. The pain is relieved at once, and the patient gets well. That is simple, acute, circumscribed periostitis.

There is another form called diffused periostitis, which corresponds to diffused cellulitis in the soft tissues, and is distinguished from abscess; and this diffused periostitis is one of the most fatal and rapid complaints that can occur. It either destroys the patient's limb and leads to amputation after spontaneous fracture of the bone, or, more frequently, it leads in feeble persons to death. Diffused suppurative periostitis is exactly like diffused suppurative cellulitis. There is no boundary wall of lymph; no limit of the disease. It strips the periosteum from the bone and forms an immense sac of pus with marked constitutional symptoms.

On account of the very severe constitutional symptoms it produces, the name of typhoid of bone has been given to it. It occurs almost always in children, affects especially the lower part of the femur and upper part of the tibia, and produces intense constitutional symptoms resembling typhoid fever. The child has high temperature and sometimes a slight cutaneous eruption like typhus; becomes rapidly and intensely sick; and swelling and œdema begin about the lower part of the femur, usually above the joint and deep in under the fascia lata, so that it does not make much external showing at any particular point; general œdema, with great pain, and very severe constitutional symptoms.

The progress of the disease, if let alone, is that suppuration forms under the periosteum on the shaft of

[1] These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

the femur without any boundary being set up by the pouring out of lymph; strips up the periosteum; bursts through the periosteum; makes a large sac of pus held by the fascia lata; and in consequence of its denuding the shaft of the femur of periosteum, the bone, lying in this mass of pus so long, rapidly becomes carious. Sometimes the disease goes through the bone and affects the medullary cavity, if it goes on long enough. It is very difficult, almost impossible for this abscess to burst; the fascia lata making a secure bag for it. It retains the pus, and you are conscious of a large fluctuating sac. The child sinks into a state of great exhaustion. If the disease goes still further unrelieved, the medulla of the femur having been invaded, the shaft becomes carious and extremely brittle, and in some slight movement breaks; and you have spontaneous fracture of the femur, shown by great pain and by the drawing up of the two ends of the bone. This is an extreme condition and it is usually followed by death. Occasionally, it is said, the disease appears on the upper part of the femur. It does not, as a rule, affect the joints; but the shaft under the periosteum.

This disease is unfortunately often overlooked in its earlier stages when something might be done to control it. It is mistaken for typhoid fever, or rheumatism; and it is not until extensive destruction has taken place that the presence of a fluctuating sac is detected. Then if it is laid open, and the surgeon passes in his finger, he finds the shaft of the femur lying smooth as a stick, without any covering, running through this sac of pus. Amputation in that case is frequently the only means of saving life; the disease of the femur having gone so far that it is incapable of repair. If the disease can be recognized, and is recognized early, no doubt much can be done to relieve it.

The commencement of the disease is down on the bone just as felon is on the finger, but the depth of surface is vastly greater than in the hand.

The true treatment is early and deep incision. This must be made, however, with great caution. The skin and cellular tissue should be cut through; then the fascia lata nicked and pricked, and slit up on a director, and the finger passed in, and perhaps the director, and moved about until pus is reached. When found, free incision should be made, and the cavity washed out. It is better, probably, to make two incisions on opposite sides, put through a drainage-tube, and irrigate constantly through the tube. If this can be done at a very early stage, the femur may be saved, otherwise not.

Almost all the cases I have seen have been hospital cases; and those I have seen in private houses have been just as far advanced as when they are brought to the hospital. All the cases I have seen have been in the advanced stage, where there was a large sac of pus, the femur already denuded, and destruction gone on beyond the chance of doing any good. I have once or twice seen spontaneous fracture, several times amputation, and several times death. The worst amputation is that which has to be done in the feeble person above the middle of the femur; and which is very liable to be fatal, on account of the severity of the operation, the location of it, and the weakness of the patient. Sometimes there is no other resort to try.

This disease is not very much insisted on in textbooks, but, as it is the cause of loss of limb and life, I have dwelt a little more upon it; and you will find in the poorer population of all cities, among feeble children, these conditions come on not very rarely.

Exposure to cold and blows, going in bathing in improper seasons of the year, being wet and going about in wet clothing, blows about the tibia and femur in the feeble child ill-nourished, will bring on this condition, or some other form of suppuration of bone. Sometimes it brings on abscess in the bone itself, of which we will speak presently.

CARIES

Is an ulceration of the bone; a disintegration and breaking down; washing out of lime salts; changing of cancellous tissue into either a tubercular cheesy mass, or fat; and the formation of a soft vascular mass, which rapidly loses its firmness, and remains as a soft substance inside the cancellous tissue of the bone. As you might suppose from that description caries almost always occurs near the epiphyses, rarely in the shafts. It is about the joints that you see almost all the cases of caries. Caries is not confined to any age, but it is more frequent in the young; and necrosis, I think, is more common in the adult than in the child.

There seems to be no reparative effort in caries. It is an ulcerative process, and goes on very slowly and insidiously; not very painful; no very acute symptoms; and destroys large surfaces on the inside of the bone, and finally gives rise to an abscess, in many cases with a sinus leading down into the cavity. Through this, after a long while, the patient may succeed in throwing out the pus and all the broken-down cancellous tissue; and in some cases the disease will heal up spontaneously under constitutional treatment and without surgical interference; but, if it is recognized, it unquestionably does better with surgical interference; and in some cases, if it can be attacked early, it seems as if it could be almost aborted; that is, you have the symptoms, for instance, of a slight amount of swelling and œdema; a tender spot on the foot: lameness in walking; perhaps a little hectic at night; occasional occurrence of sweats; if the symptoms persist a good while and the surgeon makes a prompt incision down upon the bone, he finds usually the periosteum thickened and somewhat separated from the bone. He finds, to his surprise, when he presses upon the bone that it is a shell; it lets a blunt instrument push into it; break through this little outer shell and you find a carious cavity, which was originally the cancellous tissue of the bone. It has all been thinned out and absorbed, so that it is semi-fluid; and there is nothing but a shell of bone surrounded by periosteum. In this condition of things, if the cavity is carefully curetted and drained, and packed and washed out, frequently a good result ensues.

NECROSIS.

Caries is somewhat different from necrosis in this respect, that you may scoop out all the carious cavity down to a point where it seems that nothing more can be scooped out without violence, and may have that promptly followed by repair. Such is not the case with necrosis. If you attack necrosis and attempt to cut it away, before nature has separated it and marked the line of demarcation between living and dead bone, you do not succeed in establishing repair; but the necrotic process goes on, until the limit is set by nature, and the piece can be removed. This loose piece is

sometimes called a sequestrum; and it is only after it is thoroughly detached that it can be removed with any great advantage. It may be hastened to a certain degree by cutting through the shell of bone that surrounds it, and giving it free exit; but it is hardly useful to attempt to tear it away before it has become loosened itself, because you cannot end the disease until nature has stopped the necrosing process.

Necrosis is like gangrene or mortification of the soft parts. Some portion of the vessels of the bone become obstructed; the Haversian canals become shut up with inflammatory exudation or coagula; the nutrition is cut off from quite a piece of bone, and it dies; and then nature makes the effort to separate it from the living tissue by an active process of exudation, inflammation and suppuration around it. This gives rise to abscess. Then the abscess drills a hole through the bone; then comes up to the surface under the fascia, and finally makes a small outlet, and leaves one of those little red pouting sinuses. You pass the probe, and come down upon a little hole, of which you are conscious in the bone, about large enough to admit a shot; and then you strike inside a bare portion, which may or may not be loose, according to the length of time the disease has existed. Meanwhile, nature surrounds this bad piece with a strong circle of vessels, and active inflammatory processes, which finally slough it off and let it lie loose in the cavity. Now comes in a very extraordinary process of nature to prevent fracture of the limb while this destruction takes place. Suppose the necrosis takes place in the tibia. While the dead bone is being separated and got ready to be thrown off, new bone is thrown out all around to strengthen the diseased shaft; and an involucrum, or shell, is formed around the diseased piece; and the bone enlarges, and is very much broader than the tibia of the other side. In the midst of this enlargement you find the sinus which leads down directly through the bone to the sequestrum. The formation of new bone is a very important provision on the part of nature to prevent fracture of the limb while separation of a dead piece of the shaft takes place. But at the same time this change defeats, so to speak, the other object of nature, which is to cast off the dead piece, because it encloses it firmer and firmer in the shell. The result is that a sequestrum, *per se*, is never discharged from the living tissues. It is held in sometimes for years; and it rattles about, so to speak, inside the tibia in this cavity, surrounded by new bone: never healing; always keeping up a slight discharge; but never having an opportunity to escape.

There is not much pain in this process. It is a slow process. I have seen sequestra in the tibiæ of patients who have gone about, and the duration of the disease reach forty years without any operation; without much impairment of health, and without a great deal of pain. But the disease does not get well until the surgeon interferes. So then, when we have found this sinus, the true practice is to cut down and chisel away and trephine away a large portion of this shell of new bone, to open up the cavity in which the sequestrum lies. If it is loose we take it out; and if not, we wait for it. If we take it out, it promptly heals, and becomes a strong serviceable limb.

These are the marked differences between caries and necrosis. Caries is essentially destructive throughout. It is an ulceration. It occurs frequently in youth; almost always about the epiphysis. It is slow, insidious, but it does not get well, as a rule, without operative interference; and if the cavities are scraped out, it usually gets well. Necrosis, on the other hand, is a disease of strong adults, frequently. The diseased piece can never escape. It is incurable except by operation; and the operation usually is curative. Sometimes, however, it unfortunately happens, that the bone is so thoroughly diseased, that the same process is repeated in different portions of the shaft, over and over again; and occasionally you see the tibia so riddled with sinuses, and so deformed by the growth of new bone, that it is practically useless; and in such a case amputation is the best treatment for the patient.

ABSCESS OF BONE.

There is a form of suppuration in the bone which is called abscess of bone. The peculiarity of this seems to be that it is essentially a pus formation, without caries or necrosis, taking place somewhere in the medullary tissue of the bone. It generally occurs somewhat near the joints; but may be in the shafts of the long bones. Unlike the other affections of which we have spoken, it is intensely painful. The agony is great and lasting. The patient loses sleep, emaciates, has unbearable pain all the time, and there is no apparent cause for it; he will point out the location of the pain, but you cannot see any change on the outside. You may, perhaps, by taking the finger and rapping about on the bone, come upon a point where he winces every time, and says it is exquisitely painful; and you may find a slight degree of œdema. There is not much swelling, but constant acute pain, which must be distinguished from neuralgic pains, which latter may last months or years. This pain is due to the formation of a small amount of pus; rarely more than a drachm, in the bone; shut in; trying to bore its way out. It is, I suppose, comparable to the pain of felon in the hand. If this disease is recognized, a cure is quite easy and certain. Cut down upon the bone and trephine the shaft and open the medullary cavity and give exit to the pus, if it is found. If it is found, I say, because sometimes after trephining you are disappointed that you do not strike directly upon pus, and have been deceived perhaps to the extent of one-half to one inch in the location of the pain. It is not exact, and you have not hit the exact spot. In this case by taking a gimlet, or something of that kind, and boring up and down in the medullary cavity, you almost invariably strike the pus; and you are surprised to see how little there is, and you are also surprised to see how absolute the relief is; and how promptly this cavity will granulate and heal up. These, if they can be recognized and treated, are an extremely satisfactory class of cases. Unfortunately, like the cases of acute diffuse periostitis, they frequently are not diagnosticated until they have produced destructive effects in the bone itself.

OSTEOMYELITIS.

There is a disease of the marrow of the bone which is like a diffused periostitis; that is to say, it is a diffused inflammation of the cavity of the bone and that membrane, which lines the inside of the bone, sometimes called an endosteum. It is not a distinct membrane, but made up of cellular tissues and fat cells, whose vessels nourish the inside of the bone. This disease, as you might suppose, shut away inside the cavity of the bone, is usually the result of trau-

matic causes; either a compound fracture, or an amputation. Those are usually the causes of this disease which is named osteomyelitis, or an inflammation of the marrow of the bone. After amputations it is not infrequent. After compound fractures it occurs occasionally, and is frequently fatal. After amputations it is not fatal, as a rule. But after compound fractures it frequently is. The reason of that is this, that after the amputation you have the end of the bone exposed; the bone sawed off; the medullary cavity open; and if the disease comes on there and osteomyelitis takes place in the stump, the stump does not close, never heals, keeps up a pouting, discharging sinus communicating with the medullary cavity. This is a safe exit, so to speak, for the suppuration which is taking place; and prevents, probably, the absorption of this material higher up into the system; so that, as a rule, the person with osteomyelitis after an amputation recovers. But if you have a compound fracture, and the bone is broken into the medulla, the cavity is pretty much covered over. If this acute inflammatory process begins it has no exit, and travels up the shaft, and rapidly gives rise to intense symptoms, and frequently terminates in septic infection, in septicæmia; and occasionally in that process called embolism of fat; and in the carrying up of other septic materials into the system; so that osteomyelitis after compound fracture is generally accompanied with intense constitutional symptoms, and terminates often in a fatal septicæmia.

In a case of osteomyelitis after an amputation, the stump does not heal. The patient goes about without much pain. Exploration of the end of the bone shows that a piece of the central portion has separated; that a cast, so to speak, of the inside of the bone has formed; and, after a while, cutting down upon it and scraping back the tissues, you can seize this cast of the interior of the bone and draw it out; this is a true sequestrum of the inside of the bone. If it can be extracted entire, this is speedily followed by healing and cure.

SCLEROSIS.

In consequence of a very slow infiltration into the Haversian canals and connecting cavities of the bone which nourish it, the bone salts get deposited in excess, sometimes, and the bone thickens and hardens without any acute suppurative process; grows thicker and harder and heavier; and what was originally perhaps, a shaft of bone, becomes increased to twice the usual thickness; and this process is called sclerosis, or hardening. Such a bone becomes very heavy and large. The disease is slow and it is not productive of very acute symptoms, except dull pains.

It is sometimes the result of poisons; occasionally the result of syphilis; and it is apparently, as far as I can see, irremediable, and sometimes leads to amputation. If it is directly the result of syphilis, it is more likely to show itself upon the surface of the shaft, in the form of hard, bony nodes which grow beneath the periosteum. These can be benefited often by blistering the skin; and frequently by the taking of large quantities of specific medicines, which affect the system in the tertiary stages of syphilis; but in the other process in which the bone grows hard slowly without syphilitic infection, the bone sometimes remains in that condition for years, without producing any great trouble except its weight and dull pain.

ABSORPTION — POROSIS.

On the other hand, there is occasionally a condition of bones in which they absorb and grow thinner and thinner; absorption of the shell takes place; and the bone becomes exceedingly brittle and weak. Those are the rare cases in which what is called spontaneous fracture takes place, without the history of any injury, or any force that was sufficient to break the bone. Instances have occurred in which the patient, in this feeble condition of bone, is lifting only a book from the table, and drops it, and finds that the humerus is broken. This is absorption, porosis.

Unfortunately we do not know its cause; and do not know how to relieve it.

It must put us on our guard always with regard to prognosis in all troubles about the bones, and especially in the subsequent use and strength of fractured bones, because, occasionally, in spite of the best care, atrophy, or wasting, or porosis of the bones does occur after the injury; and the fracture, although it joins, does not become strong. The arm shrinks and dwindles and breaks, or becomes practically useless. It should be distinctly understood that this process is beyond our control; that we can in nowise be held responsible for it. We should be on our guard as to giving too favorable a prognosis.

ATROPHY.

Atrophy sometimes takes place, by which the bone wastes away until, in some cases, the humerus has become shortened an inch or two in consequence of this process, and the elbow has approached the shoulder. A very small bone is felt between, which is feeble and brittle, and the bone atrophies in its entire length with shrinking. This is quite rare, but occasionally takes place.

HYPERTROPHY.

The opposite change, or hypertrophy, or bony outgrowths, which are distinct from sclerosis, occasionally occur and make great deformities; sometimes come on the collar bone making large bunches. We suspect that they are syphilitic, but they do not always yield to syphilitic remedies. They form on the face, on the superior maxillary bones, and give rise to that sort of face sometimes called leontiasis; here bony outgrowths take place, push the nose back, and growing out beyond the nose, push the eyes up out of the orbit.

These are true exostoses or bony growths from the bone itself; and when operated on and cut away are found to consist of pure bone.

The only treatment is to cut and trephine and chisel them away, in the hopes that when the flesh has healed over it the growth will not recur. Occasionally, these growths form in a curious way on the forehead, in the front wall of the frontal sinus; and the inner part of the growth lies in the inner part of the frontal sinus. After cutting through the skin and stretching it back, we find we can lift the bone out of its bed in the frontal sinus, and a cure will then speedily ensue. But this seems to be a somewhat different sort of growth from those which grow with large bases from the superior maxillary bones.

In certain classes of the chronic insane, in chronic dementia, there seems to be a change in the bones with regard to the phosphates, and the bones become weak. It is probably true that a good many cases of fractures of the ribs, which occur among the insane in asylums,

are due to very slight force, like spontaneous fractures anywhere; and while they may be ascribed to brutality or carelessness on the part of attendants, I am inclined to think this is often not the case; and that they are in that condition that they will break almost spontaneously on account of the feeble state of the system. This occurs occasionally among those in perfect mental health. I have once or twice seen myself fracture of the rib caused by coughing in an otherwise reasonably healthy individual; in a person somewhat obese and of about sixty years of age. In this case, after a violent attack of bronchitis and repeated coughing, the rib gave way after an expulsive effort. This should prove to us that in so thin and slight a bone as the rib it may become porous, and give way without any positive severe violence.

OSTEOMALACIA.

A very curious condition is osteomalacia, in which spontaneous fracture takes place over and over again. In these cases the patients frequently live to grow up, and the limbs are deformed with innumerable fractures. In such cases among children the slipping down off the chair on the floor will cause the leg to give way; and these breaks, fortunately for the individual, heal promptly, and then give way in another place the next time. This is a little different from the condition known as rickets or rachitis; because that is a condition of the bones in which they bend rather than break. In true rickets, the proportion of earthy salts and organic matter, as existing in the healthy bone, is reversed. The result is cartilaginous, weak, flexible bones, with rather enlarged joints. The spine bends; the breast bone bends; the head sinks between the shoulders; the legs curve out in all directions. Frequently the tibæ curve forward so that they are arched; and various other deformities occur.

In this condition, considerable can be accomplished by apparatus to keep the child's limbs straight; and by building up the child's strength with proper treatment, such as iron and cod liver oil, tonics, nutritious food and open air.

Bones break sometimes, apparently, spontaneously, but really as a result of tumors which are forming in them insidiously. This is especially true of cancer, or osteosarcoma of the femur, tibia or other bones. These occasionally give rise to what appears to be at first spontaneous fracture; and the force which breaks the bone is generally very slight — turning over in bed has broken a femur in the middle of the shaft in a case of unsuspected cancer, or osteosarcoma.

This form of malignant disease generally begins in the medullary cavity, grows and extends, rapidly absorbs and pushes out and thins the shaft or shell of the bone until it becomes so brittle that it gives way; and the cause is wholly, in these cases, malignant disease; so that in elderly people a case of spontaneous fracture, or fracture from insufficient cause, of the shaft of the bone should give rise to a great deal of suspicion as to what made it, and whether it is not probably due to commencing malignant disease of the bone itself. In the shaft, I say, because it is well known that old people break the neck of the thigh bone and neck of the humerus from absorption of the bone, without any form of malignant disease.

Various tumors grow in bones, some of an erectile nature, which pulsate and are mistaken for aneurisms. They form in the medulla, rapidly accumulate a mass of enlarged vessels, throb and beat, absorb the bone just as an aneurism does, push out in a fungus pulsating mass, weaken the limb, and are recognized as a soft pulsating swelling about the femur or tibia, but are truly vascular tumors in the bone itself.

Myeloid disease also deceives us often in regard to the condition of the bone. It is true that myeloid disease rarely occurs in very young subjects; but its favorite site is the head of the tibia, and it forms very slowly; expands the head of the tibia; weakens the limb; gives rise to pain; generally to febrile symptoms; and is difficult to diagnosticate, at first, from caries occurring in the head of the tibia. Caries in the head of the tibia in young subjects is common; myeloid in the head of the tibia in adult subjects is not very uncommon. They frequently are mistaken one for the other. An incision, which seeks to relieve the caries and scoop it out, and falls upon myeloid disease, soon shows us what the mistake is; and in that case amputation is the only resort, and has to be done above the joint. The disease is incurable, malignant. Amputation should be done early to save the patient.

Now, it is necessary to know this sort of thing because it must give us great caution in operating, and in bearing in mind that we cannot tell exactly what we have got to expect when we operate on deep tissues; and that the alternatives must be ready in our mind; and that we must be prepared, and perhaps have prepared the patient, by saying, that we will endeavor to remove the disease; but that we must do what is necessary in order to save life; and if we find any incurable trouble, we may have to amputate.

MEDICAL TEACHING IN GERMANY.[1]

BY CHARLES F. WITHINGTON, M.D.,
Instructor in Clinical Medicine, Harvard University.

Americans who are likely to consider the subject of medical study in Europe, fall into three classes:

First, the small number of those who, either having received their general education abroad, or having been impressed with the excellence of European medical teaching, decide to take their entire course of medical study and their degree at some European university. I cannot but look upon this as an error for those who intend to practise in our country, for such men find themselves on entering upon their professional career at home at a disadvantage in the following ways: — Their therapeutic armamentarium is rather different from that to which American patients are accustomed, and though they can, of course, readily enough learn the differences between the European and the United States pharmacopœias, yet they are likely to find that a good deal of the sort of medication which is swallowed with avidity or at least with resignation by the hospital patients of Berlin or Vienna, will meet with decided opposition from the self-respecting American stomach. Again, the man who has received his entire medical education abroad knows nothing of these professional traditions and usages to which patients here expect conformity, and which alone can make one's relations with his fellow practitioners endurable. Finally,

[1] Read at the meeting of the Suffolk District Medical Society, October 28, 1893.

a lack of personal acquaintance with any of one's professional neighbors or with any of the older or more prominent physicians of the city or State where one is to settle, must be counted as a great disadvantage.

The second and numerically the largest class of persons contemplating foreign medical study is composed of men who have taken their medical course and degree at home, but who wish further preparation for practice, and are considering whether they can best secure such practical experience as they desire, at home or abroad. Yet it must be freely admitted that if these young men can afford but one year in addition to their required curriculum, a resident house-officership in a good general hospital offers advantages superior to any they can find under other circumstances in any country.

Third, comes a class which I hope and believe is destined to become an increasing one, of men who having already become established in practice, feel a need of temporarily interrupting their work by further study with a view either to specialization, to consultation practice, or to such a picking up of lost threads, such a broadening of the professional horizon, as Harvard offers to her professors in the "Sabbatic year," but which we medical practitioners, while we need it quite as much as any other class of professional men, find it harder to get. If it is not possible to obtain it every seventh year, yet at a longer interval or for a shorter period, it is not, as I have reason to believe, impracticable. The practitioner who, with any of the motives I have just sketched, wishes to change temporarily his horizon, and to "go to school" again, will generally, if possible, cross the water to get what he wants, despite the excellent polyclinic and post-graduate advantages that our large cities now offer.

In a paper like the present, it is manifestly impossible to attempt to cover the whole field of foreign medical teaching, and I shall, therefore, in what I have to say to-night limit myself to a consideration of Germany, and especially Berlin.

Medical study in Germany differs from that in England and in our own country, in that it is always pursued at a university, where it shares in the broadening influence produced by the bringing together of various departments of learning about one common centre. There are about twenty of these universities, the largest being those of Berlin and Munich. As the capital of the chief German State, Berlin stands easily the intellectual centre of Germany and probably of the world. Her university, though less than a century old, comprises nearly seven thousand persons and numbers among its professors some of the brightest lights in the firmament of science and letters.

The German student of medicine passes to his professional studies either from the gymnasium, where he is supposed to have spent nine years in liberal studies, consisting chiefly of classics and mathematics; or he may come to medicine from the Réal School, where modern languages and science replace the classical training of the gymnasia. The gymnasium, however, is held by the best medical men, and by the government also, if we may judge from the distribution of official patronage, as the only adequate preparation for professional study, the Réal School being considered as an educational concession to the popular element. As the gymnasium takes boys at an average age of about nine, they are ready at eighteen or at nineteen (adding the year for compulsory military service) to begin their medical studies, unless they choose, as a few do, to take some semesters with the philosophical faculty of the university before passing on to the medical. Unless they do this, their basis of general culture is less than that of our best medical students, for the gymnasium cannot be held as at all equal to our best American colleges. On the other hand the Germans gain two or three years in time over our college and medical students.

The required medical course occupies eight semesters, (four years). At the end of the second year comes the first examination, the *tentamen physicum*, which covers chemistry, organic and inorganic, mineralogy, physics, botany, anatomy, physiology, zoology, embryology and histology. Near the end of the course occurs the examination on the other usual subjects of medicine, for the doctorate, or medical degree, in case the student chooses to apply for it. But as it is in many cases held to be a useless luxury, being rather expensive and quite unnecessary for medical practice, the student often reserves his money and energy for the State examination, which is essential to engaging in medical practice, which is a severe examination, conducted by government officials, and which makes of every successful candidate in a certain sense an officer of the government and invests him with corresponding authority and responsibility.[2]

I do not believe that the average German medical student is as well equipped as the average graduate of our best schools, that is, those having a four years' course. For, in the first place, the time of actual study is not so long. The winter semester nominally lasts from October 15th to March 15th, and the summer semester from the middle of April till the middle of August. Here are apparently nine months of term time. But no pretence is made of beginning work before November 1st or of continuing it after March 1st. In fact, the "vacation courses" begin March 1st, two weeks before the close of the regular term for which the students have paid. The same amputations are applied at both ends of the summer semester, and when to these lengthened vacations we come to add a two weeks' holiday at Christmas, and the first, second and third days' celebration of the various religious and secular festivals, there is probably not left more than seven months net out of the twelve for work.

Again, our academic "hour" for teaching purposes is fifty-five minutes. In Germany, the first fifteen minutes are always thrown off and the remaining forty-five minutes are, according to my observation, often considerably further reduced. So that the German lecture or clinic averages from twenty to twenty-five per cent. shorter than our own.

As to the instruction, it is generally admirable. The examination is thorough, the diagnosis shrewd, the literature discussed voluminous, recent and widely drawn. But despite, or perhaps because of the excellence of the elucidation, the average student gets probably less advantage from it all than he would from trying to unravel a few obscure cases for himself. To be sure, he serves his time as *praktikant*, when he makes more or less for a "snap" diagnosis. But he rarely works up a case in careful detail. His point of

[2] I have heard it said by some Americans that they found the diploma examinations in Germany remarkably easy. It may be that the examiners lightened the burden a little for foreigners who lacked perfect facility with the language, and who, moreover, were not going to practise in the country. At all events, I notice that for the years 1889-90, while in the entire twenty German universities 1,115 candidates received diplomas, there were at the same time 1,030 rejected. (New York Medical Record, 1891, vol. xl, p. 556.)

view is not so much the bed-side as the lecture benches, for, at least in Berlin, he rarely gets into the hospital wards. He does not read very much, and evidently sets great store for his examinations upon the careful pen-and-ink notes which he has kept of all the cases he has ever seen. In a word, he is made the subject of a constant intellectual *gavage*, in which, if you will allow the figure, the pabulum is of the best quality, and is fed to him with an unsparing hand; but it is so thoroughly predigested that very little work is left for his own intellectual powers to do, and they are likely to develop less activity than might otherwise be gained.

Conditions like the foregoing, which are not specially favorable for the student who is learning to make diagnoses, are, on the other hand, of advantage to the practitioner. From the latter point of view, the abundance of clinical material is very useful. Not only is the material very great in every European city where a large portion of the population is so poor that it must receive medical aid in sickness, but it is exceedingly available. Patients are always willing to be shown, being generally treated with fair consideration, and even when the visitor notices something lacking in this regard, it must be confessed that the patients themselves do not generally appear to be aware of the omission. Post-mortem examinations are, of course, made in all fatal cases, and hence clinical study is never subjected, as must often happen in America, to the incompleteness due to lack of pathological evidence.

The chief clinical teachers can, when they wish to illustrate any particular point, bring forward an immense amount of material. For instance, Mendel is said to have shown at one demonstration of epilepsy thirty-five patients in an hour. Certain of the medical *causes célèbres* make a living by going about from clinic to clinic, the fact that they are already under treatment with one clinical teacher making no difference in their acceptability to another. Special attractions are sometimes even sent for and fetched in a carriage like our coy voters on election day.

To work up properly such immense amounts of material involves tireless industry, and perhaps this is the most striking characteristic of the great medical teachers of Germany. The *breadth* of knowledge of such a man as Senator is something almost incomprehensible. If it be true, as has been said, that Vienna stands for specialism in medical training, it is also true that Berlin stands for breadth of medical learning. Senator's work covers not only the usual field of clinical medicine, but nervous diseases equally well, while at his polyclinic one of his most popular exercises is in connection with the diseases of children. Of course, much of the work, bacteriological, microscopical and clinical, is prepared by his assistants, but one feels that it is all done under his personal orders and supervision, while his incessant stream of publications indicates over what a long frontier of medical science he is pushing forward his explorations.

Senator's clinic at the Charité is called the Third Medical; the first is headed by Leyden, and the second by Gerhardt. These work on simultaneously, but at different hours (Gerhardt, by the way, at eight in the morning), and between them divide all that is of medical importance in the 1,800 beds of that hospital. Henoch, stricken with years, but unstricken with any other infirmity, watches over the children's wards and the children's polyclinic. Jolly, dean of the medical faculty, lectures on neurology and psychiatry. His clinic of mental diseases, occupying some 150 beds in the new Charité, was one of the first of its kind in Europe, having been founded by Griesinger, who was the first, I think, to introduce the non-restraint method in the treatment of the insane. Westphal, who succeeded Griesinger and preceded Jolly, is said to have carried on the department for four years, and perhaps more, without ever once applying a strait-jacket to a patient.

Resisting the temptation to specify individual teachers like Bardeleben in surgery, Liebreich in materia medica, Du Bois Reymond in physiology, Bergmann, the surgeon who tracheotomized the Emperor Frederick and impaled Morell Mackenzie, now in charge of the surgical university clinic, and Olshausen, at the head of the great Frauenklinik near by, I must, nevertheless, give a word to Virchow, whose work in pathology was for years the crowning medical attraction of Berlin. He is now rector of the university, and as such gives the right hand of fellowship and the appropriate moral advice to every matriculant. The cares of administration, political activity (albeit his party has just been signally defeated), paleontological research, these and other interests, still leave him at the age of seventy-two able to give, according to the last official programme, eighteen hours per week of instruction in pathology.[2]

The subjects best taught in Berlin are probably internal medicine, which I have just referred to, nervous diseases and bacteriology. The neurologists are doing a great deal of work on the anatomy of the nervous system. Where else in the world would we find going on simultaneously three elaborate courses on the anatomy of the brain? Here they are, by Waldeyer, Mendel and Siemerling. They are most admirably illustrated by fresh and hardened preparations, and especially in the case of Siemerling, by a series of stained sections of great beauty illustrating every possible level in brain or cord, and capable of demonstration by lantern and screen to a large number at once. Similar work is being done in some other laboratories, notably Mendel's and Oppenheim's, in which, in diffuse affections of the nervous system and in ascending or descending degenerations, practically the whole brain and cord of the patient is reduced to an enormous series of sections illustrating the condition at every possible plane.

In the youngest of the medical sciences, bacteriology, Berlin occupies, as is well known, a leading position.

To illustrate at once what is being done in this branch, and at the same time to serve as an example of the thoroughness with which the Germans organize and carry on scientific investigation, let us briefly describe one of the newest medical institutions of Berlin, one so new that many of my hearers who are familiar with that city have never seen it. This is the Institution for Infectious Diseases, which may be regarded as the first fruits, and perhaps thus far the most useful outcome of Koch's tuberculin discovery. In the enthusiasm which followed the announcement of tuberculin, the government promptly voted the sum necessary to carry out the enterprise, and the institution was opened in August, 1891, with Koch as

[2] With the beginning of the present semester Virchow retires from the rectorship.

director, and a large staff of skilled assistants, among them Pfeiffer, Behring and Brieger.

The Institution is situated just west of the Charité Hospital, and covers a tract of land about 650 by 200 feet in dimensions. It comprises seven wards or barracks of most approved hygienic construction, having all necessary kitchen and service rooms, baths, closets, etc., a general ward, isolating rooms, and a sun-room or sitting-room for patients who are able to be up. These provide for men, women and children suffering not only from such contagious diseases as diphtheria, but from tuberculosis in all its forms, including joint affections and lupus. One building has even been utilized for variola, while others contain puerperal fever, and even influenza-pneumonia. Rather too heterogeneous a mixture of infections, we may say, for the good of the patients treated; but a tolerably good isolation is practised, and the grouping of so many infections directly about the centre of bacteriological research gives obvious advantages for study. In the administration building is a small amphitheatre for lectures, having, among other equipments, a stereopticon and white screen for the display of microphotographs.

Behind this building stands another, which serves two important purposes: first, that of disinfection. The articles (clothing of patients and bedding from the wards) go through a regular order of rooms into and out of the steam disinfection-apparatus, and the disinfector himself is subjected to a bath and change of clothes between the time he loads and unloads the apparatus. Under the same roof, but securely separated, is the autopsy room, where the director personally assigns to various members of his staff the work, bacteriological, chemical and microscopical, which the case demands.

For the carrying out of these researches, an old three-cornered building opposite the hospital department has been fitted up. This, the "scientific department" of the Institution, is a remarkable series of laboratories. Here are brooding-rooms, kept by automatic regulators at an even temperature of 99.5° F. Here are stalls for keeping the animals that are made the basis of experimental investigation, not only the guinea-pigs and rabbits (which since the days of bacteriology have borne away from the long-suffering frog the palm of physiological martyrdom), but also dogs, cats, doves and an occasional monkey. The animals which are already infected are kept in quarters by themselves, and, when they have finally fulfilled their mission, their bodies, together with the micro-organisms they have entertained, are annihilated by cremation in a furnace built for the purpose.

Here are rooms for microphotography, equipped with heliostats to hold the elusive Berlin sunshine and the strongest artificial lights for hours when there is no sun. Dark rooms for the development of these plates, as well as for the macrophotographs which are taken in the adjoining rooms, and by which the clinical pictures of disease, as, for example, lupus, can be perpetuated. A library and reading-room are filled with the latest publications of other workers in the same field. Finally, we notice in one of the narrow entries a door leading to the quarters where all this multifarious work is directed, with a small plate bearing the modest inscription, "R. KOCH."

The educational value of this institution is, of course, greatest to the regular staff of workers, including those under-physicians who are detailed to this duty from the Charité. But their work is, through publication, made the property of the scientific world, while men are always going out from it as did the clever Japanese, Kitisato, to extend the work in other lands.

For the average student who goes to Berlin to study bacteriology, the Hygienic Institute is a more available place for personal practice in bacteriological work. In this building is maintained the sanitary watch and ward over the city. Regularly every two weeks are brought hither specimens of drinking-water from each of the eleven different stations which supply Berlin. These specimens are tested both chemically and bacteriologically, and if the filters (also devised in this institution) are found not to be doing their work, immediate attention is given to the matter. Here are good opportunities for practical study under the instruction of Rubner and Günther.

Courses for beginners are organized several times in a year, each course occupying all the time; that is, eight hours daily, for a month. The work is so systematized that no time is wasted. Each man makes his nutrient media, plants and dilutes his cultures, stains and examines his growths, and in general gets a *coup d'œil* at the subject, which, of course, is superficial, but which is of great service, at least in enabling one to judge of what the special workers in this department are doing. Other more advanced instruction, of course, is also given here.

In closing, I have only a few practical suggestions to make to any contemplating medical study in Germany. In the smaller universities you will probably spend less money, learn more German, see fewer cases medically, and learn far less that is of interest non-medically.

Having decided to study one or more semesters in Berlin, you can matriculate if you see fit, though it is not necessary. For this nothing is necessary but your passport as a citizen of the United States. Your medical diploma is not of the slightest use. Matriculation gives you a right to attend any "public" courses, gives you some reduction of price at theatres and concerts, and confers a certain immunity against police arrest, which may be convenient if you are sportively inclined. Neither need you be deterred by age from matriculating, for you will find among your fellow-students white-headed men in the sixties. Matriculation costs about seven dollars in money and an hour or two in time. If a matriculant, you pay through the university *quaester;* if not, in person to the respective teachers for whatever courses you elect. The usual price for a private course occupying two hours a week throughout the term is five dollars, and for a more or less number of hours in the same proportion, so that fifty dollars for a term will pretty thoroughly fill one's time, twenty hours per week of private courses and as many public courses as one can get time for. There is also usually no objection to an occasional attendance at other clinics than those for which you are regularly enrolled.

Vacation courses usually cost about the same for the four weeks that the university courses of the same number of hours per week cost for four months. Gynæcological and touch courses are dearer. The number of courses offered is usually from eighty to ninety. For one of the bacteriological courses above referred to, occupying the whole of every day for a

month, the cost, including everything, is about twenty-five dollars.

Living in Berlin is cheaper than in the other great European capitals: one can live economically for not much over a dollar per day.

Women receive no recognition in any German-speaking university so far as I am aware, except Zurich. There are a few individual professors, however, who are willing to connive at the presence of women in their courses, especially if they can ascertain that some of their colleagues have committed a similar daring indiscretion.

PRELIMINARY REPORT UPON INVESTIGATIONS CONCERNING THE CONTAGIUM VIVUM OF SMALL-POX.[1]

PRESENTED TO THE WORSHIPFUL COMPANY OF GROCERS, LONDON, BY STEPHEN C. MARTIN, M.D., BROOKLINE, MASS.

THE following is submitted as a partial or preliminary report of the results thus far reached in my investigations regarding the germ of cow-pox. I present it simply as a very concise statement of the facts that I have been able to demonstrate with certainty up to the present date. This will be followed by a full and complete report on the subject, as soon as I have succeeded in thoroughly elucidating certain facts, principally the morphology of the germ, which are not yet perfectly clear to my mind.

A large number and variety of bacteria obtained from vaccine virus can be grown upon the various culture media. Experimenting with gelatine, glycerine-gelatine, milk-rice, agar-agar and glycerine agar-agar, I obtained pure cultures of many varieties, none of which, however, produced cow-pox when inoculated upon the animal.

A year ago I abandoned the use of all culture media except the hardened sterilized serum of bullock's blood. With this at a constant temperature of 37.5° Centigrade, I have since conducted all my experiments. So soon as I adopted this course, I got cultures that produced cow-pox, even after passing through several generations of culture tubes. These cultures, however, were not pure, but contained quite a variety of bacteria. In every instance the blood serum was liquefied.

In November last, from a colony upon the surface of the blood serum, in a tube inoculated with heifer-transmitted cow-pox, I started a series of cultures, which have now reached the ninth generation. From both the surface growth and the condensation water of each of these cultures, I have made inoculations upon calves, and in every instance produced a perfect vesicle of cow-pox. The material "takes" with the same certainty as the lymph from the vesicle. From the vesicles produced by it upon the calf, I have vaccinated a number of children, in every case inducing vaccinia of the most perfect type, the areola not commencing until the beginning of the ninth day, a well-marked febrile reaction, and the crust not falling till the twenty-fifth day or later.

I also have a second series of cultures which I started from another specimen of vaccine lymph, that presents a precisely similar appearance, both gross and microscopical, to the first series.

The history and appearance of every culture tube, is exactly the same. After three days in the thermostat, numerous small white colonies are to be seen upon the surface of the medium, in the course of the lines drawn by the needle, and a cloud appears in the lower part of the condensation water. Each colony occupies a little depression, which it has formed for itself, by liquefying the medium about it. Later the liquefied blood serum flows down from the colonies, carrying the growth with it, and so producing liquefaction in its course and forming white lines, occupying shallow, eroded sulci, running down into the condensation water. At the bottom of the latter, a heavy cloud settles, consisting for the most part of disintegrated blood serum, while the upper portion of the water presents a remarkably clarified appearance. When a culture is seven days old, I inoculate the next tube in the series from it and remove it from the thermostat. No growth develops upon blood serum at the temperature of the room; or upon glycerine agar-agar, either at the temperature of the room or at 37.5° Centigrade.

I have not as yet tried other culture media.

The growth is but a feeble one upon the surface of the blood serum, though such a marked change takes place in the condensation water; and in some lots of blood serum it will not grow upon the surface at all, although developing well in the water.

The bacterium varies in form according to the various conditions of its nutritive environment and the consequent rate of its development. The most constant and prevalent form is a short, fine bacillus with rounded or nearly square ends. Those parts of the culture, where the nutriment is apparently exhausted, show the same bacilli in short chains, longer bacilli, and bacilli much enlarged at one end or the middle, as if in preparation for spore formation.

Where the nutrient medium is fresh, the plant divides more rapidly and forms very short bacilli, and often even a pure micrococcus form. The latter too, is frequently seen forming chains of five or six. Chains are observed, made up partly of bacilli and partly of micrococci.

The micrococcus form is found, for the most part, in the early colonies at the upper part of the culture tube, where the nutrient medium retains its freshness by the constant draining away of the liquefied and exhausted portion. On the other hand, where this latter abounds, as in the sulci, and the pockets and condensation water, into which these drain, the bacilli greatly predominate, and the "balloon" forms appear.

Cover-glasses of the growth stain well, after a few second's exposure to Ziehl's carbolic acid Fuchsin solution.

I have repeatedly inoculated tubes from isolated colonies that manifestly grew from a single bacterium; and the resulting cultures have invariably shown all the forms enumerated above.

My opinion now is that my tubes contain but a single plant, which assumes different forms according to the various conditions of nutrition. The typical stages of its development being a coccus, which becomes a rod; and then a "balloon," the latter being either a spore (*dauerform*) or a degeneration form. It is, of course possible, however, that there may be two separate plants present, a very small micrococcus and a bacillus. Further investigations can alone decide this point, and until I have made such, I cannot speak decidedly as to the morphology of the germ.

[1] Forwarded from the Bacteriological Laboratory, Harvard Medical School, Boston, February 1, 1891.

CONCLUSION.

The object of this communication is simply to record these facts:

(1) That the germ of cow-pox is a bacterium.

(2) That it can be grown upon certain kinds of blood serum.

(3) That after an indefinite number of generations of such growth, it retains unimpaired its pathogenic properties.

Experimental science suffered a severe loss in the passing away of Stephen Crosby Martin on Sunday, November 5, 1893.

Dr. Martin was the second son of Henry Austin Martin (M.D., 1845), and graduated from the Harvard Medical School in 1874, becoming a Fellow of the Massachusetts Medical Society immediately afterwards. Having no especial taste for general practice, and guided by his father's interest in the propagation of vaccine virus, it was to this branch of medical work that his attention was particularly directed from the beginning of his medical life; and from this time he took entire charge of what has always been the best-known and most reliable source of vaccine virus in this country.

As it had been of the father, so it was the constant endeavor of the son, at all times and at any cost of energy and expense, to secure and take advantage of new or improved methods in the preparation of the virus sent out under his seal. Naturally, therefore, his interest was excited by, and his attention directed towards, the advances of the last ten years in the knowledge of the bacteria, for these advances pointed unmistakably towards a new field of investigation of the virus of vaccinia. All analogy showed that the active principle must be vital, and therefore subject to isolation and specific study; and that, these steps being accomplished, it might be possible to secure a growth in the laboratory that would serve the purpose of protection against small-pox, and that would at the same time be absolutely free from any possibility of contamination, or of producing such unfortunate results as have been reported after the employment of humanized virus.

Led by these considerations, and at an age when most men are content to go on in the lines of work already laid down for them, Dr. Martin became a student again, and took up the science of bacteriology in the Harvard Medical School. Entering the laboratory devoted to that branch of instruction early in the fall of 1888, and under the advice of the head of the department, he devoted an entire year to the study of the methods employed in general investigation before attempting to enter upon the special subject that interested him. Beginning upon this at last, his earnest and persistent work was rewarded with results of such importance that, by the advice of those specially interested, a preliminary communication was made to the Association of American Physicians at its meeting in Washington in May, 1890. (This communication is to be found upon page 181 of Volume V, of the Transactions of the Association, and is correct, with the exception of the date attached to the notes, which should be May 11, 1890, and *not* May 11, 1889, as printed.) After this communication, the work was prosecuted with unremitting vigor, until, in February, 1891, the accompanying statement was prepared and submitted to the Grocer's Company in London.

As will be seen — if the observations were correct, and with others made later — the whole chain of evidence was completed; that is to say, a pure culture of a specific micro-organism was obtained from ordinary vaccine virus; this culture was carried through an indefinite number of generations; inoculations with these pure cultures invariably produced typical vaccine vesicles in calves, and in some of the children experimented upon; and in one case of the latter, in which the experiment was tried, the child was refractory to inoculation with ordinary vaccine virus. From all the vesicles upon the calves, the typical organism could with certainty be isolated and cultivated. So much facility had Dr. Martin attained in the special manipulations necessary, that he could at any time, and with practical certainty, start a fresh culture from the calf.

Thus it will appear that, more than once, the complete result was obtained, the production of typical vaccine vesicles in human beings; but there was a marked difference in the certainty of the effects produced by the inoculation of pure cultures in human beings and in calves. In the former case, of the few experiments tried, fewer still showed any results; but in the latter the results were uniform and typical, and virus from vesicles thus produced was, if anything, more active and certain than that obtained in the ordinary way.

At no time did Dr. Martin receive aid, aside from suggestions as to methods, except in the settling of some of the problems connected with the biology of the organism discovered by him. This was from Dr. John Amory Jeffries, whose brilliant career was so suddenly cut short in the spring of 1892; and it was most assuredly Dr. Martin's wish that no final results of his work should appear without acknowledgment of this aid, covering some three months of the fall of 1890.

But just at this most important stage of the investigation — in the spring of 1891 — Dr. Martin's work was cut short by the death, under trying circumstances, of a brother; and his strength, never of the best, had not recovered from this shock before the appearance of the symptoms, in the fall of 1891, that produced constantly increasing pain and prostration, until his vitality was exhausted and his sufferings were terminated by death.

During this entire period, the sufferer never lost his courage nor the hope, and almost the expectation, of being able at last to take up and complete the work so successfully begun. Some months before his death, and when an operation had been decided upon, the result of which was necessarily in doubt, Dr. Martin wrote out full notes of all his work. These will furnish a most valuable contribution if they shall be edited and published.

It is as a tribute to the qualities displayed — to the persistency under discouragement, to the energy and determination to succeed — that these lines are written. Certainly every one brought in contact with him in the laboratory joins in all the words of praise for work done, and regrets for what was left undone, that can be put together, as well as in the deepest sympathy for the family deprived of such a member.

HAROLD CLARENCE ERNST.

FURTHER OBSERVATIONS ON REMOVAL OF THE STAPES.[1]

BY FREDERICK L. JACK, M.D., BOSTON, MASS.

SINCE bringing the subject of removal of the stapes for improvement of hearing to the consideration of the Society last year, the operation has been tried in thirty-two additional cases. These, together with the original series of sixteen, make forty-eight cases in all for observation and study. The results have been carefully noted, and care taken to have the tests in hearing as accurate as possible.

In reviewing the cases there is much to encourage the adoption of the procedure, but its clinical application will require modification. The new is always interesting, and the tendency is to urge one on; yet it has seemed best in so important a matter to advance slowly.

In bringing the subject before you this year, it is hoped that a report of the present condition of the first series may prove interesting, and that brief histories of a few subsequent cases, illustrating further some of the conditions met with, and suggesting problems still awaiting solution, will be profitable.

[1] Read before the American Otological Society, July 18, 1893.

Of the original sixteen cases, three were in active process of suppuration at the time of the operation; nine were the effects of chronic purulent inflammation. These ears, with one exception, have remained healed. There were three of otitis media insidiosa, and one of Ménière's disease.

Most of these cases have been seen once or twice during the year by members of the staff at the Infirmary, and nearly all have been again tested within two or three weeks by Dr. Crockett or myself. It is about one year since they were operated upon — time enough to form some idea as to the permanency of the results in hearing, and to note anatomical changes, if any, in cases where the oval niche was visible.

In a case of chronic suppurative inflammation of both middle ears, in which the right stapes was removed a year ago, the oval niche, one month afterwards, was found granular, a condition probably due to the neglect of the patient to continue treatment. The ear healed in a short time after removing a portion of the growths with forceps and making application of a saturated solution of copper. On July 8, 1893, examination of the right ear revealed a thin membrane over the oval niche. Ear perfectly dry. Hearing in the right better than in the left ear, which still continues to discharge. Before the operation the hearing was more acute in the left than right ear. Tests in hearing on July 8, 1893, as follows:

$$W = R\ \tfrac{3}{60},\ L\ \tfrac{3}{60}$$
$$V = R\ \tfrac{8}{25}\ \tfrac{30}{85},\ L\ \tfrac{1}{25}\ \tfrac{3}{85}$$
$$\text{F. C.}\ \tfrac{a}{b}\ \tfrac{c}{c},\ R\ \tfrac{10}{85}''\ \tfrac{30}{85}''$$

Hearing was practically the same as when tested immediately after the operation a year ago. This seemed rather surprising, considering the subsequent inflammation in the oval window, with every condition favorable for the occlusion of the opening by adhesion.

The wound in the drum in most cases was found cicatrized. In a number of cases where the drum, previous to operating, was wanting, as in the case just spoken of, a thin cicatricial membrane over the oval window could be distinctly seen.

A matter of considerable interest is the effect of removal on the labyrinth. The patients were closely questioned for any symptoms of vertigo, but it was found in one case only, that of a woman forty-seven years of age. Dizziness was, however, an old complaint with her, and was very likely due to dyspepsia. She volunteered the information that the trouble was less frequent of late than for a short time after the operation. In a few cases, vertigo, which was complained of before the operation, had entirely disappeared.

The influence of the operation upon subjective noises, judged by these cases, is uncertain. Many in whom tinnitus existed previous to the operation, have been entirely free from this annoying symptom for a year. The reverse, though, is true in a few cases, a slight noise being noticed now at times.

The improvement noted in hearing the tuning-fork, (Politzer) both by air and bone, was found essentially the same as when tested a year ago.

The test by König's rods showed in one case a slight gain of five thousand (5,000) vibrations per second; in another, the loss of the same. In one case the considerable gain of fifteen thousand (15,000) vibrations after the operation was still held.

The test for hearing the watch indicated in some cases a slight gain, in others a slight loss. In cases of slight loss for the watch and rods, this, of course, indicating a diminished perception for high tones; the hearing power for the voice was apparently increased. This peculiarity in the relation between hearing the voice and high tones is frequently found among deaf people.

We now come to the point of greatest importance, to the patient at least; namely, a report of the hearing power for the voice. In applying this test the same words were used in all cases, for, as shown by Wolf, the pitch of the tones of speech ranges from sixteen vibrations per second to four thousand thirty-two (4,032) vibrations, nearly eight octaves, and vowels are heard at a greater distance than consonants. The opposite ear was tightly plugged with cotton, and the finger of an assistant pressed firmly into the meatus. In those cases where the foot-plate remained, there was practically no change from preceding tests. On the other hand, where the oval window had been completely cleared the hearing was practically the same as found immediately after the operation.

In the only case at that time of removal from both ears, the hearing remained perfectly good for five months, and was then somewhat impaired after a severe head-cold which closed the Eustachian tubes and caused marked retraction of the drum membrane in the neighborhood of the oval niche. The drum returned to its normal position after inflation of both middle ears through the catheter, and hearing was thereby restored. This would seem to prove, as there was no stapes in either ear, that the obstruction to hearing was due to the drawing of the cicatricial membrane into the window. About four months ago, a triangular piece of membrane was removed, under cocaine, from one side in the upper posterior quadrant, with the object of contracting the cicatricial drum. By this it was hoped to counteract the tendency of the membrane to sink into the opening. This was partially, but not wholly, successful. This case was numbered XII, and briefly reported last year as one of progressive deafness from chronic non-suppurative inflammation (hypertrophic) of several years' duration. No history of otorrhœa, but a cicatrix was found over the head of the stapes on the left side. The hearing in the left ear before operation was as follows: whispered voice not heard; loud voice, four feet; watch, $\tfrac{2}{60}$; tuning-fork C, through the air 15″ by bone-conduction in the left ear; König's rods, 30,000. Operation under ether, June 26, 1892. Stapes removed.

On July 8, 1893, about one year after the operation, the hearing was better than immediately after: whispered voice, three feet; loud voice, 21 feet; watch, $\tfrac{1}{100}$; tuning-fork A, 13″ by bone-conduction in the right; König's rods, 35,000.

On September 27, 1892, at the patient's request, the right ear was operated upon, although the hearing was fair. Whispered voice, six inches; moderate voice, 10 feet; watch, c/60. Nine months afterwards (July 8, 1893): whispered voice, 10 feet; moderately loud, 32 feet; watch, $\tfrac{1}{100}$. More concisely given in table.

$$W = R\ \tfrac{1}{100},\ L\ \tfrac{1}{100}$$
$$V = R\ \tfrac{8}{25}\ \tfrac{32}{85},\ L\ \tfrac{10}{25}\ \tfrac{35}{85}$$
$$\text{F. A.}\ \tfrac{a}{b}\ \tfrac{c}{c} = R\ \tfrac{18}{15}'',\ L\ \tfrac{15}{15}''$$

Weber equal.

König's rods, 40,000 not heard.

The tests were made after the use of the catheter, and, for the reason already spoken of, show a little better results than before inflation. The ears have remained perfectly healed. No dizziness and less tinnitus than before. The special importance of this case lies in the fact that there is no stapes in either ear. The only plausible theory for the remarkable improvement is that there is unobstructed conduction of sound-waves through the oval window, and that there they fall upon a healthy perceiving apparatus beyond.

In general, the operation described last year is employed.[2] There are a few additional details however, worthy of brief notice. During the operation the patient's head must be perfectly still. To ensure this ether should be given. As suggested in the paper of last year, an exploratory opening (partial myringectomy) may be advisable, to reveal the presence of adhesions and to determine the mobility of the stapes. For this, the use of a solution of cocaine is often sufficient. It is important to carry the posterior and upper cut as close to the auditory ring as possible, for in not a few cases the joint is on a line with this ring, or is situated a little above it. The small flap in the drum may be put back in place, and is best kept in position by the paper dressing recommended by Dr. Blake. Removal of the bone is made difficult or impossible by firm anchylosis, usually of the foot-plate, or from high position of the oval window, or what is practically the same thing, a prominent auditory ring. The crura are sometimes very delicate — perhaps atrophied by pressure — and easily break on manipulation.

If in disarticulating the incudo-stapedial joint the incus is considerably displaced, its removal is advisable, particularly if it interferes with a view of the head of the stapes. The long process of the incus, when in place tends to prevent the subsequently healed membrane from sinking into the oval niche, a condition which in one case, previously mentioned, of double extraction of the stapes a year ago, is the only obstacle which prevents the patient from almost perfect hearing for the voice.

As regards the application of the operation to some of the different classes of ear disease.

In cases of otitis media suppurativa, after the otorrhœa has ceased, the incudo-stapedial joint is often firmly fixed by bands of adhesions. Briefly described, this condition of the bone offers a mechanical hindrance to the transmission of sound-waves to the vestibule. Relieving this obstruction by removal of the stirrup has increased the hearing power for the voice very materially.

Another set of cases is very similar pathologically, otitis catarrhalis adhæsiva. There is proliferation of tissues with anchylosis of the ossicular chain. Here again, good results by removal of the bone have been demonstrated.

There is a third class, otitis media insidiosa (sclerosis), in which it is generally believed that the anchylosis is not fibrous, but osseous (Tröltsch, Toynbee). This condition is usually characterized by a high degree of deafness and tinnitus. Appearances of the tympanum are either normal or nearly so. Judging from a few experiences with this troublesome condition, the region of the foot-plate would appear to be the principal seat of the bony anchylosis. I can only say in evidence of this that in most of these cases the foot-plate, in part or whole, remained behind after the removal of the head and crura. This accident is at present unavoidable and insurmountable. As might be expected, the improvement in hearing is not as great as in the other cases. Larger experience with this class of cases may, however, give better results.

The importance of a differential diagnosis before operating is of course great. To the tests already employed in diagnosis, the vibromata may form a useful addition in determining the existence or non-existence of fixation of the stapes. It seems hardly necessary to say that diseases of the internal ear are not affected.

The following cases recently operated on best illustrate several important points.

CASE I. Partial removal of the foot-plate with stapes-hook. Rupture of the basal membrane and outflow of the perilymph.

B. S., forty-eight years old. History of progressive deafness for fifteen years, the result of an insidious middle-ear inflammation (otitis media insidiosa). The tuning-fork test revealed increased bone-conduction on the left side. Hearing for the voice less than one-half for usual tones. The left ear was operated upon February 27, 1893. Dr. W. S. Bryant was present. The operation was performed in the usual way up to the point of extraction, when the crura broke close to their insertion to the base plate. At the point of fracture the bone was found unusually slender. The plate could now be clearly seen, and attempts to pick it out, both by Dr. Bryant and myself, were unsuccessful at first. The point selected was the posterior upper edge, where the thin plate, to a large extent, overlaps the margin of the oval niche. The point of the hook was carefully kept downwards, away from the facial nerve. So firmly fixed was the bone that the hook failed to engage, and it was only by fracturing the plate in the centre, where it seemed somewhat thin, that portions were removed. Immediately on breaking through, there was an outflow of fluid from the labyrinth. A few small pieces of the foot-plate were removed and the fluid absorbed by cotton. Patient remained in bed five days, and was made very dizzy and nauseated on raising her head from the pillow. Hearing a little better than before the operation. In two weeks patient returned home. Hearing good, a little dizzy on turning suddenly, no nausea. I have recently heard that the vertigo disappeared shortly after her return home, that the hearing was as good as before the operation, and the ear had given no trouble. The oval window in this case was unusually large and shallow, and the foot-plate could be easily seen. The region of the Fallopian canal was carefully avoided.

The escape of perilymph then does not necessarily destroy the hearing. This point had been demonstrated on pigeons by Kessel. It was possible to demonstrate the presence of labyrinth fluid in but a very few cases. The slight evidence gained from these cases seems to show that the hearing was much better where the basal membrane was not ruptured by the operation. The margins of the fenestra ovalis and articulating surface of the foot-plate are encircled by a hyaline cartilage, as shown by the investigations of Toynbee, Tröltsch, Rüdinger and others. These conditions, when not too far destroyed by pathological changes, would admit of removal of the foot-plate without rupture of the membrane beneath.

[2] Transactions of the American Otological Society, 1892.

Besides firm fixation of the foot-plate, we have anchylosis of the crura of the stapes with the niche of the fenestra ovalis described by Politzer. In this class of cases the operation has met with the best results. Mobilization of the stapes has probably also met with its best results here. This proliferation of tissue is naturally more abundant in ears having passed through a suppurative process, although in the non-suppurative cases the stapes is often found firmly fixed.

Case II. Fixation of the stapes, result of chronic suppurative inflammation. Removal of the bone followed by marked improvement in hearing.

B. D., fifty-two years old. Hearing nearly destroyed, the result of long-continued suppurative otitis media. Examination on April 3, 1893, revealed extensive destruction in the right membrane tympani. The left membrane had been entirely destroyed with the exception of a very narrow edge at the insertion in the annulus tympanicus. The only ossicle that could be made out was the stapes, the head of which was firmly bound by adhesions. There was a slight mucopurulent discharge from the ear. There was no hearing in the right ear, it being totally deaf for all sounds through the air. The tuning-fork C was not heard at all by bone-conduction. Upon the left side a loud voice could be heard through a conversation-tube. Bone-conduction good.

Considering the fact that the stapes was firmly anchylosed and that the bone-conduction was normal, the conditions seemed favorable for operative interference. The adhesions around the head were divided and the knife carried a little way into the niche before the bone was sufficiently movable to attempt its extraction. Traction on the bone produced some dizziness which was quite marked on its removal. Immediately after the operation the ordinary voice could be distinguished at four feet. This marked improvement continued for two days to the patient's delight, when inflammatory reaction set in and the hearing steadily decreased. While this lasted the hearing was very bad. The ear is now healed and the hearing is improving. At present it is:

Watch not heard on contact.
$V = \frac{1}{5}{}_{5}$; T. F. C. $\frac{a\ c}{b\ c}\ \frac{0''}{14}$
Weber not heard.

The results in this case were excellent up to the time of reaction, which entirely closed the oval niche with swollen mucous membrane. Reaction has been the exception, and was in this case very likely due to the presence of a purulent discharge in the ear.

The next case, one of those forlorn hopes for which as little might be expected from removal of the stapes as from any other known means of treatment, is briefly reported.

Case III. Deaf mute. Double extraction of the stapes.

Miss G., of Pittsburg, nineteen years old, recently a scholar at Clarke Institution for deaf mutes. Hearing began rapidly to fail about ten years ago. Family history good, and has always enjoyed good health. In December, 1892, when I saw the patient, both drum membranes were nearly normal in color and position. The long process of the incus was visible in both ears. No hearing for any sounds by air or by means of the conversation-tube. Tuning-fork said to have been heard through the cranial bones. On December 29th the operation was performed on the right ear in the usual way, under ether. Little resistance was encountered in the removal. There was no dizziness and the patient was up and about on the next morning. No reaction. The hearing was improved, isolated words and the tuning-fork heard through the conversation-tube. Encouraged by this slight gain, and at the patient's request, the left ear was operated upon two weeks later. Some difficulty was met with in dividing the incudo-stapedial joint, caused by a rather long bony projection on the tip of the long process of the incus. As before, there was no reaction or discomfort other than usually attends the administration of ether. The hearing was not improved. A loud noise through the otophone caused a slight pain for a day or two. A lesion of the auditory nerve or sound-perceiving apparatus was strongly suggested by the tests made before the operation, and it was confirmed afterwards by the results.

In reviewing the year's work the following conclusions are drawn:

(1) The operation is followed by the best results in the class of cases where, from the increase of tissue, the effects of suppuration or hypertrophic inflammation, the stapes offers an obstruction to sound-waves; by its removal the hearing is improved. The results in cases of otitis media chronica insidiosa on account of failure to extract the foot-plate are not encouraging.

(2) Inflammatory reaction is unusual and followed by no bad results.

(3) The hearing is not necessarily impaired by the subsequent growth of a thin cicatricial membrane over the fenestral niche.

(4) Some cases of tinnitus and aural vertigo are relieved, and there is little chance of causing permanent vertigo in cases where it had not previously existed.

(5) It rarely happens that a patient improves for all tones. Improvement in hearing the human voice is out of proportion to the improvement for other sounds, and the reverse sometimes occurs.

(6) Failure in some cases may be due to hæmorrhage into the labyrinth at the time of the operation. It is believed to be a rare complication, but was thought to have occurred in one or two cases.

(7) In removing carious ossicles, the stapes if found diseased should also be removed.

Clinical Department.

A CASE OF SUDDEN DEATH IN AN INEBRIATE.

BY E. P. HURD, M.D., NEWBURYPORT.
Medical Examiner, Third Essex District.

Frederick Frederickson, a Norwegian, aged forty years, was admitted to the "Houston Institute," Newburyport (an institute for the cure of inebriety by a secret method), July 4, 1893. There is nothing in his antecedents to be recorded except that he was of a healthy, long-lived family, and had never been sick prior to his entering the "Institute." He had been intemperate for twelve years, taking a variable number of drinks of hard liquor and of beer every day, and indulging in frequent sprees, to the impoverishment of himself and family. He was also an inveterate smoker.

He was examined at the Institute by the attending physician, who noted nothing pathological except a weak, intermittent pulse and heart (supposed tobacco heart). He was placed under the usual treatment, alcohol and tobacco being soon completely withdrawn, and various tonics given in their place.

August 7th, he left the Institute "cured," but with more or less pain and discomfort in the region of the heart; there was some shortness of breath and complete inability for exertion; he was unable to work at his trade of silversmith.

The night of the 17th he was unable to sleep on account of severe pain, of a stabbing, burning nature, in the region of the heart, and general restlessness and distress. In the morning, he went to the Institute for relief; became rapidly worse, asked to be taken to his home, not more than a block distant, and died on the way.

This was the second sudden death occurring among the patients of this Institute within a week.

The directors of the "Houston Cure Company," realizing the unfavorable light in which the Institute was placed, and believing that the treatment there given was not responsible for these deaths, desired to vindicate themselves before the public by procuring an autopsy on Frederickson. There was, in fact, no little excitement at the North End by these two sudden deaths, both happening within three days.[1]

On requisition of the mayor, I performed an autopsy on the afternoon of the 18th; Drs. F. A. Howe and C. W. Stiles were present.

The immediate cause of death was fatty degeneration of the heart. This did not appear to be dependent on atheroma or occlusion of the coronaries, which seemed everywhere sound and competent, though embedded in an abnormal amount of fat. In places, as in the wall of the left ventricle below the auriculo-ventricular furrow and at the apex, the muscular tissue was entirely replaced by adipose, which could be easily torn through by the finger-nail or handle of the scalpel down to the endocardium. There was everywhere a great increase of the normal fatty tissue.

The solid organs of the abdomen were hyperæmic and more or less altered. The spleen was congested and softened; its pulp the consistence of *bouillie*. The liver was hypertrophied, filling the whole of the left hypochoudrium, encroaching on the stomach and pressing upwards the diaphragm, thereby embarrassing the heart; it was firm, hard, and cut with great resistance, as if cirrhosed. The kidneys were enlarged and smooth; capsule opaque, injected and easily detached. The parenchyma was injected, and a copious bloody exudation followed section. Both cortical and medullary portions were swollen, of dark-brown color, and soft; in fact, any difference existing between these portions was hardly to be distinguished. These organs were apparently in a state of sub-acute inflammation. The stomach was empty. This organ was not attentively examined.

The autopsy exonerated the Houston Institute, by showing that this man died of fatty disease of the heart and other lesions, in all likelihood the result of chronic poisoning by alcohol.

Primary fatty degeneration of the heart found apart from valvular lesions or marked atheromatous changes in the arteries, in a young or middle-aged person with no known hereditary predisposition or diathesis, is strongly suggestive of chronic alcoholism. In fact, it is regarded by some authorities as almost peculiar to this form of poisoning.

Pains similar to those of angina pectoris — in fact, so markedly resembling typical angina pectoris as to be easily confounded with it — may occur in other conditions besides coronary stenosis, as in the case above reported.

Doubtless inebriates in the condition of Frederickson, are not fit subjects for Houston or other "institutes" for the cure of inebriety, and will live longer on a moderate allowance of alcohol. There was, however, nothing in the antecedent history of this man to indicate that he was not a fit subject for the abstinence treatment, and it is impossible to tell how much the morbidity may have increased during the five weeks that he was at the Institute.

[1] The first case was that of John L. Jones, an epileptic who died suddenly, during the period of withdrawal, by a convulsion.

AN EPIDEMIC OF SCARLET FEVER; ETIOLOGY.

BY DAVID DANA SPEAR, A.M., M.D., FREEPORT, ME.

ON the 21st of September there appeared in my field of practice an epidemic of scarlet fever, which in one week's time assumed the proportion of twenty-five cases, mild in character but well marked, going through the several stages in a typical manner, having the rash, the high fever, the angina, and finally exfoliation of the derma.

The interesting point in all these was the inception. All of my patients were attendants at one and the same primary school, in which there were two school-rooms — one on the first and one on the second floor. All of the cases occurred from the school-room on the first or lower floor. All of the cases occurred from eight to eleven days after the opening of the fall term.

The school-room had just undergone a thorough overhauling and repairing. Many of the old benches had been taken up; quite a large portion of the old floor had been taken out and replaced by new floor-boards; a good deal of dust was disturbed and let loose in the room, which, however, was swept and painted, and the walls tinted, before the opening of the school.

Some two years ago several cases of this same disease broke out in the same room; and every three or four years, over the space of some fifteen or more years, a case or two of scarlet fever has appeared among the attendants at this school.

In 1875, there very suddenly appeared in this village a large number of cases of scarlet fever; and during that fall and winter a large number of scholars from this school were attacked. I treated ninety-eight cases. An account of this epidemic was given in the *Medical Record* of New York (Vol. X, page 782, for 1875). In that article the conclusions were drawn, (1) that in one case it was barely possible that the disease occurred independently; (2) that an unaffected person may be the carrier of the disease over many miles; (3) that the character of the disease was not determined by any peculiar feature of the disease from which one becomes infected, but rather by some existing condition in the person attacked.

The additional conclusions from this present epidemic seem to be that the contagion of scarlet fever can be kept alive for a long space of time. I have

no doubt but that the school-room from which this present epidemic started, has preserved the germs for infection since September of 1874.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY FRANCIS S. WATSON, M.D.

RESECTIONS OF THE KIDNEY.

Kummel [1] publishes an interesting article on the subject of "Resections of the Kidney," in which, after referring to some experimental researches with regard to resections of the kidney in animals, he describes his own experience of three such operations in human subjects — noting similar operations already performed by Czerny in 1889, and by Waitz in the same year.

Of the writer's three patients, the first was a woman, aged forty-one, from whose right kidney he removed a stone of the size of a walnut. Finding a portion of the kidney practically destroyed by multiple abscesses, he removed that part of the organ. The wound made in the kidney was only partially sutured — that part of it left open was sewed to the skin — and packed with iodoform gauze. The wounds healed completely, though slowly; and the patient made an excellent recovery.

The second case was a male, aged fifty-four. The chief symptom was pain and tenderness in the region of the right kidney, and hæmaturia. An incision was made parallel with the costal arch. On exposing the kidney there was seen at its upper end a yellowish area about the size of a walnut. This, together with a wedge-shaped section of the kidney, was excised. Sutures failed to control the hæmorrhage. The kidney wound was thereupon fixed to the outer wound, and packed with gauze. The wound healed rapidly. The patient left the hospital at the end of three weeks, apparently well. Six weeks later he returned. A tumor of the bladder was then discovered. This was excised through a suprapubic cystotomy. Rapid healing and recovery followed. The wound made in the bladder by the excision was sutured. Ten weeks after the last operation the patient died of pneumonia and empyema.

The third case was one of echinococcus of the kidney, in a woman of thirty-four. In this case the kidney was reached by a similar incision to that practised in the two preceding cases. The kidney was greatly enlarged. Numerous echinococcus cysts were found, and freely incised. The cysts were then excised, together with portions of the kidney adjacent, by wedge-shaped incisions. The sutures failed to control the hæmorrhage, as in the second case; and the kidney was, as in that instance, fixed to the outer wound and packed with iodoform gauze. About one-half the kidney was removed, the pelvis not being injured. This patient made a good recovery.

TUMORS OF THE BLADDER.

Fenwick [2] reports the results of his observations and operations upon thirty-two cases of bladder tumors, in all but two of which tumors were removed.

In three cases the tumors were reached by the perineal incision, in nineteen by the suprapubic route, and in eight through the dilated female urethra.

Only two deaths occurred as the result of operation. In both, death was due to suppression of urine; and in both the tumors were small papillomata. Both patients had had attacks of influenza not long before the operations.

In one of the other patients there has been no evidence of recurrence, more than four years having elapsed since operation. All the other patients who had benign tumors were alive and well at the date of the report, four years or less having passed since the operation.

In one case of carcinoma, recurrence occurred three months after thorough removal; and in four other cases recurrence is noted.

Early operation is urged by Fenwick in all cases of benign growths, and also the benefits to be derived from the use of the cystoscope, in skilled hands, in making diagnoses.

SOME NOTABLE CASES AND OPERATIONS.

(*a*) Cabot [3] reports a case of "Calculous Pyelitis, with Complete Suppression of Urine for Seven Days: Relieved by Operation," as follows:

The history pointed to the previous destruction of one kidney by calculous disease and to the plugging of the ureter of the other kidney by a calculus. In spite of the long-continued anuria (seven days), the patient had had no uræmic symptoms until the last day. Hoping to find and remove the obstruction in the ureter, Cabot performed a median abdominal section, the incision being made between the symphisis pubis and the umbilicus. The right kidney was found to be enlarged to thrice its natural size. The left kidney was normal in size. No stone could be felt in either of the kidneys or ureters. The left kidney was then exposed by an incision in the left loin. Careful bimanual palpation of the left kidney — one hand being in the abdomen, and the other in the wound in the back — failed to reveal any stone. The operation was then abandoned. The abdominal wound was sutured throughout; that in the loin was partially closed, and drained. Three hours later a catheter was passed into the bladder, and thirty-seven ounces of urine were evacuated from it. Polyuria followed for some days, and then gradually ceased. Convalescence was satisfactory. A fortnight after the operation some grains of calcareous matter were washed out of the bladder. Cabot attributes the dislodgement of the obstructing calculus from the left ureter to the accidental kneading of the kidney which occurred while endeavoring to feel the stone by means of his bimanual examination through the wound.

(*b*) Milton [4] reports the "Extraction by Laparotomy from the Human Bladder of the Largest Stone ever recorded as successfully removed."

This stone weighed thirty-four and one-half ounces. The patient was an Egyptian, aged sixty. A mass extending to the umbilicus could be felt, and a sound passed into the bladder came at once upon a stone. An abdominal incision was carried from the umbilicus to the pubes, exposing the anterior surface of the bladder. An attempt was made to strip the peritoneum from the anterior face of the bladder; but it failed.

[1] Arch. für Klin. Chir., Bd. lxiv, 2d Heft., p. 310, 1893.
[2] British Medical Journal, June 10, 1893.
[3] Boston Medical and Surgical Journal, August 31, 1893.
[4] Lancet, September 16, 1893, p. 667.

Thereupon the peritoneum was incised freely. The bladder was next incised, from its summit to its neck anteriorly — its peritoneal covering being, of course, divided. After making two lateral wounds in the course of the first bladder incision, the stone could be delivered by upward pressure exerted by two fingers in the rectum. The bladder wound was closed, except for a small opening at its lower part, with silk-worm-gut sutures; the peritoneum with catgut, and the outer wound, except at its lower angle, with silver wire. There was no peritoneal reaction afterward; and the patient recovered from the operation, but died about two months later. The autopsy showed advanced disease of both kidneys. The largest diameter of the stone was six inches.

This case is especially interesting in view of the recent advocacy from various quarters, of opening the bladder through its serous surface as well as below, in order to get more room to work in, in certain difficult cases.

(*c*) Dittel has recently reported a case of total extirpation of the prostate, with recovery, in a man of thirty-two, who had been suffering from severe hæmaturia. A suprapubic cystotomy showed the source of the bleeding to be from a tumor (afterwards shown to be a fibroma) springing from the prostate. The growth was thought to be too large to allow of satisfactory removal through the suprapubic wound, and it was reached from below by an incision from the coccyx to the anus, separating the rectum from its attachments and then exposing the prostate by an oval incision. The urethra and bladder were not opened in this operation. Through this opening the prostate was wholly removed. The bladder was drained through the urethra, and the wound packed with iodoform gauze. The patient made a perfectly satisfactory recovery.

SURGICAL INTERFERENCE IN CASES OF RENAL TUBERCULOSIS.

In our last report we included a summary of an article of Facklam's,[5] upon the question of surgical interference in cases of renal tuberculosis.

In the September number (1893) of the *Annales des Maladies des Organes Genito-Urinaries*, is published a short critical review of the same subject by Dr. E. Vigneron. Dr. Vigneron points out that surgical interference in cases of renal tuberculosis dates back only twenty-five years, and that the subject has been exhaustively treated only since 1890. He refers to the articles of Tuffier, Facklam and Heydenreich as the most recent and important contributions to the subject; and he compares his own conclusions — arrived at independently — with those of the other surgeons just named, as follows:

NEPHROTOMY IN RENAL TUBERCULOSIS.

Facklam: 36 cases, general mortality 33.33%, operative mortality, 13.8%.

Vigneron: 54 cases, general mortality 38.18%, operative mortality, 12.7%.

Vigneron advises against early surgical interference in renal tuberculosis, following in this respect the teachings of Professor Guyon.

His conclusions in regard to nephrotomy are, that the operation affords relief in many cases, and that radical cure may follow its performance in some rare instances. In this connection, he cites the case of a child upon whom Guyon performed a nephrotomy six months before, and whose general and local conditions showed such remarkable improvement that a permanent cure is looked for.

He considers nephrotomy indicated when the patient is suffering, is losing ground, and when both kidneys are affected.

The success of the operation depends upon the manner of its performance. It is essential to open freely *all* pus cavities, and to remove, so far as possible, all cheesy masses; to drain freely; and to suture the edges of the renal wound to the lumbar incision, so as to allow the interior of the kidney to be easily cleansed and dressed. If these steps are not taken, the operation is useless.

The following figures are given in regard to nephrectomies:

(1) ABDOMINAL.

Tuffier	11 cases,	mortality, 26.3%
Facklam	13 "	" 30.0%
Vigneron	19 "	" 26.84%

(2) LUMBAR.

Tuffier	45 cases,	mortality, 28.2%
Facklam	75 "	" 28%
Vigneron (primary)	65 "	" 40%
Vigneron (secondary)	20 "	" 35%

Vigneron accounts for the higher rate of mortality in the series of cases which he has collected by the fact that it includes a larger number of cases operated on in the earlier days of nephrectomy, when the technique of the operation was less perfect.

The author urges secondary nephrectomy rather than primary, and considers that if it is so done the mortality is much less than with primary nephrectomy. The best time to choose is a few weeks after a nephrotomy, as soon as the general condition of the patient has improved.

Nephrectomy should be considered only in those cases in which the disease is unilateral. Vigneron considers that renal palpation and the endoscope will, in most cases, make a decision in this respect perfectly possible.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

JAMES J. MINOT, M.D., SECRETARY.

STATED Meeting, Saturday, October 28, 1893, Dr. A. L. Mason in the chair.

DR. C. F. WITHINGTON read a paper entitled

MEDICAL TEACHING IN GERMANY.[1]

DR. J. C. WARREN: My experience dates back twenty-five years, and it is interesting to me to hear what is going on abroad at present in medical teaching, and to see what kind of impression it makes upon my mind as compared with what the teaching of that time made. Twenty-five years ago I went abroad as a graduate of the medical system of teaching in this country, and I had that as a standard to gauge what I saw there. In making a comparison to-day, I feel that there is not that tremendous superiority which existed at that time. At about that period there was a grand exodus from this country to certain parts of Europe. It seems to have gone by generations. At the beginning of the century Edinburgh or London

[1] See page 585 of the Journal.

was the centre of medical learning. During the first quarter of the century Paris was the great centre of medical education, and our fathers went there. About the time when older members of the present generation began to finish their medical education there was an increased exodus to Europe from this country, and it was stimulated by the rising reputation of the German universities. That set of men brought back to this country what there was of best in the methods of teaching in Germany at that time. The Germans always used to say to me, as they did to other Americans at that time, that the Americans were very practical; and I think we fully deserved that opinion, because we assimilated with our usual adaptability all the good things we found, and brought them back and grafted them on American soil; and I think we have now the product, I will not say the finished product, but a pretty thoroughly elaborated product, to compare with the mother universities. I feel that we can look perhaps with a great deal of pride upon the result. I do not think we appreciate what strides the best schools in this country have made in the progress of medical education. I had it impressed very strongly upon me at the Pan-American Medical Congress in Washington this summer, when the guests from the southern part of this hemisphere were invited to see what we were able to show them in the United States in the way of medical sciences and of medical education. It came over me then that insensibly during this period of time the best schools in this country have been improving wonderfully. Among those schools I may mention Harvard, the College of Physicians and Surgeons in New York, the University of Pennsylvania, Johns Hopkins; and I dare say there are others. I had this also impressed upon me, that the institutions I have named are pretty universally conceded in this country to be the leading institutions, and are looked upon with pride not only by the graduates of those institutions, but also by the medical profession at large of this country. They take a just pride in the progress those institutions have made.

The question comes, How far have we developed? Have we the right to consider ourselves equal to either of the three geographical centres of learning which I have spoken of? There is, I think, very little doubt that we are fully equal, if not superior, in our methods of teaching to the universities in Great Britain; and I find that this is a pretty common opinion amongst those who are familiar with the subject. The examinations which are required of one who wishes to obtain a license to practise in Great Britain are higher, perhaps, than in most of the medical schools in this country, but we ought to remember that they do not represent the teaching that is done there. The examinations are far above the teaching that is given in the English medical schools. They have to be prepared for especially by a sort of cramming process. There are coachers who prepare one for medical examinations in Great Britain. We all know in a general way that the medical schools of London are composed of the staffs of the various hospitals. They have magnificent hospitals in London, magnificent material, but their organization must necessarily be far below that of such a great university as Dr. Withington has sketched. There are no such great laboratories and places for investigation, and no such massing together of great names. The teachers in London are scattered; their work is not in unison; their separate schools divide up into a great number of little schools; and I do not believe the instruction is as good as it would be if in the hands of one or two great universities. To be sure, there is a great university at Edinburgh that has a far larger number of students than any in this country. The same principle, however, I think, prevails there; and I doubt if the average student gets anything like as systematic an education as in the best schools of America. In regard to Paris, I do not know how much the system has changed under the republican government. I doubt if there has been any change. I must say the system which I saw there was very unsatisfactory indeed. The opportunities for an advanced student were far inferior to those which existed in Germany. There are certain special branches in certain parts of France which are rich in splendid material, and I have no doubt, if a person wishes to study a certain subject, he might go to certain parts of France and have opportunities that, perhaps, might not be afforded in Boston or in New York even. We all bow down still to the power of German science. We are still under its sway. That is the Mecca of to-day, but I am not sure that it is going to remain so for any great length of time. I doubt, and I think Dr. Withington's statement confirms my doubt, whether the average student really gets, after all, a better education during his four years in Berlin than he gets in Boston or in Philadelphia. I think Americans, with their practical methods, have wonderfully systematized the teaching in all the specialties of medicine, and also have wonderfully improved the preliminary instruction, the laboratory work; and I feel pretty confident that the standard which we provide for the average student of to-day is nearly of as high quality. When we come to the advanced instruction, we have as yet hardly any centre which can compare with a great centre like Berlin, where there are so many brilliant scientific lights still presided over by the genius of Virchow, giving to it a prestige which he is able to keep up to its present point of greatness; and I have no doubt that in certain branches of medical science it is far ahead of any other part of the world, but I should not say it was in all. I should not wish to particularize, partly because I do not know. I think there is little doubt that we are gradually equalling them in many departments; I do not see why, with the phenomenal increase of this country in material prosperity, we should not be able to surpass them in the beginning of another century; and I do not think it is being too enthusiastic to predict that the early part of another century will find the centre of medical education in an entirely different quarter of the globe from what it has been in before.

Dr. F. C. Shattuck: I am very glad to have heard Dr. Withington's interesting and valuable paper. It is profitable for us now and then to take account of stock, as it were, to see where we are absolutely and relatively to those to whom we have been accustomed to look up and to whom we still look up. In so doing it seems to me that we can fairly feel encouragement. There has, of course, been advance on the other side of the water with the advance in knowledge. With this advance we have kept apace, but we have also greatly improved our methods of and facilities for instruction, and we note a very real increase in what is demanded of those entering medical practice. Formerly it was impossible to get a really good medical education in this country, and the attainments and achievements of

many Americans in medicine and surgery during the early years of the century are evidence of American intelligence and of the practical turn of mind of which Dr. Warren speaks. The result is in striking contrast with the paucity of means. At that time a few men went abroad for their whole medical education. Gradually many began to go for clinical advantages, as medical education here was chiefly a matter of didactic lectures, and the only chance for clinical work was in the private practice of the preceptor. Hospitals were small, as was the number of those requiring hospital care, and these hospitals were not intimately connected with medical schools. Ample clinical facilities are now offered in this country in many schools, and the rapid development of laboratories of all kinds is meeting the demand. I was glad to hear Dr. Withington say that, in his judgment, the advantages of Europe to-day are rather for practitioners than for less advanced students. I was somewhat struck to-day by a conversation with a very excellent hospital interne. I asked him about his plans for the future, whether he should go abroad, etc. He said he expected to go, but not to study medicine, as it seemed to him that he could get everything here if he went to work in the right way. I do not mean to say that I entirely endorse this opinion, but I am sure that he would not have spoken so even ten years ago. With reference to clinical instruction, I was much interested in what Dr. Withington said about the methods of undergraduate teaching pursued in the German universities, the predigested pabulum given to the students, the limited opportunity to train their powers of observation. This seems to me a serious defect. The English schools have their defects, as Dr. Warren has pointed out, but they have one great merit. The hospitals and schools being most intimately associated, as they are, every student can and must serve terms as clinical clerk and dresser in the wards, thus coming into close contact with the disease. It is to be hoped that clinical teaching in this country will develop along English rather than German lines, though we should aim to adopt what is best in both.

DR. D. W. CHEEVER: I should like to say a word, principally of retrospect. I think it is, as Dr. Shattuck has said, very much to the credit of American life and American institutions that in the early days of our country, after the Declaration of Independence, for the first twenty-five or thirty years, so many men of distinction in medicine and surgery did arise in this crude region where there were no opportunities, where the doctor had to make his own clinic, where he had to seek with great peril for every anatomical research, and where he had to develop entirely the characteristic of self-reliance in practice, and especially in surgery. Some noted things were done in surgery in the country fifty and seventy-five years ago, which have never been surpassed; so also some discoveries were made in medicine. At that time it was the exception for any one to have the means to go to Europe to study; and I fancy that those who studied with Abernethy and Sir Astley Cooper could be counted on the fingers' ends. Certainly I recall only two or three gentlemen in Philadelphia and Boston who came back after the facilities and the advantages of foreign study; and they easily took the first place in this continent, and carried on the advance of medical knowledge. I belong myself to that period which studied in France. What I had not learned in Boston I got in Paris. I lived there some length of time. At that time the advantages there were these: immense anatomical material (which was very scanty here), so that there one could study anatomy at will; in addition to that (and which grew out of it), very fine instruction, in operative surgery. The French had easily surpassed others for a good while in mechanical dexterity in surgery; and the opportunity for operative courses in Paris was enormous. In fact, it was only limited by the purse of the individual; and even so, the expense was not very great. In addition to that there were great clinical facilities, of which there were absolutely none in Boston except those afforded by the Massachusetts General Hospital, which was then much smaller than now. Clinical teaching in the amphitheatre in the course of operations was almost unknown at the time I was a student. Very little was said. A thing was said to be a cancer and was cut out, and a limb said to be crushed and cut off; but no amount of teaching in explaining the details of operation. Of course, the contrast when I got to Paris was enormous in the amount of clinical material and in the enthusiasm of teaching. But the great fault of Paris at that time, and I am sure that it is still so, was that the facilities were scattered — the hospitals miles apart, the great men scattered about in different hospitals. You had no concentration of opportunities. You were obliged to go a great distance to see skin diseases, another great distance to see diseases of women, another great distance to see surgery; you wasted time in locomotion and fatigue. It has always seemed to me with regard to the English schools, having twenty years afterward visited London and seen some of the best men there, that wherein they excelled was in individual teaching. You get individual teaching in England. I dare say you get it in Edinburgh. You get individual teaching from the fact that the schools are small; you are in close contact with the teachers, and have practically clinical instruction very much as if you were with a single practitioner and seeing his cases and seeing all his work. The great loss of time, however, in London to the stranger is in the fact that the hospitals are scattered, and there is no great centre as there is in Vienna and Berlin; but in those two or three great cities the advantages must be unequalled for saving time and for seeing everything, and for finding everything you want in the same place. Now, with reference to Boston, I, of course, share with others in the appreciation of the fact that we have improved a good deal in medical teaching; and I think one reason why we are advancing so fast in clinical facilities is from the change in our population. We get an immense foreign population of the poorer class. They go to hospitals, submit to hospital discipline, are less fastidious about being shown and being made clinical material of. There is less prejudice against hospitals and autopsies than formerly. At the City Hospital there are many more autopsies than formerly, and we have an immense *clientèle* to draw from. The change in the language and habits of these people is enormous. The institution has become practically polyglot; you need five or six languages to know what you are about. This class of people — comprising Swedes, Italians, Russian Jews, Poles — are poor people; they seek hospitals. This, I think, is why the City Hospital has grown out of proportion to the city; and is becoming, perhaps, a large burden upon the tax-payers. But this is going to give us precisely those opportunities for

concentrated clinical instruction which I think will end in making Boston, by and by, a metropolitan centre for medical knowledge.

DR. J. C. WHITE: I have listened to the paper with a good deal of interest. I suppose Dr. Withington's remarks will apply chiefly to graduates who go abroad to study. I think we sometimes talk in an unwarranted manner of foreign schools, when our personal experience is chiefly limited to the graduate courses, which are given at them. For our clinical teaching at home we have good hospitals, and those hospitals have good staffs, which are largely composed of teachers in the Medical School, but the remarks that have been quoted here as coming from young men, apply to those favored ones only who receive hospital appointments, but these are exceptional instances. The great majority of our students do not have such facilities at all, and they will not get them in my opinion until schools have their own hospitals and can apportion the term of interne service to every student fairly and evenly. Our hospitals now give a few students eighteen months to two years of such advantage. That same period might be divided among four students with great advantage to the class as a whole, that is, four times as many students could be receiving proper education in the hospitals. In other words, it is the managers of the hospitals that control the time of service of students, it is not under the control of the schools at all. The few men who have these privileges get advantages they could not get in the same time abroad it is true, yet that is no way to measure the clinical teaching that every student receives here.

I do not wholly agree with what Dr. Warren said with regard to the French school at present, I think it has grown immensely within the last few years, in many ways. It has given up its old method of complete satisfaction with itself which the Vienna school still largely retains. The latter can be said to be scarcely growing at all in some ways. The reason is that the French teachers no longer look upon French medicine as a national school by itself. It is medicine in general which they are studying, and some of the greatest teachers in France at this time are going to school; having their laboratories where they work and teach their students every day. The most notable feature in foreign schools at the present time is this great change that has taken place in the method of their teaching; the renunciation of sectional doctrines, the cultivation of a broader, international spirit.

DR. E. W. CUSHING: It seems to me that Dr. Withington's paper, in the tone of it, hardly does justice to the spirit in which medicine is studied and taught in Germany and in Berlin. I have nothing to say in regard to the methods of undergraduate study as they are there and here. My education in America was many years ago. All the more complete part of my education I got in Germany. A system must be judged somewhat by its fruits. Whether the Gymnasium or the Realschule is the best training for students is to be seen by the clinical teaching of the foremost men that grow out of it; and Germany can show that that is a good way to breed great teachers and students and workers. Leaving out of consideration the great teachers, I have noticed on many occasions that on almost any subject connected with medicine there was a certain profundity of erudition, a certain thoroughness of training in students, both in Germany and in France for that matter, training in the details and fundamentals which did not seem to obtain in this country. The main difference, however, in the facilities for studying in Germany and here, is in a system which does not obtain to any great extent in this country, and I think could well be introduced, although I am not posted particularly in medical teaching, that is, that the students can go to whatever university they like and have their time credited. If a student in Berlin thinks he cannot get enough clinical material, and wants to go to Vienna, that time is credited. In that way he can pick out his teacher and his place of living, spending his four years to his own best advantage. Also there is a very elaborate system by which the teachers are moved about. When I was in Berlin, we will say in 1885, Schroeder had an assistant who was then completing his term of five years; then he became professor in Halle, then in Göttingen, now he is professor at Würzburg, and finally he may get back to Berlin. That is the only way in which a clinical teacher gets ahead; and all the best physicians finally get back to Berlin, whereas a man who will not leave Berlin and devote his life to be a teacher, will not get to be professor. In that way the government of the great universities have the pick of the whole country, and there is a regular rotation by which a man starts in life with the idea of being a teacher. The government gives recognition of that spirit, encourages scientific research. After the last French war, when Berlin was established as capital of the German Empire, the government tried to make that the centre of the empire and of the world, if possible; to supplant Vienna and have Berlin the intellectual head of the kingdom; to draw the educated youth of the country to that place, and not by force, but in such a manner that no professional man could feel that he could afford to enter on his profession without going to Berlin. To that end vast sums were spent in building the finest hospitals of the world and in equipping and supporting them, as a political measure and as a measure of aggrandizing the new capital. I have just had an opportunity of going about to see the hospitals of this country; and I am free to say there is no such hospital in this country as the new one in Berlin, Am Urban. The government and society protects and respects a man as a teacher apart from his making any money out of his position; and although that feeling is growing in this country, and must grow a good deal before it will be comfortable for a medical man to devote himself to science as apart from money making. If he tries to devote himself to science, some older and shrewder professional friend comes along and says, "Don't bother too much with pathology; you can hire a pathologist for five dollars. If you work on science, people will think you have no practice." But with the support of the government, the recognition of a whole great circle of scientific workers, who are aiming to be teachers without obtaining a great practice, goes to breed a spirit of zeal for scientific work in itself which has developed in this country very much in the last ten years. Whether by the beginning of the next century it is going to eclipse Germany I very much doubt; but the zeal for science, the seeing of very thorough work in any one department, is what a graduate going to Germany can find. The vast aggregation of clinical material, the ease of following out the instruction in any one department, is what he can get in Vienna. He can study one thing all day in Vienna. If he knows what he wants to study, he can lay his day out and study that one thing.

If he wants to study all sorts of things, he can do that also. I think if a man has had his hospital course here, and wants a year of post-graduate course, he will do better in Vienna, on account of the ability of choosing what he wants to do and of being able to pursue any particular line of study. In Berlin he can find the highest possible development and thoroughness in any one study; especially in the subjects of surgery, gynæcology, bacteriology, there is a perfection of technique and a completeness of equipment hard to find elsewhere. I dare say the same may be true of other subjects which have not come under my immediate observation. I will close by saying, that everywhere in Germany, Austria, France and Italy, I have had to admire the zeal and erudition of the teachers, their interest in their subjects, and the kindness and courtesy with which foreigners in general, and I myself in particular, have received information, facilities for study and civilities of all kinds, in such a way that, I, for one, feel under deep obligations to the teachers of those countries.

DR. WITHINGTON: I did not say anything in the paper about the instruction in England; but as that has been referred to, I will say that I think we have nothing to be ashamed of in our best medical schools as compared with London. In one respect they have the advantage, and that is that their examining boards are distinct from their teaching boards. With such a stiff series of examinations they cannot afford to let their instruction drop very much below what it is at the present time. As regards comparison between results of our own schools and those of Germany, one thing ought to be borne in mind, that while we may contemplate with a tolerable degree of satisfaction the comparison between our *best* schools and the best schools of Germany as far as undergraduate work is concerned, yet that no such comparison can be made between the *average* medical schools of our country and those of Germany.

THE NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting held at the New York Academy of Medicine, Tuesday evening, October 3, 1893, DR. M. ALLEN STARR, President, in the chair.

MEMORIAL OF PROFESSOR CHARCOT.

This paper was read by the President. The author gave a brief sketch of Charcot's life, and reviewed the work of the great neurologist. Prof. Jean Marié Charcot was born in Paris, on the 29th of November, 1825. He was the son of a wagon-maker, a man of such limited means that he was not able to give all his children an education. Jean Marié received his early education at the Lycée St. Louis, at that time the best academy in Paris. After his preliminary education was completed there, the choice of the medical profession was made not without some hesitation, for the inclination of the young man was for the life of an artist, and it was possibly the lack of means which finally determined him to take up medicine. After passing through the medical school and serving as an interne in La Salpétrière — an alms-house for old women, then almost unknown, but later to become famous as the seat of his wonderful activity — he took his doctorate degree in 1853. For the next three years he served as chief of the medical clinic in the medical school, supporting himself meantime by giving private lessons. He was then appointed physician to the Central Bureau of Paris, on a moderate salary. In 1860, after passing a rigid competitive examination, he became entitled to a hospital appointment, and two years later he was able to select the service at his old hospital, La Salpétrière. He found a large number of old people collected together in this poor-house, many of them suffering from chronic incurable diseases. He had the opportunity to watch the progress of disease, both acute and chronic, in old age; and, most important of all, he had unlimited pathological material to complete his clinical observations. It is to this latter fact that he owed the beginning of his reputation, for at that time pathology was just beginning to reveal the true reasons for disease. By the careful study of his cases, by his power to seize upon salient features which gave points for differentiation, by his persistent following of cases from the ward to the autopsy-room, and by the exhaustive study of the material collected there, he began to reach conclusions and to arrive at facts which were veritable discoveries in the medical world. The articles written by him between 1860 and 1870, each of which adds a distinct fact, observation or conclusion to the sum of medical science, soon began to attract attention; and the young physician found his rounds beginning to be attended by students who liked to watch his careful study of cases or see him demonstrate the lesions which he found. In 1866, a small room in the hospital was set aside for the purpose of instruction, and he began to hold clinics and to lecture. The lectures were soon crowded by graduates in medicine, and the next year he was invited to give an open course of lectures at the École Practique of the medical school. Here he had an opportunity to cultivate the power of teaching, and soon showed that wonderful facility of clear, direct statement and power of graphic illustration which later made his lectures the most attractive in the world. His first open course had for its subject cerebral hæmorrhage and softening. In subsequent lectures he discussed the clinical and pathological differences between paralysis agitans and multiple sclerosis: the arthropathies, which have since been known as Charcot's joint disease; trophic disturbances following cerebral and spinal diseases, etc. Thus within four years he had risen from the position of an unknown teacher to the position of one of the best lecturers in the Paris school.

In the year 1870, all female epileptics and hysterics who were not insane, were transferred to La Salpétrière. This afforded Charcot new material for study; and in 1872 the study of hysteria in its multiform manifestations became one of his duties. The same year he was appointed Professor of Pathological Anatomy in the Faculty of Medicine in Paris, the highest prize in the French medical world. In 1882, a Professorship of Nervous Diseases was founded in the medical school, and Charcot received the appointment, with the establishment of a public clinic at La Salpétrière. From that time to the present year his annual courses of lectures have been attended by students of medicine from every land; and it may be truly said that few men of eminence at present living and working in neurology have not drawn inspiration from his model clinics.

Charcot's collected works will fill fifteen large volumes. He was also instrumental in founding a number of medical journals. His three volumes of lec-

tures, published from 1872 to 1880, have had an immense sale. Public recognition of Charcot's abilities and eminence was not wanting. He had been president of all the chief medical societies in Paris, was corresponding member of numerous societies abroad, among them being the New York Academy of Medicine and the New York Neurological Society; he was made a Member of the Institute of France in 1883, and Commander of the Legion of Honor in 1892.

Charcot's investigations in hypnotism have attracted much attention, both from the profession and from the laity. It is difficult for any one to enter upon the study of this subject, or to pursue it with any degree of thoroughness, without exposing one's self to adverse criticism and remark. It is difficult to estimate the true value of this department of Charcot's labor, but it cannot be denied that all through the years which he devoted to this study his mind has been imbued with the purest scientific motives, and that facts, not theories, were his aim.

Another criticism which has been offered is, that in his scientific zeal, he neglected therapeutics: that his interest in patients ceased with the diagnosis. Those who make these statements must surely forget that our best methods of treating functional and hysterical nervous diseases, namely, the electrical and hydrotherapeutic methods, were successively developed and successfully employed by Charcot.

Charcot was a man of great dignity, of calm, even temper, of slow thought and utterance, but of much reserve power. In appearance like Napoleon, and in manner reserved and observant, he was not the type of man to be popular. With patients suffering from trifling affections he showed no sympathy; probably no interest. With patients whose diseases were severe or obscure or of a rare type, he was kind, attentive, interested, and was ready to spend valuable time in most careful investigation. His relation to his pupils was also one of mutual interest and affection. He was never familiar with them, yet he always respected and sought their opinions, was never autocratic in the direction of their work, and was always the subject of their devoted admiration and respect. His family life was a delightful one. He was married early in life to a lady of considerable wealth, who was enthusiastic in his work, and by whose aid many scientific undertakings, otherwise impossible, were carried through. He had two children, one a boy, whom it was his fond desire to see succeeding him as a physician, and who gives promise of being worthy of the name. Charcot, like every man of eminence, had his enemies — critics in science — rivals in medicine; yet, after all their criticism is exhausted, we must admit that he remains the greatest French physician since Trousseau, and the greatest ornament of the profession of the present age.

At the completion of Dr. Starr's address, Dr. E. C. Seguin gave a few personal reminiscences of Professor Charcot. He referred to the generosity of the great physician in placing at the disposal of his students his abundant material and the use of his laboratories, and in allowing them to receive the full credit for their labors, instead of appropriating it to himself. Many of Charcot's pupils, Bourneville, Bouchard and others, have been helped by him in every possible way to attain honorable positions. In disposition he was quite different from the popular idea of the Frenchman. He was not quick, nor hasty nor mercurial. Every thought was carefully matured, and he collected his material for a long time before reaching or publishing his conclusions. He was averse to theorizing. He was a close analyst and a devoted follower of the induction method in reaching conclusions. Primarily, Charcot was a pathologist, and his reputation will always rest on his achievements in this field of medicine. His work in hypnotism, by which he was greatly fascinated, can only be regarded as a mere fragment — a digression which in the future will count as nothing.

A CASE OF GENERALIZED PARESIS ENDING IN COMPLETE RECOVERY,

by Dr. E. C. Seguin.

The history of the case is as follows: The patient was a boy aged thirteen years, who was brought to Dr. Seguin in October, 1886, for an opinion as to the nature and prognosis of a singular condition of increasing muscular weakness, which had come on during the preceding eighteen months. The boy's family history was fairly good. His mother was of a nervous temperament and for a few months had been addicted to the chloral habit. Out of six children only one other, a sister, had had a nervous disease, namely, a mild chorea extending over several years. There was no trace of muscular disease, atrophic or distrophic, in the family. The patient's history, previous to the onset of this disease, was negative. At the age of six years he had a severe attack of albuminuria, which left no traces. In April, 1886, he had what seemed to be a mild attack of articular rheumatism. He was a very active and daring boy, and had numerous falls, none of which, however, were followed by serious symptoms. There was a history of masturbation, carried on for several years. There was no history or evidence of metallic intoxication, nor at any time was there any indication of hysteria. The only positive causative element in the case was the self-abuse. This practice, the boy stated, he had given up in the spring of 1885, when he himself noticed that he had slight difficulty in articulating his words. Five months subsequent to this the boy's symptoms were first brought to his father's attention by the fact that he twice fell out of the saddle and by his suddenly dropping the oars in a boat and acting as if paralyzed for a few minutes. Even before that, it was recalled, he had become rather awkward in buttoning his clothes and in using the knife and fork, and that after reading aloud for a few minutes his articulation became thick. Very gradually he lost his energetic ways and became awkward in everything; his attitude had changed so that he stooped, the neck hanging down and the abdomen protruding. His facial muscles lost much of their expression and his laugh was constrained and unnatural. All these symptoms developed and progressed very slowly during the years 1885 and 1886. The boy was subject to "sudden collapses," as his father called them, characterized by the sudden loss of control over many muscles, resulting in falls or in dropping objects from the hand. These last-named symptoms suggested petit mal, but this affection was excluded after careful observation. The symptoms were entirely of a motor order; no numbness, no anæsthesia, no neuralgia, no psychic or trophic symptoms. All his organic functions were normally performed; nutrition was good. The eyes were normal. The legs were apparently strong, and the boy could rise from the dorsal recumbent posture on a flat couch and also from a squatting

posture, but these acts were done feebly, slowly and with great effort. The spine was not tender and presented no deviation, excepting an antero-posterior one. Local paresis of the muscles was demonstrable only in the extensor group of the right forearm. No muscles showed atrophy or hypertrophy. The knee-jerk was normal. No sensory symptoms, excepting a sense of fatigue in the muscles of the lips and tongue, as well as those of the forearm on exertion. On electrical examination the reaction of the nerves and muscles to both currents was normal. The sexual organs showed no visible signs of masturbation. Grasp on dynamometer; right hand 11, left hand 16.

The above were the facts of main importance elicited at the first examination made by Dr. Seguin in October, 1886. The boy remained under his care from that time on for about two years, during which period he decidedly improved in motor power and skill, and his height increased by six inches. The treatment from the first, in the absence of any possible pathological diagnosis, consisted in the systematic, long-continued administration of tonics, such as the bichloride of mercury, phosphorus, arsenic and strychnia. At the same time, a mild faradic current was applied systematically every day. Also, from the first, a cold sponge bath was ordered on rising or at bed-time, followed by a thorough dry rubbing and a manipulation of all the muscles. Another part of the treatment consisted in gentle gymnastic movements of the hands, arms, trunk and legs.

The case was lost sight of by Dr. Seguin from the close of the year 1888 until September of the present year (1893), when on inquiry, he received a letter from the boy's father stating that his son is now in the junior class at college, that he stands well in his class, and excels in wrestling and other athletic sports. The treatment advised by Dr. Seguin had been faithfully carried out for nearly three years longer by the father, followed by a gradual, but continued, improvement in the boy's condition. His weight at the present time is 166 pounds. Circumference of chest: expiration, 33 inches; full inspiration, 39 inches. Circumference of waist, 31 inches; of mid-thigh, 22 inches; of biceps, 13 inches. His endurance is good and he is able to raise from the ground an iron rail weighing 600 pounds. His grasp on the dynamometer at present is, right hand, 72; left hand, 53. This, Dr. Seguin said, is the strongest grasp he has ever met with.

DR. B. SACHS said that in listening to the first part of Dr. Seguin's paper — before it told of the boy's remarkable recovery — the case reminded him of a primary muscular dystrophy, of the facial, scapular, humeral type, with perhaps some extension into the lower extremities. Such a case has recently come under his observation, with many symptoms very similar to those narrated by Dr. Seguin. In cases of progressive primary dystrophy, particularly in pseudo-hypertrophic conditions, he has seen marked temporary improvement following treatment, although he has never observed a complete cure. Again, in Dr. Seguin's case there might possibly have been some nuclear trouble, with a mingling of symptoms pointing to the spinal cord or medulla. If the case was one of primary muscular dystrophy, the question arises whether the cure will be a lasting one. He has seen a number of cases with a condition of pseudo-hypertrophy, in which the muscular tissue first enlarges and then rapidly atrophies.

DR. GEORGE W. JACOBY suggested that Dr. Seguin's case might have been one of poly-myositis ending in complete recovery, and followed by a secondary hypertrophy of the muscles, which now exists.

DR. J. F. TERRIBERRY stated that it was against the laws of pathology to assume that an inflammatory process in the muscular tissue is followed by hypertrophy of the muscle, with increased force.

DR. E. D. FISHER said that when we take into consideration the fact that the boy grew six inches taller while he was under Dr. Seguin's care, the lesion was probably not a spinal one.

The discussion was then closed by DR. SEGUIN. He stated that the suggestion made by Dr. Sachs with reference to the possibility of curing a case of muscular dystrophy in its early stage was an interesting one; he was not prepared, however, to advance the case as an instance of that disease. Neither did it resemble a case of myositis. There was no pain; there was a general weakness, which was sometimes so pronounced that the boy was unable to hold objects in his hands, or he would lose all control over his muscles and fall to the ground.

Recent Literature.

Naphey's Modern Therapeutics, Medical and Surgical including the Diseases of Women and Children. A Compendium of Recent Formulæ and Therapeutical Directions from the Practice of Eminent Contemporary Physicians, American and Foreign. Ninth edition. Vol. II, General Surgery, Gynecology and Obstetrics. By ALLEN J. SMITH, Professor of Pathology, University of Texas, Galveston; late Assistant Demonstrator of Morbid Anatomy and Pathological Histology, and Lecturer on Urinology, University of Pennsylvania; and J. AUBREY DAVIS, M.D., Assistant Demonstrator of Obstetrics, University of Pennsylvania; Assistant Physician to Home for Crippled Children, Philadelphia. Philadelphia: P. Blakiston, Son & Co. 1893.

The volume which we have before us has passed through nine editions, which is an evidence that it fills a need in the community. The views of authors have been collated by the compilers, but in many instances are diametrically opposed to one another, and the reader is allowed to select for himself and adopt the view which strikes his fancy. Many of the authorities quoted we are not familiar with. There can be no doubt but that the book contains a great deal of useful information; and, as a whole, we can only congratulate the authors on the accomplishment of a work so satisfactory.

Reactions. A Selection of Organic Chemical Preparations Important to Pharmacy in Regard to their Behavior to Commouly-used Reagents. By F. A. FLÜCKIGER, Ph.D., M.D. Translated, revised and enlarged by J. B. NAGELVOORT. Authorized English edition. Detroit: George S. Davis. 1893.

This volume is a revised and enlarged edition of the German text. It contains the results of Professor Flückiger's researches upon more than one hundred organic pharmaceutical preparations, to which the translator has added, in many cases, the results of his own experience. The book is of special interest to the pharmaceutical profession, and will be very useful.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 14, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

EPIDEMIC INFLUENZA.

THE reports of a threatening epidemic of influenza, which have been published during the past two weeks, have been most alarming. So far, they have been almost entirely confined to the daily press, and have served a most useful purpose in making startling and vendable items for the metropolitan Sunday papers.

There has undoubtedly been a return of the disease to some extent abroad, especially in England and some parts of Germany. The number of cases reported in London is said to have doubled during the last month, and over thirty members of Parliament were reported as ill at one time with that or some allied disease. On the Continent the epidemic is said to be even more marked, not being confined to political gentlemen. In the Upper Rhine and Main regions it approaches the virulence of the plague, and a fifth of the whole population of Hesse-Darmstadt is reported down with it. Parliamentary work at Vienna ten days ago was at a standstill because all the officers of both houses were suffering. In Berlin, also, the type of the disease, which is fast becoming general, is said to be more severe than in former epidemics. The alarming nature of their report is somewhat mitigated by the continuation of the account in one of these letters, which says: "Its latest form differs from the Russian variety. The disease is not so dangerous or prolonged as the more familiar grip, but is more infectious. It is almost like measles in this respect. The victims include all classes."

The London *Lancet* of December 2d makes the following statement in regard to influenza:

"There seems a strong tendency to a pretty wide diffusion of this disease in the metropolis. The attacks are not so serious or fatal as on some occasions, but they are very typical — characterized by abrupt onset, a sharp pyrexia, generally subsiding in a day or two, unless complicated with catarrh, which is not always the case. It is decidedly infectious, in some houses almost every member being affected."

From the *British Medical* of the same date, we take the following:

"Reports which reach us from our correspondents show that influenza in epidemic form continues to prevail extensively in the neighborhood of Cardiff and throughout South Wales, in Birmingham and the Black Country, in Liverpool, Manchester, Blackburn and various other parts of Lancashire. It is extending into the Potteries, and our Edinburgh correspondent writes that, after a short lull, it has broken out again in that city, and in a more grave form; some large offices, including the post-office, have had a long sick list, and the death-rate has risen during the last three weeks from 17 to 25, and last week to 27. The mortality last week was 138, and of this number no fewer than 90 deaths were due to diseases of the chest. In this epidemic again the large towns appear to be the foci of infection, which spreads thence into suburbs, and finally into country districts. The epidemic continues to be severe in Berlin, while in Frankfort and Hesse it is said that 20 per cent. of the inhabitants are suffering. In Posen and East and West Prussia, the epidemic is very prevalent, so that in some places one-fourth of the workmen are off duty. It is spreading also in the suburbs of Hamburg, and is present in Lubeck."

It will be remembered that in the first great outbreak of recent years, that of 1889, influenza declared itself with us in a violently epidemic form about ten days before it developed or was reported as epidemic in London or England.

The occurrence of some undoubted cases of influenza has been reported from Chicago and New York. The returns of the daily press from St. Joseph, Mo., reported 400 cases in three days a week ago, and at Denver, Col., we were told it was then even more prevalent than in 1891. It will, however, be time for a general alarm to be issued when the reports so far published have been confirmed by competent medical advices, which as yet we have not received. Careful inquiries among practitioners and at the hospitals fail to elicit any facts tending to show the presence of any unusual form or degree of influenza in Boston or its vicinity at the present time, although some medical men report having seen individual cases, and a few speak of having seen families afflicted with the disease.

It is to be hoped that the reports will be found to be exaggerated, and that the community will be spared another epidemic. For epidemic influenza is even worse than epidemic foot-ball; it is rougher and more dangerous.

THE ADMINISTRATION OF HOSPITALS FOR THE INSANE IN NEW YORK.

THE laws of New York and Massachusetts have placed those States in the foremost rank of intelligent and liberal care for the insane. The enactments regulating the commitment to asylums, and the care while there, of the insane, and especially the State Care Act of New York, have been in the main wise and beneficent. They are chiefly due to the persistent efforts of the State Board of Charities, and especially of Mr. Letchworth, Chairman of the Board, and Mrs. Lowell, and to the excellent administration and advice of Dr. Stephen Smith, the former Lunacy Commissioner.

The essential points of superiority in the New York system are (1) the control of the hospitals by an unpaid board of managers free from personal and political motives; (2) the appointment of medical officers by merit and not through political favor; (3) the maintenance of State hospitals of a high grade of excellence

for the curable insane and for those needing hospital care; (4) the removal of the chronic and pauper insane from poor-houses, jails and county asylums to inexpensive buildings under the supervision of the officers of the hospitals, with the establishment of farms or colonies for such of the insane as do not need much medical care, where they can be treated as nearly like sane and industrious people as possible.

The weak point in the New York law is that a plan for centralizing in a State Commission power as to details of management of the hospitals, which was overwhelmingly defeated in the Massachusetts legislature, has become part of the New York statute, and that the Lunacy Commission, which ought to be a purely supervising and advisory board, has executive functions which are not only needlessly vexatious to the hospital managers and medical officers and prejudicial to the interests of their patients, but also may be destructive of good morals. Moreover, the law is in danger of making a corrupt political machine out of what ought to be a philanthropic and unselfish body.

There are indications that what was feared has happened, and that the Lunacy Commission, which it is possible to construct into part of a great party machine, has made the enforcement of a bad law even worse than the law itself. The managers and medical officers of the hospitals for the insane have taken courage from the political upheaval in favor of good government in their State, and are attempting a reform, in which we wish them every success.

MEDICAL NOTES.

THE REVOLT OF THE BRAZILIAN MEDICAL STAFF. — The entire medical staff of the Brazilian navy, which has been loyal up to the present time, has joined the forces of the insurgents and placed itself under the orders of Admiral Gama.

A NEW JOURNAL. — A new journal, devoted to diseases of children, has recently appeared in France. It is entitled the *Journal de Chirurgie et de Thérapeutique Infantiles*, and is edited by Dr. Variot of Paris.

CHOLERA. — There has been a decided increase in the cholera in Constantinople during the last two weeks, over thirty new cases occurring daily. There have been several deaths from the disease in Tripoli. In Russia there has been, on the whole, a diminution in the number of cases. In Italy a few cases occur from time to time in Leghorn, Genoa and Naples; but the epidemic is practically at an end in these cities. The outbreak in England, which was speedily checked, has not recurred and no cases have occurred since the last report.

YELLOW FEVER. — The yellow-fever epidemic at Brunswick is practically at an end, no cases having occurred since November 23d. The quarantine camp was closed on Thanksgiving Day, and the people allowed to return home. In all there were one thousand and one cases and fifty-three deaths: forty whites, one Mongolian and twelve blacks.

BOSTON AND NEW ENGLAND.

VACCINATION AND QUARANTINE OF CONTAGIOUS DISEASES AMONG SCHOOL CHILDREN REFERRED TO THE BOSTON BOARD OF HEALTH. — At the last meeting of the Boston school committee, the following order was passed: "That the Board of Health be requested to assume the responsibility of issuing certificates of vaccination required by law, and of passing upon all cases of contagious diseases, determining when children may return to school after such disease or exposure thereto, and giving the requisite certificates: and that the said Board be further requested to include in their estimates for the next fiscal year a sufficient sum of money to enable them to attend to these new duties."

SUICIDES FROM CYANIDE OF POTASH. — Since the publicity given the mysterious deaths of the members of the Toole family in South Boston from cyanide of potash, the drug has become a popular one for suicides, three self-inflicted deaths having been due to this drug.

SMALL-POX IN BOSTON. — During the last week ten cases of small-pox have occurred in Boston. On December 7th the disease was reported from a family at the South End; and within two days the father, three sons, three daughters and the servant were taken to the hospital. A cousin of the family — a woman — was also taken ill at her home and sent to the hospital. None of these cases can in any way be traced to the cases occurring from the *Catalonia* in October. The cousin came from New Brunswick about a month ago, and was the first member taken ill; but the most careful investigation shows no connection with the previous cases. All these patients had a family gathering about Thanksgiving time, and two of the guests present have also been taken ill with small-pox during the week — one at Somerville and one at Hyde Park. The tenth case in Boston is that of one of the table-girls at the Homœopathic Hospital, who had never been vaccinated, but who has had no discoverable exposure. Of the eleven patients now in the hospital only one had ever been vaccinated, and that one is slightly ill. Of the seven discharged well since October 30th, three had been vaccinated, and were but slightly ill; while the others were seriously ill. Two of the present patients are dangerously ill, and their recovery is considered doubtful.

A NEW HARVARD RECORD FOR STRENGTH. — The Harvard record for total ascertained strength, which has been held since 1885 by Mr. S. T. Foster, has been surpassed by a member of the present junior class, Mr. Edward Klein. His total strength, as measured by Dr. Sargent's method, is 1,445 kilogrammes, which is 97 kilogrammes more than the previous record. This total is distributed as follows: lungs, 23; back, 340; leg, 740; upper arm, 201; right forearm, 78; left, 63.

Massachusetts Insane Asylum Reports. — The annual reports of the superintendents of the various State insane asylums are being issued from the office of the Secretary of the Commonwealth. Danvers Lunatic Hospital had at the end of the official year, September 30th, 869 patients, seven more than last year. The report of Dr. Page calls attention to the unavoidable overcrowding at times, which necessitated the use of extra cots in the day-rooms and corridors. "The vital objection to this overcrowding," he says, "arises from the necessary mingling of acute cases with the many chronic patients, which is a serious obstacle to the recovery of the former." The average weekly cost of maintaining each patient was $3.55. At the Worcester Lunatic Hospital there were 886 patients, five less than last year, 439 men and 447 women. The daily average number of patients has been 878.78, the largest within the history of the hospital. The cost of maintenance per patient has been $3.58 per week. At the Worcester Insane Asylum, there were 454 patients, 231 males and 223 females, a gain of five over the first of the year. The average daily number has been 447, or 82 more than the normal capacity of the institution.

Diphtheria at West Newton. — An unusually large number of cases of diphtheria and scarlet fever are reported from West Newton, Mass., there being about twenty-five cases of the former disease and nearly as many of the latter.

Small-Pox in Portland. — A case of small-pox is reported from Portland, Me., the patient, a man of thirty, had been ill for two days in a large boarding-house, which is now under quarantine.

NEW YORK.

Epidemic Diphtheria. — Diphtheria is epidemic at Tivoli, on the Hudson, and one or two adjacent villages, and a large number of deaths have occurred. In order to prevent the further spread of the disease the State Board of Health has enforced strict quarantine regulations, including the closing of all the schools and churches.

Electrical Execution. — The most successful electrical execution that has as yet been made was that of the murderer, Delfino, at Sing Sing prison on December 4th. The apparatus was in perfect working order, and death was instantaneous. For four seconds a current of the strength of 1,760 volts was employed, and it was then reduced to 160 volts and so maintained for forty-six seconds.

Dr. Paul Hoffman. — Dr. Paul Hoffman, Assistant Superintendent of Public Schools, who was injured by a Broadway cable car on November 24th, died in consequence of the injuries thus received on December 2d. Several of his ribs were fractured, and a few days after the accident pneumonia set in. Dr. Hoffman, who was fifty years of age, was born in Switzerland, though of German parentage. He was a graduate of the Medical Department of the University of Berlin, and had travelled extensively; at one time being physician to the Sultan of Johore. He had resided in New York for a number of years, but never practised medicine there. In 1877, he became connected with the Department of Public Education, and in 1881 was appointed to the position which he held at the time of his death. Dr. Hoffman had charge of the school children's exhibit from the city of New York at the Chicago World's Fair.

Mortality. — The advent of winter weather has occasioned a considerable increase in the city's mortality. The number of deaths reported during the week ending December 2d was 759, representing an annual death-rate of 20.63 per thousand of the estimated population; against 676, representing an annual death-rate of 18.39, in the preceding week. The average death-rate of the corresponding weeks for the past five years was 19.60. During the week there were 109 deaths from contagious diseases, an increase of 32 over the previous week. During the week ending December 9th the number of deaths reported was 731, representing an annual death-rate of 19.86, against 20.43, the average for the corresponding weeks of the past five years. There was a decrease of 17 from the preceding week in the mortality from phthisis, though there was an increase of six in the deaths from bronchitis. Three deaths were attributed to influenza, against one in the week ending December 2d.

Miscellany.

THE ANCIENTS AND LEPROSY.

Much of the difficulty encountered by the commissioners in obtaining the family history of lepers in India is accounted for by the *Indian Medical Gazette*, by reference to the ancient beliefs handed down to the people and still authoritative among them. It gives the following translations from the sacred books:

Susruta, Nidanasthanam (Chap. V, p. 223). — "They say that leprosy originates from murder of Brahmins, women and good men, theft, and such like acts."

Charaka Samhita (Chap. VII, Treatment of Leprosy). — "Those who insult Brahmins, or elders, and commit other sins, (get leprosy)."

Manu Samhita (Chap. XI, 49th *sloka*). — "The stealer of Brahmin's gold gets bad nails; the alcohol drinker gets black teeth; the murderer of a Brahmin get consumption; and the violator of a *guru's* (spiritual guide's) wife gets leprosy."

Manu Samhita (Chap. V, 166th *sloka*). — "The wife who commits adultery is an object of contempt in this life, and becomes a jackal, or gets leprosy and other sin-begotten diseases in the life to come."

It is thus popularly assumed that a leper must have committed some such sin as adultery with a *guru's* wife, or, as commentators add, with a stepmother, etc., and the like. What a sinner such a man is thought to be, may be judged from the following prescribed atonement:

"The violator of the wife of a *guru* after confessing his guilt, must lie on a hot iron bed, and embrace a red-hot iron female effigy till death, which will purify him."

The ideas of physicians upon the heredity and con-

tagion of leprosy, were not less accurate than those of modern writers, as is shown by the following statement of the great medical writer, Susruta:

"Women and men, having their blood and seminal fluids corrupted from leprosy (not of the white kind), get their offspring lepers."

"The diseases named below are transmitted from one person to another by sexual intercourse, by touch, by the breath, by taking meals in the same dish; by sleeping in the same bed and sitting on the same seat; by putting on the same garments, by wearing the same garland, and by using the same ointments: — leprosy, fever, consumption, ophthalmia, and small-pox of different kinds."

THE INCREASE OF INSANITY IN ENGLAND.

MUCH has been written lately about the great increase of insanity in England in the last few years. The daily and periodic press especially have delighted in the alarming state of affairs and while some competent observers are inclined to believe in an increase of the disease, the general results of statistics furnished by the Commissioners of Lunacy are offered to this view.

Dr. Rayner, in a recent article,[1] says that an analysis of these statistics shows three clear and definite facts: (*a*) that in the last two decades there has been a progressive diminution in the number of mentally afflicted under the age of twenty-five years; (*b*) that there has been an inconsiderable increase between the ages of twenty-five and forty-five; and (*c*) that practically all the excess of increase has been in persons above the age of forty-five years. The decrease of insanity in the population in the first twenty-five years of life, if satisfactorily proved, would go far to convince those who have actual experience of the insane that this must correspond to a diminution in the total production of mental disease. The tendency to increasing degeneration in the families of the insane, resulting in later generations in mental defect, is a well-established fact. If, therefore, there has been a diminution in the early decades of life, this must correspond to, and be the result of, a lessening of hereditary influences.

The increase in actual number of persons confined in asylums is owing to several factors. Yearly the advantage of institutional treatment for the insane is better appreciated, and families are more willing to send their afflicted members away from home. Another reason is the transfer of pauper and criminal insane to the proper asylum instead of confining them to almshouses and jails. An eminent alienist physician, of large experience in prisons, recently expressed the opinion at a public meeting that a not inconsiderable part of the decrease of criminals was due to the fact that many weak-minded persons, formerly classed as criminals, were now relegated to asylums. The statistics in support of this view are, however, not easily available. Still another reason is found in the greatly increased survivorship of persons mentally affected when cared for in asylums.

The only form of mental disease in which a great development is alleged is general paralysis; but the apparent excess is probably chiefly due to increased care in diagnosis and to such cases being more largely sent to asylums. This form of disease, however, with an average asylum duration of two to three years, would not greatly add to the permanent numbers, except by an increase much beyond that which is claimed for it.

The asylum population (whatever the causes) has increased since 1871 by about 30,000, and if the facts relating to increased survivorship under asylum treatment have any cogency, this (survivorship) would by itself account for the small advance in the census numbers of the insane under the age of forty-five, from 2.24 per 1,000 of population in 1871 to 2.26 per 10,000 in 1891, without resorting to any theory of actual increase.

The ultimate conclusion is that the evidence at present available admits of the interpretation that there is no real excess in the amount of occurring insanity, but is even compatible with the possibility of an absolute diminution, which has certainly occurred in the earlier decades of life, and is probable in the well-to-do classes.

[1] British Medical Journal, November 25th.

SOME MORE INTUBATION STATISTICS.

IN the much vexed question of the relative merits of tracheotomy and intubation, there is one factor which should be allowed its due weight and which has not yet been sufficiently regarded, namely, the availability of the one or other operation in private practice. So far, the greater number of cases reported, upon which statistics and arguments have been based, have been those occurring in hospital practice. The operation of intubation is so comparatively new that the general practitioner has, as a rule, not seen a sufficient number of cases to base an opinion upon. It is for this reason that the publication of small individual experiences is likely to be of more frequent occurrence during the next few years, and of considerable value, especially when published unincorporated with other statistics.

Dr. R. J. Stanton, of New York, reports[1] 70 cases intubed by him in the course of general practice, all but two having occurred in tenement-houses, where for obvious reasons the patient's chances for recovery were poor. "Of these 70 cases, 46 terminated fatally, and the 24 recoveries gave a percentage of 34.3 successful cases. Of the 46 deaths, 14 were due to extension of membrane, five to sepsis, four each to asphyxia and pneumonia, three to uræmic convulsions, and two each to exhaustion, pulmonary œdema, nephritis and bronchitis." Of the four deaths from asphyxia, two were apparently due to membrane pushed down ahead of the tube, and two followed upon the child's pulling out the tube in the physician's absence. One of the deaths from pulmonary œdema seems hardly to belong to the unsuccessful cases of intubation, as the death occurred four days after the removal of the tube, which had been worn a week, and without any occurrence of laryngeal obstruction.

Of the cases operated on, 42 were males and 27 females, one not noted; 15 males recovered (or 35.7 per cent.), and 9 females (or 33.3 per cent). The ages ranged from ten months to seven years. The youngest successful case was fourteen months, the average age being three years and five months. Three cases (one fatal) had secondary tracheotomy. The longest period during which a tube was worn was sixteen days, by a girl four years old. In three

[1] New York Medical Record, November 25th.

cases the tube was passed into the œsophagus and swallowed; in two it was passed in the dejecta on the second and fifth day. The other case died of sepsis after secondary tracheotomy, within twenty-four hours.

Dr. W. B. Johnson, of Paterson, N. J., reports[2] 19 cases with six recoveries, one after secondary tracheotomy. Nine boys were operated upon, with five recoveries, or 55.5 per cent.; while 10 girls gave one recovery or 10 per cent. The recovery after secondary tracheotomy was in a boy three years and four months old. Of the 13 deaths, two were due to extension of the membrane, three to sepsis, two to asphyxia from membrane, and two each to pneumonia, cardiac paralysis and exhaustion. The youngest child to recover was a boy two years and seven months old. The longest time a tube was worn was ten days.

BOYCOTTING THE CHARITÉ.

THE Berlin Correspondent of the *Medical Press* sends the following account of the recent boycott of the Charité Hospital of Berlin:

For some time past the Social Democrats have had reason, or what is the same thing to them, they believe they have reason to find fault with the management and nursing staff of the Charité Hospital, and have in consequence "boycottirt" it. The Social Democrats are a very powerful body with a firm organization, and the result is that about 200,000 members of the different sick societies have determined to have nothing more to do with this hospital until fresh arrangements are made in accordance with their views. The leading spirit in the new enterprise is a young medical practitioner, named Zadek, who has the reputation of being a fanatical Social Democrat, and who has at any rate done some good work as a city deputy in the debate on typhoid fever. The grounds of complaint lie in the structural and sanitary condition of the hospital, and in the management and treatment of patients. On the latter point, however, no charges are brought against the medical staff, but only against the subordinate officials and nurses. As regards the structural deficiencies of the building, the charges may not be unfounded, as the old Charité is one hundred years old, and the new over sixty. Quite recently additions have been made to the existing accommodation, the children's pavilion, the obstetrical and gynæcological kliniken. The surgical department and the Koch barracks are models of their kind, but it must be confessed that the ancient buildings are not representative of the latest developments of science.

The second charge is that the patients, and especially those in the syphilitic department, are treated with inhumanity and deprived of their liberty. The Charité has to take in all patients sent by the police, and amongst these the *puellæ publicæ*. Those patients who commit excesses and cause a great deal of trouble cannot in the interests of order be treated exactly as the others, and it is not denied that in numerous instances some hardships have been on the one side inflicted and on the other endured. What will be the upshot of the movement, or what hospital the exacting Social Democrats will take under their protecting care, in place of the one that has excited their wrath, one cannot at present pretend to say.

[2] Journal of the American Medical Association, November 25th.

METEOROLOGICAL RECORD,

For the week ending December 2, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,135: under five years of age 699; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 310, acute lung diseases 367, consumption 245, diphtheria and croup 142, typhoid fever 43, diarrhœal diseases 42, measles 22, scarlet fever 22, whooping-cough 16, cerebro-spinal meningitis 14, small-pox, erysipelas and malarial fever 3 each.

From measles New York 18, Milwaukee 3, Philadelphia 1. From scarlet fever Cambridge 7, New York, Philadelphia, Boston and Somerville 3 each, Milwaukee and Everett 1 each. From whooping-cough New York 8, Philadelphia and Cincinnati 2 each, Washington, Milwaukee, Cambridge and New Bedford 1 each. From cerebro-spinal meningitis New York 7, Washington and Somerville 2 each, Cleveland, Milwaukee and Everett 1 each. From small-pox New York 3. From malarial fever New York 3. From erysipelas Philadelphia 2, Cleveland 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,317,846, for the week ending November 25th, the death-rate was 20.2. Deaths reported 5,185: acute diseases of the respiratory organs (London) 969, whooping-cough 120, diphtheria 114, scarlet fever 78, fever 67, measles 53, diarrhœa 43, small-pox (Bradford 10, Birmingham 4, London and Bristol 3 each, West Ham 1) 21.

The death-rates ranged from 10.8 in Halifax to 35.2 in Oldham; Birmingham 30 7, Bradford 28.0, Cardiff 24.9, Gateshead 13.8, Hull 27.2, Leeds 24.3, Leicester 23 5, Liverpool 30.9, London 26.5, Manchester 29.9, Newcastle-on-Tyne 22.5, Norwich 25.0, Nottingham 23.2, Portsmouth 17.8, Sheffield 29.5, West Ham 26.6.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 2, 1893, TO DECEMBER 8, 1893.

By direction of the President, the retirement from active service this date, December 4, 1893, by operation of law, of COLONEL CHARLES PAGE, assistant surgeon-general, under the provisions of the act of Congress, approved June 30, 1882, is announced.

FIRST-LIEUT. CHARLES WILLCOX, assistant surgeon, will be relieved from temporary duty at Angel Island, Cal., on the arrival there of MAJOR BENJAMIN F. POPE, surgeon, and will report in person to the commanding officer, Boise Barracks, Idaho.

FIRST-LIEUT. FRANCIS A. WINTER, assistant surgeon, U. S A., is relieved from further duty at Fort Wingate, New Mexico, and from temporary duty at Fort Bayard, New Mexico, and will proceed to New Fort Bliss, Texas, and report in person to the commanding officer for duty at that station.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, December 20th, at 8 o'clock.

Paper: "Remarks on the Functions and Therapeutic Uses of the Thyroid Gland," by J. J. Putnam. The discussion will be opened by Dr. W. T. Porter with a review of the recent work as to the physiology of the thyroid gland.

F. C. SHATTUCK, M.D., *Chairman.*
HENRY JACKSON, M.D., *Secretary.*

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The next lecture will be given on Wednesday, December 20th, at 8 o'clock, P. M., by Dr. H. P. Bowditch. Subject, "Anthropometry and the Laws of Growth." Physicians are cordially invited.

APPOINTMENT.

Governor-elect Greenhalge, of Massachusetts, has appointed HERBERT L. BURRELL, M.D., Surgeon-General upon his Staff for the coming year.

BOOKS AND PAMPHLETS RECEIVED.

Inebriety. By R. M. Phelps, M.D. Reprint. 1893.

The Providence Lying-in Hospital; Ninth Annual Report, 1893.

A Diatribe on Diphtheria. By James Hedenberg, M.D. Reprint. 1893.

Results of Aseptic Cœliotomy. By Wm. H. Wathen, A.M., M.D. Reprint. 1893.

Chirurgie des Voies Urinaires; Etudes Cliniques. Par le Dr. Loumeau. Bordeaux. 1894.

REMARKS ON SENDING PATIENTS AWAY FROM HOME.[1]

BY FREDERICK I. KNIGHT, M.D.

IN no department of medical practice, probably, has there been more hasty, ill-considered advice given than in that of climato-therapy. Thousands of patients go away every year at great inconvenience and expense, oftentimes with sacrifices which are never made good, who would have been far better off in every way, if they had remained at home.

Many of these go on their own responsibility, it is true, and it is no more strange that an invalid, having failed to obtain relief at home, should be attracted by glowing accounts of climate published by the proprietors of health-resorts, than that he should purchase and take any of the proprietary medicines so flatteringly advertised by the press, medical, secular and religious. Many, also, are guided by the advice of friends, and there is no subject on which the layman with slight personal experience feels more competent to give advice. We all know how ready some of our patients are to honor us by freely praising and lending to their friends prescriptions we have endeavored to carefully adapt to their individual conditions. In the same way many people having been properly advised, to their benefit, in regard to climate, are not satisfied till they have persuaded all their friends, whom they know to be out of health, to try the same. I am well aware that all patients do not do this, for I have known not a few who, when written to, as patients who improve by change of climate invariably are, decline to advise, and refer their correspondents to some competent authority for counsel.

It is strange, however, that more care is not exercised by physicians, who take it upon themselves to prescribe change. Sometimes advice is given on the street without the slightest exact knowledge of the patient's condition (I have known applicants for life-insurance to be passed in the same way). It also not unfrequently happens that the physician, having exhausted all his resources in vain, is tired of his patient, and his patient is tired of him, and being aware of this, and that his patient is liable to desert him at any moment for his rival, advises change, without much consideration of the place to which he is to go.

The consultant frequently receives a call from a country patient bringing a card, or saying he was recommended by Dr. A. He feels flattered at the consideration of Dr. A. in sending him one of his richest and best patients for consultation. When the examination is over, the diagnosis made, and it is proposed to communicate with Dr. A., the patient says: "Oh, Dr. A. is not my doctor! Dr. B. is the one we always employ; but Dr. A. told me that I had better consult you." In the same manner Dr. A. advises the patients of Dr. B. that they had better not risk another winter in New England, but get off somewhere.

What is it necessary to know in order to advise patients properly in regard to change of climate? In the first place, it is necessary to know the condition of the patient. In this regard it is not enough to know that he has tuberculosis, or laryngitis, or bronchitis. Treating the name of a disease by climate is no better than treating it by medicine. Colorado is good for some cases of tuberculosis; so is cod liver oil; but either may be very bad. I have been not unfrequently consulted by patients, who have either made up their own minds, or have been advised to make certain changes, and who seem to come for a formal endorsement of what they have already decided to do. A few years ago I was asked to see a lady and her invalid daughter at one of our principal hotels. On calling, I found that by the advice of their family physician they had rented their comfortable home, and were on their way to Colorado for the purpose of restoring the health of the daughter. On examination, I found the patient in the last stages of phthisis, with only a few weeks to live. I advised their going home; they had already given that up; but they did not go to Colorado. Last month I was asked to see a patient, with reference to Colorado, who had pneumothorax of one side, and disease also of the opposite lung.

Even patients with such advanced disease are not always amenable to advice. A few years ago I persuaded a gentlemen, who came to me with his heart set upon the Rocky Mountains, to spend the winter in Nassau. He did exceedingly well there. The next season he avoided me, and slipped off to Colorado, and promptly died.

A lady once came to me with her young son, who had been sent East from the Rocky Mountains the year before on account of heart disease. The physician, under whose care he had been in the East, had pronounced him "all right," and they were on their way back to the high altitude. They took me in on the way for confirmation of this opinion and action. It did not take long for me to convince myself that it was *all wrong*, and so I said with regret, to the mother. As they were going to Philadelphia, I advised her to visit two physicians there, whom I mentioned, not to say anything about my opinion, nor of that of one Philadelphian to the other, and if we all agreed in opinion that the boy should not go back, I should expect her to be satisfied to stay East another year. She did as I requested, and as we agreed without reference to one another, remained East.

It is necessary, in the second place, in order to give proper advice in regard to change of climate, to have some knowledge of the condition of the climate into which it is proposed to send the patient, and of its probable effect on his condition. In many cases, it seems as if it were sufficient that a place had a certain general reputation as a health resort for physicians to send patients thither, no matter what their individual condition might be. In this way, patients with advanced phthisis, and patients with degenerate heart and blood-vessels are sent into high altitudes, and, on the other hand, patients with incipient tuberculosis of the lungs sacrifice golden time by being sent into moist tropical countries. Something should be known, also, of the variation of climate at different seasons of the year. Because certain parts of our country are delightful in the autumn or spring, it by no means follows that they make good winter resorts; and, on the other hand, many a patient has lost all the gain at a winter resort by ignorantly remaining too late in the spring. The usual range of temperature for different seasons should be known, as well as the average amount of moisture in the air, the amount of sunshine, prevalence of winds, etc.

In this connection it is well to consider the social

[1] Read before the Boston Society for Medical Improvement, October 23, 1893.

conditions in which the patient will be placed, and especially the quality of the food which he can obtain. There are patients with good appetite and digestion, who will thrive on the canned food of the sheep-ranchman, but there are many who are only helped downhill by it.

It is well, also, to consider in a general way the suitability of the climate for the wife or other relative who must go along with the patient. It may be that she will be found to have a fatty heart or some other condition, which will absolutely forbid the climatic change proposed.

Again, it having been determined that there would be a risk in remaining at home, as compared with taking advantage of a change of climatic conditions, a very serious and seldom considered question arises, Can the patient properly make the change? This is often a question of expense, and should be ascertained, when possible, before mentioning the subject to the patient himself. It is cruel to set forth the great advantage of change of climate to one to whom it is utterly impossible to accept your advice. To advise a wife that going to Europe is the one thing that will restore her health, when this gratification is wholly beyond the ability of the husband, is very reprehensible, and may lead to unnecessary hard feeling in families.

Here comes in the question of a short, temporary change, or long-continued or permanent residence away. Short, temporary changes may suffice for the relief of acute conditions, but rarely for chronic ones. A patient may afford a short change, who cannot afford a long one. It is a very rare thing, though I have seen such cases, that one season's residence away from this coast will suffice for the arrest of pulmonary tuberculosis, however slight. It may not always be wise to tell this to the patient beforehand, but the fact will have its weight on the physician's own mind. Another consideration which has an important bearing is whether the patient can engage in any occupation. While it is undoubtedly better for most patients to do nothing for the first six months or year, there are certain out-door employments which may be pursued without harm. It is therefore important to know something of the nature of an occupation and its fitness for the case under consideration.

For instance, the digestion and mental temperament will have to be carefully considered in case it is proposed to put a patient on a sheep-ranch, where the life may be like this. Two men live in something which they have erected for a house, miles from anybody else. In the early morning these men rise, cook such a breakfast as they can, also the dinner which each takes with him, one walking east and the other west, till noon, when each eats the dinner which he has brought, turns round and walks "home" to meet his companion, takes supper and goes to bed, never seeing any human being for weeks but the same old chum, and him only at night. Weak lungs may stand this, but it takes also a strong stomach and a healthy brain.

So it may be said, in brief, that in order to advise properly in regard to change of climate, the physician should know:

(1) The exact condition of the patient, as far as it is possible to determine it.

(2) The condition of the climate and its probable effect upon the condition of the patient.

In this connection it is well, also, to consider the social surroundings in the proposed resort, and the food which it will be possible to obtain.

(3) The condition of those who must necessarily go with the patient, and the probable effect of the new climate upon them.

(4) The pecuniary condition of the patient in reference not only to his getting to his destination, but in regard to his ability to stay there long enough, and to provide what will be necessary for himself and family. This should be ascertained as far as possible without consultation with the patient, and before the subject of change of climate is mentioned to him.

A CÆSAREAN SECTION FOR TWIN MONSTROSITY: RECOVERY.[1]

BY JOHN F. CROSTON, M.D., AND MAURICE D. CLARKE, M.D., OF HAVERHILL, MASS.

By Dr. Croston.

At 9.15 on the morning of Monday, July 17, 1893, I was called to see Mrs. ——, aged twenty-four, primipara, who had come to full term, and who gave a history of having had labor pains since the previous Saturday, and had very likely been in labor about twelve hours. She was a person of slender physique, but had always enjoyed good health, nothing untowards having happened during the pregnancy except at the beginning of the fourth month, when she had a slight hæmorrhage from the uterus, which was controlled in a couple of days by opium and rest in bed. The family history was good; and she remembered nothing unusual in the labors of her sisters or near relatives, and had no knowledge of plural births in their families.

She informed me that the "waters" had come away during the night; and, upon examination, I found the os dilated, the membranes ruptured, and the lower extremities of a fœtus, low down in the vagina, and with toes pointing backwards towards the sacrum, presenting. Her unusual size led me to make a careful abdominal palpation, which disclosed the presence, apparently, of another fœtus in utero. I advised immediate delivery, and set out forthwith to accomplish it, under chloroform anæsthesia. After several vain attempts to extract the fœtus by the extremities, it being impossible to bring the feet lower down than the vulvar orifice, I proceeded to make a second examination per vaginam. Carrying the examining finger well up, I found the extremities of the second fœtus impacted at the brim, and, going still farther, I recognized, for the first time, the fact that I had to deal with a monstrosity and that the fœtuses were joined at the trunk.

At this juncture I sought a consultation, and Dr. W. D. Collins came to my assistance. He agreed with me as to the diagnosis; and we made a second attempt to deliver the woman, but failed. Dr. Maurice D. Clarke, who had been previously sent for, arrived at this point; and, he agreeing as to the diagnosis, the question of operation was discussed, and the Cæsarean section chosen after mature reflection. The husband's consent was obtained with little difficulty, and the operation was performed immediately by Dr. Clarke.

By Dr. Clarke.

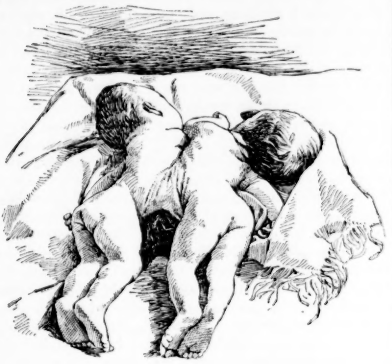
I examined the woman as soon as I arrived and found the condition described by Dr. Croston. I

[1] Read before the Essex North District Medical Society, October 11, 1893.

could see no use in further attempts to deliver after the ordinary fashion, and I agreed with the others that the question was one of a selection among operative procedures. There seemed, to my own mind, but three methods to be considered, — embryotomy, symphyseotomy, and a Cæsarean operation. The operations for the removal of the uterus and for delivery without incising the uterus (laparo-elytrotomy) were not considered and probably would not have been adopted. Of the others, the Cæsarean section appeared to us to afford the mother the best chance, embryotomy being likely to be complicated, tedious and difficult, if not impossible, while the cutting of the symphysis was not certain to allow room enough for delivery, to say nothing of other objections. For myself, I confess to a dread of a "loose" pelvis. As a matter of fact, the monster could not have been extracted entire per vaginam. So that we reached for ourselves the conclusion of the books, that the Cæsarean section is the operation for election by the average surgeon.

This point determined, I proceeded at once, upon Dr. Croston's invitation, to operate, with what might be termed comparative antiseptic precautions, by which I mean, that the woman's abdomen had not been soaked over night in antiseptics and was not washed with ether, that the operator's hands were not treated with oxalic acid and permanganate of potash, that neither dressings nor instruments had been previously sterilized by heat, and the ordinary living-room in which the operation was done had no previous preparation. On the other hand, the instruments were put into boiling water, the woman's abdomen was scrubbed with bichloride solution and the hair of the mons veneris shaved, and the hands of the operator and assistant were soaked in the mercurial solution. The patient was anæsthetized by Dr. Collins with ether, Dr. Croston assisting the operator. An incision of six inches in length was made in the linea alba below the navel, a rubber tourniquet tightened around the cervix, and the uterus at once incised. We were fortunate in not striking the placental site, and there was no hæmorrhage of moment. The monster was then pulled out with considerable difficulty on account of its previous impaction at the pelvic brim, and the placenta followed immediately. The elastic tube was removed, the uterine rent closed at once with eight deep silk sutures, the pelvic cavity hastily sponged with gauze, and the abdominal wound united with six deep silk sutures and four superficial ones, and covered with the usual dressings.

The little operative work that falls to the lot of surgeons outside of the large cities had suggested to me that a chief danger lies in shock from prolonged operations and continued anæsthesia, and it was my intention in this case to proceed with all legitimate haste and avoid at least this source of trouble. This intention may be said to have been fairly carried out, the giving of the ether having been begun at 1.10 P. M. and the patient being in bed at 2, and may have assisted recovery. For the rest, nearly everything seemed to favor it, the patient being a young and vigorous woman, in her first pregnancy, and not worn by a prolonged labor. The surroundings were not perfect, and the antiseptic precautions were not of the *fin de siècle* order (which may account for the temperature), but there was a trained nurse and good care.



This case makes the eighty-seventh Cæsarean section in this country since the improved method of operating was introduced in 1882, according to the figures of Dr. Robert P. Harris, of Philadelphia, the recognized authority upon the subject. Of the first 43, 22 women and 6 children were lost; of the other 44, 13 women and 7 children were lost, the result in one case not being known. I have been unable to find abnormal size of the fœtus among the enumerated occasions for the operation, and I supposed at the time, and since, that this was the first ever performed on account of a monstrosity. In fact, Dr. Harris wrote me that no one in the United States ever delivered a monster by abdominal section and he did not know of a parallel in any other country. The mention of this case, however, brought to light the fact, as Dr. Harris has since written me, of an operation performed in Philadelphia in 1881, by Dr. James Collins and the late Dr. Philip Leidy and hitherto unreported. The monster was a double female, one having a unilateral hare-lip, and weighed fourteen pounds. One head, protruding, was amputated; the rest was delivered by the Cæsarean operation. The placenta was extracted by the vagina. The uterus contracted at once and there were six silk sutures inserted. The woman had been in labor five days, was much prostrated at the time of the operation, and died in three days of exhaustion. The uterine wound was well closed. With this information, therefore, this operation of mine loses in priority of performance, but retains its place as the first successful Cæsarean section for this cause.

BY DR. CROSTON.

After the operation the patient was put to bed, surrounded by hot-water bags, and, upon recovering from the effects of the ether, was given a teaspoonful of hot milk every half-hour, and brandy *pro re natâ*. Seven hours after the operation the temperature was 101.4° and the pulse 118. Morphine (gr. $\frac{1}{4}$) with atropine (gr. $\frac{1}{100}$) was given that night for the relief of pain and repeated in three hours, succeeded by three hours' sleep. On the morning of the second day the temperature had dropped to 99.2° and the pulse to 100, rising by evening to 102° and 106 respectively. Urine was passed normally. The morning of the third day found the temperature still at 102°, pulse 93, and the abdomen was markedly tympanitic and tender. One-half ounce of magnesium sulphate was ordered, to be repeated in four hours if necessary. The first dose proving ineffectual, a second was given, followed in two hours by a copious dejection. There were six movements in rapid succession, and the tympanites wholly disappeared and did not return. The dressings were changed on that day. On the morning of the fourth day the temperature was still 102°, but the pulse had dropped to 80 and was of good character. The nourishment was increased in amount, and beef-juice and egg-nog allowed. From this time on, the temperature continued to drop, becoming normal on the morning of the eighth day and so continuing until convalescence was fully established. The abdominal sutures were removed on the tenth day, union by first intention having taken place throughout the whole extent of the wound. From this time convalescence was uninterrupted, and at this writing (September 1st) the woman is perfectly well and able to do light work about the house. The menses appeared normally.

The composite fœtus weighed twelve and one-half pounds, and consisted of two females of equal size, each of the average size at full term and each gaping

widely from the pubes to the navel from incomplete closure of the lateral halves of the body, otherwise normal. They were dead when born. They were

united from the sternal notch to the navel in front, and from corresponding points on one side only, by a continuance of the skin, best shown by photographs taken on the spot. There was one cord and one placenta, both unusually large.

PLACENTA PRÆVIA AT THE BOSTON LYING-IN HOSPITAL.[1]

BY CHARLES W. TOWNSEND, M.D.

AMONG the 6,700 deliveries at the Boston Lying-in Hospital in the past twenty years there were 28 cases of placenta prævia recorded. This proportion, four per cent., is four times larger than that stated by Müller, of not quite one case to a thousand births, but is explained by the fact that difficult and abnormal cases are particularly apt to be sent to the Boston Lying-in Hospital, so that the proportion of these cases is necessarily increased.

Of the 28 cases, 15 were marginal or lateral, the placenta reaching to the border of the inner cervical ring; eight were partial, the placenta overlapping the os to a greater or less extent; and five were central, the implantation of the placenta being directly over the os.

The proportion of multiparæ to primiparæ, instead of being six to one as is usually stated, was less than two to one — 17 to 11 — the difference being due partly to the large proportion of primiparæ delivered in the hospital. The proportion of multiparæ was greater in the partial and central cases, there being three primiparæ to five multiparæ in the partial class and only one primipara to four multiparæ in the central class.

Marginal or Lateral Placenta Prævia, fifteen cases.

In four cases there was no hæmorrhage until there were recognized labor pains, while in eleven hæmorrhage was noticed at varying intervals before the advent of labor. Two of these flowed about once a month so as to simulate true menstruation; three began to flow in the seventh month, two at eight months, and three at eight and a half months. In one this point is not stated. Seven went on to full term, six gave birth prematurely at eight months, two of these being delivered artificially, and two gave birth at the seventh month, one of these being delivered artificially. The hæmorrhage was slight in six, considerable in four, profuse in three; while in six the records also spoke especially of the postpartum hæmorrhage.

As regards the treatment of these cases, the majority of the patients came to the hospital in labor with the history of flowing as given above, and proceeded to give birth to their children without artificial help; the diagnosis of lateral placenta prævia being made by examination. Others, labor not being present, were kept in the hospital under close observation, and later gave birth to their children without assistance. This non-interference method was practised in twelve out of the fifteen cases. Of the remaining three, in one case where there was considerable hæmorrhage at the eighth month, a colpeurynter was inserted, and the child was born in eight and a half hours. There was also considerable postpartum hæmorrhage in this case. Two cases were delivered by manual dilatation and version; one at the seventh, the other at the eighth month, both patients having lost considerable blood — one by slow dribbling, the other by a sudden gush of one and a half pints. In the former case manual dilatation took five minutes, in the latter fifteen minutes.

As to the results in these fifteen cases of marginal attachment of placenta: All the mothers recovered. One child, born naturally at the seventh month, died in two days. One born by version died in twenty minutes, probably due to the asphyxia owing to delay with the after-coming head. The child whose delivery at the eighth month was hastened by the colpeurynter was still-born.

Case 19 illustrates this class of cases. C. D., twenty-one years old, primipara, entered the hospital with moderate flowing about two and a half weeks before the completion of her pregnancy. A diagnosis of probable placenta prævia marginalis was made by the feel of the lower uterine segment and by the hæmor-

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, March 22, 1893.

rhage. She was kept in bed a week, during which time there was a moderate leaking of blood. The hæmorrhage then ceased, and ten days later labor came on with moderate bleeding until the head came down and acted as a tampon. There was quite a severe postpartum hæmorrhage following the birth of the placenta. Mother and child were discharged well on the fifteenth day.

It may be said that the diagnosis of this class of cases is somewhat uncertain, and that some of them were simply cases of accidental detachment of a portion of the normally situated placenta. This error has been excluded as carefully as possible. In many of the cases the edge of the placenta was actually felt.

Partial Placenta Prævia, eight cases.

In two cases there was no hæmorrhage until labor began, at full term in one case, a week ahead of time in the other. In another case hæmorrhages or pseudomenstruation occurred twice a month throughout the entire pregnancy, which went on to full term. The remaining cases had hæmorrhages, first, at the fifth, sixth and eighth months and at eight and a half months and at full term respectively. Five were delivered at full term, only one of these by natural means; two at eight months; one by version; one spontaneously; and one without help at the sixth month. In this latter case there had been profuse hæmorrhages every day for three days, when the dead fœtus was expelled spontaneously, the edge of the placenta overlapping the head one-third of its extent. The hæmorrhage was slight in two, considerable in two, and profuse in three of these cases. In two, postpartum hæmorrhage was well-marked.

In the treatment of these cases of partial placenta prævia, the greater hæmorrhage demanded a greater amount of active interference. In three only the delivery took place spontaneously, the remaining five were delivered by internal podalic version, two having been first tamponed. All of the eight mothers recovered, and four of the infants; but four infants were still-born. Two of these infants were born spontaneously, two were delivered by version. It is fair to add, however, that of the two born spontaneously, one was non-viable, the other was macerated. Of the two still-born infants delivered by version, in one case there was a complicating ovarian tumor which had to be pushed out of the way before version could be done.

Case 24 is an example of the more severe cases of partial placenta prævia. A multipara (x), thirty-eight years old, was seen outside the hospital shortly after she had lost about a pint of blood by a sudden gush. She was at full term, and began at once to have labor pains. The os was two inches in diameter, and the edge of the placenta was easily felt. The vagina was packed with charpie as a temporary expedient while she was being brought to the hospital. Here she was at once etherized and easily delivered of a living child by version, the whole operation taking not much longer than one minute. A gush of blood followed the withdrawal of the arm used in turning, but the child's body acted as a tampon and stopped further bleeding. There was a moderate hæmorrhage immediately following the extraction, but the uterus contracted well and everything seemed all right. Three hours later, however, there was profuse bleeding, which was soon checked by a hot intra-uterine douche; but the patient went into an alarming state of collapse, became pulseless, the extremities cold, face blanched, heart sounds weak and irregular. The foot of the bed was raised, heaters applied, and brandy and other stimulants given subcutaneously. The patient was left in an anæmic condition, but made a good recovery.

Central Placenta Prævia, five cases.

This central form of placenta prævia is the rarest and the most serious form, so that it is worth while speaking of these cases more in detail. All of the five cases were delivered by version, a tampon having been first used in two of them. Three of the mothers died, two recovered. Four of the infants died, only one lived. It must be said, in palliation for these results, that all of the five cases entered blanched from loss of blood, two of the three fatal cases being almost in extremis. Such cases are sent to the hospital as a last resort, and in that way the fatal statistics are increased.

In one of the successful cases as regards the mother, a multipara (viii), thirty-four years old, there was no hæmorrhage until the eighth month when there was a sudden profuse flow. She was brought eleven hours later into the hospital plugged with a sponge and colpeurynter, she was extremely blanched, pulse 120 to 140, respiration 50. The os, which was about half an inch in diameter, was dilated manually in ten minutes, and the child delivered by internal podalic version. The child was dead and slightly macerated. The mother recovered after a moderate attack of septicæmia due, no doubt, to the manipulations outside the hospital and to the sponge introduced there.

Case 2, a primipara, had been flowing copiously at the eighth month for a week before she was sent to the hospital. She was delivered by podalic version without much loss of blood, but a secondary hæmorrhage occurred; she never came out of the collapse and died. The child was very feeble but was kept alive for two and a half hours.

Case 3, multipara (iv), twenty-six years old, had her first hæmorrhage at six months and three weeks, — a sudden gush while sitting on a vessel, the blood filling it one-half full. A week later she had a second severe hæmorrhage, and was brought to the hospital in a blanched condition. Manual dilatation of the cervix occupied fifty minutes, and the child was turned and delivered. During the delivery a large amount of blood was lost. The child gasped, but soon died. The mother went into a collapse, although there was no further hæmorrhage, and died in two hours.

Case 4, multipara (iv), thirty-four years old, had her first hæmorrhage, a small one, at seven and a half months. Two weeks later there was a profuse flow and she was brought into the hospital in a blanched condition. The os was at once dilated manually, in thirteen minutes the child quickly turned and delivered. It is stated that from one to two quarts of blood were lost during this procedure. The uterus contracted firmly and the patient appeared bright for an hour after coming out of the ether, and there was no further hæmorrhage. About five hours later, respiration became rapid, the pulse became small and thready and the patient died in twelve hours. The baby lived ten hours.

Case 5 I can speak of more particularly, as it occurred during my service two years ago. M. G., twenty-one years old, multipara (ii), when eight months advanced in pregnancy had several slight hæmorrhages, followed a week later by a very profuse one for which

she was tamponed by a doctor at 2 A. M. On entering the hospital at 1 P. M. the same day she was in a blanched condition, the pulse 100, weak and compressible, the fœtal heart about 210 and irregular. The patient was at once etherized, placed in a position for operation and the packing removed. The os was found to be about one and a half inches in diameter and completely covered by placenta. While satisfying myself of the diagnosis of central placenta prævia, the blood suddenly spurted out copiously by my hand. Without withdrawing my hand I at once peeled off the placenta on the left border, quickly finished the dilatation of the os and passed my hand up around the placenta. The child was easily turned, and the half breech at once checked the hæmorrhage. The child was quickly delivered and the head was followed immediately by the placenta. The uterus contracted well, but in all at least a quart of blood was lost, and there was considerable postpartum hæmorrhage, which was controlled by pressure and friction externally, and by a hot intra-uterine douche. The child was anæmic and did not cry at first, but recovered, and was with the mother discharged well on the fourteenth day.

The following table gives an analysis of these 28 cases of placenta prævia:

TABLE OF TWENTY-EIGHT CASES OF PLACENTA PRÆVIA.

	Lateral or Marginal. (15)	Partial. (8)	Central. (5)
No hæmorrhage until beginning of labor.	4	2	0
Hæmorrhage every month.	2	1	0
Hæmorrhage first at fifth month.	0	1	0
Hæmorrhage first at sixth month.	0	1	1
Hæmorrhage first at seventh month.	3	0	1
Hæmorrhage first at eighth month.	2	1	3
Hæmorrhage first at eight and one-half months.	3	1	0
Hæmorrhage first at ninth month.	4	3	0
Delivery at sixth month.	0	1	1
Delivery at seventh month.	2	0	0
Delivery at eighth month.	6	2	4
Delivery at full term.	7	5	0
Hæmorrhage, slight.	6	2	0
Hæmorrhage, considerable.	4	2	0
Hæmorrhage, profuse.	3	3	5
Hæmorrhage, postpartum.	6	2	2
Delivery natural.	13	3	0
Tampon used.	1	2	2
Delivery by version.	2	5	5
Mothers recovered.	15	8	2
Mothers died.	0	0	3
Infants lived.	12	4	1
Infants died.	2	0	3
Infants still-born.	1	4	1

THE IMPORTANCE OF EARLY ATTENTION TO THE DISABILITY CAUSED BY INFANTILE PARALYSIS.[1]

BY A. B. JUDSON, M.D., NEW YORK.

I PROPOSE to consider briefly the question whether a certain class of patients should not be committed more entirely and more early than they are to the care of the orthopedic surgeon, a consideration as interesting to the family physician as to the orthopedist, as they meet in friendly alliance to secure the greatest benefit for their common patient.

I refer to the patients disabled by infantile paralysis. The child has passed through the stage of onset.

[1] Read before the New York Academy of Medicine, November 2, 1893.

Ergot, electricity and massage have produced their legitimate effect, and we will say that the eighteen months, which are believed to be the limit of spontaneous recovery from the paralysis, are passed. The friends and the patient, with many grievous misgivings, have become reconciled, or at least accustomed, to disability and deformity which now seem to change for neither the better nor the worse. What can now be done? The question whether such a patient may not yet receive benefit from the advance of scientific knowledge, or from the daily increasing facilities for the application of knowledge, will surely spring up in the parental heart.

Now it is curious to note that the deformity in these cases is often found, upon analysis, to be a disability more than a deformity. Take a case, for example, in which the knee cannot be completely extended. When the patient is sitting there is no deformity, but when he stands the apparent deformity is due to a disability — an inability to extend the knee. How easy it would have been to prevent contraction of the hamstrings by providing for their repeated elongation by complete extension of the knee, easy, comparatively, for one who has given himself to such details, and is habitually mindful of their importance and free from the manifold cares which beset the average practitioner. And it should be borne in mind that cases sometimes occur in which shortening of the tendons begins, in a manner not well understood, at a very early stage, before simple desuetude can be fairly accused of being the author of the mischief. The prevention of muscular and tendinous shortening, then, should receive attention on the part of the early observer of the case. It is not an obscure and difficult point, but one which has, perhaps, escaped the consideration to which it is entitled.

To recur to the disabled knee, and this part of the anatomy is used simply as a convenient example to illustrate points in pathology and treatment applicable to all the joints, if the knee is kept extended at those times when walking is attempted, not only are the muscles and tendons kept in normal elongation, but the general welfare of the limb is assured. Neglected patients may be seen in the streets walking laboriously with extension of the knee produced by the hand pressed firmly at every step on the lower part of the thigh when the weight of the body is on the limb. It is doubtful whether this in any case prevents the final resort to a crutch, by the use of which the limb is made to dangle, being carried about as a worse than useless burden, twining limp around the crutch, subject to the painful affections which attack the lower extremities in cold weather in the absence of healthy circulation, and more and more impeding locomotion, until, as has happened many times, the adult patient seeks relief and improved locomotor ability in amputation and an artificial limb. If the knee is stiffened mechanically, the pressure of the weight of the body in standing and the repeated concussion of the limb, as the foot strikes the ground in walking and running, will improve the tardy circulation; but beyond this, and better than this, will be the development of unused muscular fibres and special groups of muscles, by whose action important motions will be acquired which would have been impossible if the limb had remained in suspension.

Now, in order to keep the knee firmly extended under the weight of the body in standing and walking,

and to give use and development, as far as may be, to the fragmentary muscular system of the limb, apparatus is required; but it will not be obtained without authoritative medical advice and prescription, and, as a rule, the family physician cannot be expected to work out the tedious processes incident to treatment of this kind. It falls to the lot of the specialist, who can well bear the inconvenience attending final results which are more or less imperfect, after satisfying himself that he has done all that science permits to be done, and whose daily and hourly mastery of the necessary details has enabled him to reduce perplexing and complicating conditions to familiar routine. Treatment of this kind lies far outside ordinary practice, in which the physician renders such signal service. He makes his diagnosis, advises, prescribes, remains on guard against complications, foresees the crisis and prepares for it, leads the way cheerfully through convalescence; and medical science, so dear to us all, finds but another illustration of its power and beneficence. In one home a wasting fever has been finally resolved, and the patient rises in customary, or even improved, health from a bed where the grim alternative has been decided in his favor. In another, the children have been happily carried through the perils of infection, and resume their places at the table. But in the special practice adapted to the cases under consideration, there is no fear of a fatal result and no rejoicing, and the object sought is at the best a palliation. But who will say that important service has not been rendered? for it should be remembered that the conservative and plodding practitioner along his line has for an ally one of the most potent influences in Nature in the growth of the body. The popular reliance on this force, expressed in the common question, "Will the child outgrow the ailment?" whatever it may be, is not always misplaced. Happy the physician who, imparting his confidence to the patient's friends, and relying on the exact science of the physicist, sees grace and power growing out of deformity and helplessness.

A good general rule in the treatment of deformity in a growing child is to keep the part as near as possible in the desired shape as much of the time, day and night, as is practicable, so that the increment shall be on the right side of the dividing line between the normal and abnormal. The familiar proverb says: "As the twig is bent, the tree's inclined." In the troubles following infantile paralysis the principle should be extended. We should not only persist in keeping the part as near the normal shape as we can, but we should also give as wide play as the crippled condition of the limb will allow to the functions of motion and weight-bearing. From the very earliest attempt to walk, or to make use of the muscles and joints which are imperilled by the cord lesion, extraneous assistance should be afforded. It should not be said, off-hand, that the child is too young. The first and repeated question should be: Is the child not yet old enough, or is he not already giving sufficient evidence of a desire to make use of the questionable muscles and joints to make assistance desirable or necessary?

When efficient treatment is begun it is easily continued. Improved ability is at once appreciated by both parent and child. It is well that such is the fact, for improvement does not stop with infancy or childhood. The process is slow and prosaic, but the benefit cannot be over-estimated in the opinion of the one who is in the best position to judge of its value. A slight improvement in the gait, or an ability to walk a little faster or a little farther without fatigue, confers lasting happiness, and the patient and physician are thus encouraged to go on to new achievements, until, with one step after another gained, the outcome is an adult well able to follow the ordinary pursuits of life, in place of a being who had looked forward to hopeless dependence.

Clinical Department.

TWO CASES OF ACQUIRED COMPLETE ATRESIA OF THE VAGINA.[1]

BY RUFUS A. KINGMAN, M.D., BOSTON.

Mrs. N. E., widow, thirty years of age, was born in Prince Edward's Island, and had worked as a cook. She was admitted to the St. Elizabeth's Hospital, July 29, 1891.

Eight years before she had been delivered of her first and only child, the labor lasting four days. The puerperium was marked by fever, with pain and tenderness over the abdomen, lasting for four weeks. During this time the urine trickled away through the vagina, but this ceased gradually and did not recur.

Menstruation never returned; but once a month there was increase of pain in the back and lower abdomen, the backache never being wholly absent during the eight years.

Two months before her admission to the hospital she had been operated upon by a surgeon in a neighboring city, he having found complete closure of the vagina, and she being anxious to remarry. The operation did not result satisfactorily, the bladder being opened and the cervix not being found. A second attempt, a week later, had resulted no better. The opening so made had been kept open by the daily use of a glass plug; but the surgeon leaving town for the summer, referred the patient to me for further operative treatment.

Examination, under ether, on August 4th, revealed an opening into the base of the bladder which easily admitted three fingers. Beyond this there extended a small cicatricial pocket about one-half inch deep. The lower part of the urethra was missing. By the rectum it was easily discovered that the uterus was small, and that it was lying in the second degree of retroversion. Between the cervix and the rectum there seemed to be an elastic tumor about the size of an egg.

This tumor I supposed to be the remaining portion of the vagina filled with fluid. An aspirator needle was introduced from the top of the artificial vagina, and what appeared like thick pus entered the tube. On the assumption that this was retained leucorrhœal secretion, an opening was made beside the needle with sharp-pointed scissors, and about two ounces of this purulent fluid were evacuated. The finger passed through this hole into a cavity with a smooth lining, containing at its upper margin a small projecting button, which could be nothing but the atrophied cervix.

Directing the finger downward toward the perineum, a knife was entered just below the existing opening,

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, March 22, 1893.

and was made to cut down upon the finger-tip. In this way an entirely new vaginal entrance was obtained, and a flap of tissue was raised to cover in the base of the bladder.

After freshening surfaces wherever necessary, this flap was secured in place by sutures, the opening made beside the needle being closed by one purse-string suture. The remnants of vaginal mucous membrane were now dissected up and united as closely as possible to the external skin. Iodoform powder was dusted over the wound, a sigmoid catheter was put in the bladder, and the knees were tied together.

Four days later the catheter was finally removed, and the patient passed water voluntarily, though a moderate amount of leaking continued for several days longer. The stitches were removed on the eleventh day, and from that time she had perfect control of the bladder, holding her water for two and even three hours at a time.

A plug was used a few times, but the patient soon left the hospital and returned to the care of her former physician.

I had the privilege of examining her once again during the following winter, when I found the condition just as I last saw it, save for a tight ring of cicatricial tissue just at the entrance where the mucous membrane and skin were separated by a narrow interval. This condition could very easily have been remedied by a trivial operation, but further treatment was not then permitted.

The second case is that of a physician's wife, fifty-two years of age, who has always enjoyed perfect health, and only consulted me because of the fear felt by her husband that there might be commencing malignant disease of the uterus. She had had two children, the youngest being twenty-three years of age. Menstruation had been perfectly regular up to within a few months, and without pain or discomfort. For a month there had been a slight but continuous bloody discharge.

I was told that for years the vagina had been shallow, but that recent examination had shown a puckering and apparent closure of the upper portion. This fact I confirmed readily enough, the vagina ending in a blind pouch about an inch below the cervix, marked by a dimple or depression which admitted a small probe, through a sinus, into a pocket which surrounded the cervix.

Operative interference was advised, and a few days later was undertaken. The sinus was slit laterally with a tenotomy knife, guided by a lachrymal director. It was then stretched widely with sinus dilators, and the finger explored the pouch beyond.

The cervix proved to be deeply lacerated on both sides, the scars involving the vagina so extensively as evidently to give sufficient explanation of the stenosis. The cervix and vagina had formed such extensive adhesions as almost wholly to obliterate the vaginal portion of the former. After peeling off these adhesions with the finger, the stenosed portion of the vagina was still further incised and was then packed with iodoform gauze.

The progress to complete recovery was rapid and painless. Some slight narrowing of the vagina still exists and the cervix has not been operated upon, but the patient has not one single symptom referrable to her condition, so does not at present desire operative interference.

As regards the causes of the atresia in these two instances, there can be no doubt. In the first case a long second stage resulted in sloughing of the soft parts, how extensively we cannot say, but certainly so as to cause a vesico-vaginal fistula. Then there was probably a septic condition which favored either extension of the slough or of a neighboring vaginitis, with resultant cicatricial contraction, or more likely plastic adhesion of the walls of the vaginal outlet. At the same time a septic ovaritis destroyed the functional activity of the ovaries, and menstruation ceased.

In the second case, the tears of the cervix extended far into the vagina on each side, so as to almost close it, either by their contraction, by direct adhesion, or, as I think most likely, by both processes combined. Partial retention of menstrual discharge and of the normal secretions, set up a sharp vaginitis, which increased the contraction and developed fresh adhesions.

I have no desire to enter upon a discussion of the general subject of atresia vaginæ, whether congenital or acquired, but in view of the infrequency of the latter condition, I have thought that a brief report of these two cases might prove not only interesting, but instructive. There is nothing in the management of either case which calls for especial notice, unless it be worthy of remark that so much was accomplished in the first case as the result of a single operation.

It is worth our while, however, to consider that in each case a proper appreciation of the condition at the time of injury, would have suggested treatment which could not have failed to prevent any such complete closure as has been described. Of course, every one now examines to see if the perineum has suffered injury during labor, and most men practise immediate suture where, according to their judgment, it seems called for. But if these cases teach anything, they teach the importance, not only of a more careful supervision of the puerperium than is commonly practised, but the value and the absolute need of a vaginal examination before the final discharge of our parturient patients.

The best time for such an examination is near the end of the puerperal month, and no notions of convenience or of prejudice on our part, or of false modesty or timidity on the part of the patient, should be permitted to interfere with the performance of our manifest duty.

A PECULIAR CASE OF ACQUIRED ATRESIA OF THE EXTERNAL OS UTERI.

BY BARTON COOKE HIRST, M.D., OF PHILADELPHIA.

MRS. E., aged forty-eight, married twenty-five years, never pregnant. Eight years ago the menstrual flow was absent for about eight months; after one reappearance, it did not return for a year; then again for nine months; and again for a year, since which time there has been no menstruation. Two months ago the woman began to experience discomfort in the lower abdomen. This became rapidly worse until the abdominal walls in the hypogastric and iliac regions were painful to the touch. With the increase of pain there developed very marked dysuria and irritability of the rectum.

On digital examination, a large cystic tumor was felt, filling up the entire pelvic cavity. It was impossible to find the cervix by the sense of feel. On inspection, a very slightly projecting nipple could be

seen in the centre of the vaginal vault, and a small dimple could be detected at the site of the external os. The diagnosis was plain.

Under ether, a trocar and canula were pushed through the cervix into the uterine cavity. On the withdrawal of the former, a stream of coffee-colored fluid was projected several feet from the woman's body. More than a pint was evacuated. The uterus contracted vigorously, and directly after the fluid ceased to flow its internal measurement was two and one-half inches.

The interesting and peculiar features of this case are the entire absence of a cause for the atresia; the menstrual history suggesting the menopause; the slow accumulation of fluid and late appearance of symptoms — five years after the cessation of menstruation.

A CASE OF RECURRENT PARALYSIS OF THE OCULO-MOTOR NERVE.[1]

BY EDWIN E. JACK, M.D.,
Ophthalmic Surgeon to Out-patients, Boston City Hospital; Assistant Ophthalmic Surgeon, Massachusetts Charitable Eye and Ear Infirmary.

The patient, a Swedish woman, twenty-six years of age, was first seen April 14, 1893. Some weeks previous to this she had been at the Infirmary, where the diagnosis of paralysis of the third nerve was made. She was an average-sized and healthy-looking woman, and with the exception of the present trouble, said she was and always had been perfectly well. She had measles when young, but nothing else. No history or physical signs of syphilis. Bowels and menstruation normal. The mouth and nose were slightly drawn up to the left, but a careful examination by Dr. J. J. Thomas showed no paralysis of any branch of the facial. The ears, examined by Dr. F. L. Jack, showed signs of hypertrophic catarrh. Hearing subnormal in left. The father is alive and well. The mother, who died twelve years ago at the age of about forty-five, of "rheumatism and dropsy," suffered with headaches during her life. Whether they were migrainous in character could not be told. Two brothers and two sisters are well.

Toward the end of January last, patient was taken with sudden and severe pain in the left brow, temple, cheek and side of nose. The pain was described as dull, like the blow of a hammer. With the pain there was loss of appetite and vomiting. This lasted for two or three days, during which time patient was in bed. During the first day the left lid began to droop, and in a day or so there was complete ptosis. In the course of two weeks the lid could be raised so as to uncover the pupil, and then there was diplopia, which has persisted in some degree till now.

Examination of the eyes April 14th: O. D. normal; V. = 1; H. O. S. — fundus normal. Pupil well dilated. Reaction to light extremely slight. Associated action with accommodation very feeble. V. = 0.1 — the poor vision being due to an almost total paralysis of the accommodation. With a rough correction of the refraction, V = 1. There was diplopia everywhere except in the lower part of the field from just within the extreme right to the extreme left. O. S. did not move in perfectly. On quick convergence it tended to lag behind and on looking quickly at a distance it deviated outward slightly. Marked limitation in upward movement, movements outward and downward normal. There was apparently a very slight ptosis. An examination October 12th showed practically the same conditions, except that there was no diplopia on the horizontal line.

Attacks similar to the one just described and with the same accompaniments, have occurred many times during the last ten years, beginning therefore at about the age of sixteen. Some years there have been only two or three attacks and in some five or six. In the last five years more than before, but within that time there has been no increase in frequency. The last interval, nine months, is the longest that has ever occurred, so that this year is likely to prove an exception to the previous ones. For the first few years there was no paralysis between the attacks, but the last four or five, the dilatation of the pupil, the paralysis of accommodation and in some degree the diplopia on looking upward, have been permanent. The ptosis and diplopia in the middle of the common field have usually disappeared within two or three weeks. The last time though a certain amount of ptosis remained for two months and the double vision in the middle of the field lasted longer than formerly; this has been the tendency lately. There has never been any connection with menstruation and never any headache between the attacks. The pain is limited to the region stated, never reaching to the occiput. There is a feeling of heat and sometimes of cold, but no chills. The pain comes on suddenly, without warning, and does not seem to be brought on by anything patient eats or does.

The earliest reported case of this kind was that of Gubler in 1860. Mauthner has published the account of a case seen in Graefe's clinic in 1864. With these exceptions all the cases, about twenty-eight, have been reported since 1882. Of these the majority, fifteen, are females. The age at which the attacks first came on varies from eleven months to thirty-one years, the greater number being under fifteen. In a few the age is not stated. In eleven the right side was affected, in sixteen the left, one doubtful. In most of the cases headache and vomiting preceded the paralysis, in some there was no vomiting, and in a few dizziness was present. Other symptoms occurred in separate cases, such as paresis of arm, trouble in articulation, tenderness in the region of the branches of the fifth, tinnitus and transient deafness, a twitching pain down arm and leg on opposite side, salivation and a general feeling of discomfort before the attack. The pain in most instances resembled that of migraine; in a few it was limited to the region around the eye, or in supraorbital nerve, and in one the whole head was involved. The duration of the attacks varied in different cases and in the same case from a few days to six months. The figures given, however, refer in some cases to the duration of the pain and in some to that of the paralysis. The intervals also varied, two weeks and four years being the limits. In at least sixteen, the attacks became worse and lasted longer. In all of these the paralysis, to some extent, became permanent. In a few only did the severity of the attacks decrease. In Von Hasner's case, the trouble came on before the establishment of the catamenia, later the attacks were coincident with them. In no other instance, I believe, has this coincidence been observed. In Dr. Wadsworth's case, toward the end of the headache, there was a discharge

[1] Read before the Boston Society for Medical Improvement, October 23, 1893.

of ill-smelling fluid from the right ear. The child had chronic suppurative otitis. Here there was evidently a close connection between the attack and the ear trouble. The sister of this patient had become blind from post-neuritic atrophy, the neuritis having been brought on by meningitis from aural disease. In one case contraction of the fields of vision during an attack was observed.

Senator divided these cases into two classes, the purely periodic with no symptoms between, and the periodic exacerbating ones. The doubt has been expressed, however, whether there ever has been a purely periodic case, it being claimed that a careful examination would always reveal some paralysis persisting. Charcot suggested the name "ophthalmic migraine," from the supposed analogy to migraine. Another suggestion has been to change the name to "recurrent ocular-motor paralysis" because of the different length of the intervals. Finally, it has been recommended to do away with the artificial division into exacerbating and purely recurrent paralysis, on the ground that the cases with a free interval later acquire some permanent paralysis.

The point of chief interest and importance is the nature of the trouble — functional or organic — and if organic, the kind and seat of the lesion.

Some have thought it functional, the analogy to migraine being strongly insisted on. Others have supposed a circulatory disturbance, which later gives rise to some permanent lesion, perhaps inflammatory in its nature. Von Graefe attributed the results in his case to a probable fracture of the base, which could have been followed by an ostitis or exostosis, this by inflammatory enlargement at times pressing on the nerve. He concluded that a progressive anatomical lesion was probable in every case. This was Manz's view also. Möbius and Von Hasner thought that in most instances the nucleus of the third was affected. Möbius referred the pain to an involvement of the descending band of fibres of the fifth, which lies above and a little to the outer side of the third nucleus. Mauthner and Manz inclined to an extra cerebral lesion.

In three cases there have been autopsies. In Gubler's case, which died in the fourth attack comatose, there was exudation around the right motor-oculi along the base of the brain and a blood-clot in the pons. Weiss' patient died of phthisis. The third nerve as it left the peduncle was flattened, grayish and covered with numerous granulations which contained tubercle bacilli. Thomsen's case died in an insane asylum. The right motor-oculi where it passed through the dura was gray and club-shaped; a fibro-chondroma had separated the fibres of the nerve but had not destroyed them.

The present case seems to throw but little light on the subject, except to emphasize the fact that the tendency of the disease is toward a persistence of the paralysis between the attacks. It is difficult to think of such a disease as functional, but there are certainly strong resemblances to migraine. The character of the pain in most instances and the accompanying disturbances in some are very similar. There have been though, as far as I know, no visual symptoms spoken of, such as are so frequent in ordinary migraine. Heredity and neuropathic tendencies are not so distinctly traceable. The occurrence of attacks in one case under the same conditions as previous epileptic seizures and the substitution of an ordinary migraine headache for a paralytic attack are suggestive. But the persistence of the paralysis points distinctly the other way. The history of Dr. Wadsworth's case is strongly indicative of organic trouble. It is not possible either to ignore the post-mortem findings in the three cases spoken of. In all these the nuclei were healthy, the lesion basilar.

It seems impossible that any process in the neighborhood of the nuclei, lasting so long, could affect the nuclei of the third without that of the fourth lying next to them or the neighboring third nuclei on the other side of the median line. Certainly the known nuclear ophthalmoplegias do not act in that way. It may be that there is no common cause for these disturbances, and it may be also that the seat of the trouble varies.

The prognosis, as far as it concerns improvement of the condition, must be considered bad.

THORACOTOMY IN A CASE OF EMPYEMA FOLLOWING PNEUMONIA.

BY J. C. HILL, M.D., ROCKLAND, ME.

IN the early summer I was called to see Mr. N. B., aged sixty-three. The wife of the patient informed me that her husband, up to the time of my visit, had been without medical attendance, and had been confined to his bed for over two weeks. Her description of the case outlined very clearly a case of lobar pneumonia.

For the twenty-four hours preceding my appearance upon the scene, the patient had been having very pronounced and protracted chills. I found him with a temperature of 106°, and a pulse of 98, which was weak, steady and intermittent. The eyes were sunken and dull, the countenance livid and greatly emaciated; and the patient was fast succumbing to the malady which was seated upon him. Percussion and auscultation showed marked dulness over anterior and posterior region of lower right lobe of lung. There was noticeable bulging of the right thoracic wall. Patient was having night sweats, a constant cough, and expectorated a large amount of yellowish-gray matter.

Having satisfied myself that I had to deal with a case of empyema, I made an incision into the pleural cavity, two inches in length, in the seventh intercostal space, in front of the latissimus dorsi muscle, and immediately pus welled out of the opening until two pints had been accumulated in a pus-pan at his side. I inserted a drainage-tube (the siphon arrangement under water), and leaving stimulants, both diffuse and cardiac, left the patient for the night.

The following morning the temperature was 100°, and the pulse down to 80. The heart action was stronger and less intermittent. A quantity of pus was drawn out during the night, and lay congealed at the bottom of the receptacle. I removed the tube, and irrigated the cavity with a 1–5000 corrosive sublimate solution. The patient expressed himself as feeling greatly relieved. I put him upon hydrarg. corr. chlor., gr. $\frac{1}{10}$, t.i.d., kept up the stimulation, and prescribed extract of malt in wine-glass doses every two hours. The process of irrigation was repeated every other day for ten days, then twice a week. The discharge gradually grew less in quantity until at the end of the second week the flow ceased entirely, when I allowed the incision to heal.

The patient made visible improvement from date of

operation. The chills discontinued, and in five days from the time the pleura was incised the temperature reached and maintained the normal figure. The corrosive chloride was omitted after the second week, and not resorted to again — iron, arsenic and strychnia being substituted. A rapid convalescence was reached and the patient is now, in spite of his age, vigorous, active, and in good health.

Medical Progress.

REPORT ON DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D.,
Professor on Diseases of Children, Harvard University.

AMÆMIA OF MINERS IN CHILDREN.[1]

A GRAVE form of anæmia is produced by the presence of a worm in the intestine, the Anchylostonum duodenale, first described by Dr. Dubini, of Milan. The author has been able to observe twenty-one cases in children below the age of eleven. Intestinal symptoms are more common than in other forms of anæmia. The anæmia becomes rapidly worse. The fæces are very variable, often diarrhœic, sometimes streaked with blood; in other cases the stools are normal. The diagnosis is based entirely on the examination of the fæcal material, in which the eggs of the anchylostome are found. These are characteristic, being in segments — mono-, bi-, poly-cellular. The eggs of the ascarides lumbricoides often accompany those of the anchylostome. The disease arising in an infected locality (such as mines, collieries), the presence of other anæmics in the family, especially if among them there were miners or men in similar work, the resistance of the disease to different treatments, point to the diagnosis, and this is determined by the microscopical examination of the fæces. The treatment is by the ethereal extract of malefern. The dose in children should not exceed four grammes, and should be given in an emulsion of some essence to conceal the disagreeable taste. It is necessary to repeat the treatment several times (four or five) at intervals of two to three days. As a contribution to the pathogeny of this form of anæmia, numerous experiments upon animals were made, which demonstrated very beautifully the auto-intoxication which takes place. After having prepared the toxine of the urine from two patients, after the method of Brieger-Otto, rabbits were inoculated with progressively increasing doses. The animals presented, from the first injections, all the characteristic symptoms of the anæmia in question. Quickly, upon stopping the injections, the animals returned to a state of health. Control experiments with the urine of patients after the expulsion of the worms, produced no changes in the blood of the rabbits experimented upon.

ARSENICAL NEURITIS.[2]

Barrs showed before the Leeds and West Riding Medico-Chirurgical Society, a boy, aged twelve, who was almost totally disabled by palsy, following upon a severe attack of chorea, for which arsenic was given in increasing doses, the maximum dose being eighteen drops of the liquor arsenicalis, from November 12, 1892, to January 6, 1893. During the course of the chorea the knee-jerks were entirely absent, and, beyond a little sickness on two or three occasions, there were no symptoms of arsenical poisoning. The boy walked home from the hospital, a distance of a mile or more, on his discharge on December 6, 1892, when he was quite free from choreic movement, but the knee-jerk had not returned. He was readmitted a month later with serious loss of power in the arms, legs and trunk muscles, wasting of the affected limbs, and some anæsthesia, with tenderness of nerve trunks, dropped feet and hands, and loss of all tendon reflexes. Dr. Barrs thought the paralysis was due to arsenical neuritis and not to chorea.

PSEUDO-HYPERTROPHIC PARALYSIS.[3]

Pasteur showed before the Medical Society of London, a case of pseudo-hypertrophic paralysis in a youth, aged seventeen. The thighs were small, while the calves were characteristically enlarged. The wasted parts showed diminished electrical excitability. The case was remarkable in that it appeared to be an instance of the disease having become arrested in an early stage. The lad was intelligent, but his father was an epileptic.

CROUPOUS PNEUMONIA IN CHILDREN.[4]

The paper was read before the Medical Society of London, and based on 226 cases. Most cases occur during March, May and July; the fewest in January, August and December. They occur, as a rule, independent of antecedent disease, and in the great majority the onset could not be attributed to any definite cause. Fifty of the cases occurred under the age of five years, one hundred and twenty between five and ten, and fifty between ten and fourteen. The disease was most frequent at the ages of five and nine respectively.

Connecting his table with a further series of over seven hundred cases compiled by others, he found that the frequency of the affection gradually rose from the fifth to the twentieth year. Its onset was usually sudden and its chief symptoms of invasion were vomiting, cough and pain, while rigors and convulsions were very infrequent, and hæmoptysis extremely rare. An arrangement of symptoms into groups showed that the nervous system was the one most variously affected. The average daily temperature before crisis was 103° and 104° F., and in about one-seventh of the cases, the fever was of a hectic type, though in only three was such associated with pus in the pleural cavity. The sixth was the commonest day of crisis, it being very frequent on the seventh and eighth days. In basic pneumonia it was rather later than in apical. A dull tympanitic note was often present before any differentiation was detected in the character of the breath sounds. In one hundred and forty-six cases, the base of the lung was attacked in sixty-nine, the apex in forty-five; in the remainder the seat of the disease was in other parts. The most rapid respiration noted was 68. Typical rusty expectoration was present in seven cases, the youngest being six years old. Pleurisy coexisted in sixteen cases, pus being found in three. Gangrene of the lung occurred once. A soft systolic murmur was detected as arising during the course of the disease in six cases. Pericarditis was noted in one case, the patient having had rheumatic

[4] Francis Hawkins (London): British Medical Journal, 1893, i, 698.

fever previously. Albuminuria was discovered during the disease in seven cases, and herpes in thirty-six, being in one case on the wrist as well as the angle of the mouth. Delirium was more frequent during the course of the disease than at the onset, and more in apical than basic cases. In the treatment, ice should be used with great caution when the pneumonia was on the left side, as the heart might become slowed and dangerous symptoms arise. As to alcohol, discretion was required to select the cases in which it was needed.

CHOREA IN A BOY: NECROPSY.[5]

The patient, a boy aged nine years, died December 29th, two months after the onset of the chorea, which was bilateral. A post-mortem examination was made in the afternoon. Rigor mortis had commenced in the lower extremities; no subcutaneous nodules were found. The pericardium was rough and thickened, covered with fibrinous exudation, and contained a considerable quantity of turbid effusion. The heart was slightly hypertrophied, the muscle paler than normal, but not friable. There were some very small vegetations on two of the aortic valves, and less on the mitral; the right side was normal. There were evidences of broncho-pneumonia in both lungs; the brain and abdominal viscera were normal. The rarity of fatal cases makes this one of interest, although there is no fresh light thrown on the pathology of chorea.

SCLEREMA NEONATORUM.[6]

The infant was first seen when four days old. On the second day after its birth, the peculiar condition of the skin drew the attention of a neighbor. The following appearances presented themselves when first seen: The legs, feet, arms, hands, back of shoulders and upper part of chest had the feeling of india-rubber stretched over a frame. The color of the skin varied from a deep purple to a light pink. It cried feebly, and every few seconds stretched its body to its full extent, as if struggling for breath, or as if it felt stiff all over. The pulse was 120 beats per minute, and the temperature 97°. There were no pulmonic nor cardiac abnormal sounds. The bowels had moved shortly after birth, but not again. The constipation was most obstinate. Hot-water baths and friction of the whole surface of the body was given. It was enveloped in cotton and wool, and a temperature of about 75° was maintained in the room. Several punctures in the skin were made with a view of releasing any fluid that might be there, and thus relieving the tension, but only a very little blood and yellow fluid escaped. On the sixth day the temperature fell to 87°, and the infant died that night.

ETIOLOGY OF "RÖTHELN" (GERMAN MEASLES).[7]

Reference was made to the clinical symptoms generally known as rötheln, rubaoloa, or German measles. Attention was drawn to the extreme diversity of opinion held by various writers on the etiology of this affection, and it was pointed out that these opinions differed not only as to the essential nature, specific or otherwise, of the contagion, but as to what might be looked upon as the fundamental symptoms of the disease. The author endeavored to prove, from clinical as well as theoretical grounds, that an hypothesis was not untenable which assumed that the specific contagion of measles, being a living organism, as such would be liable to undergo variation, and would be subject to evolutional changes in adapting itself to varying conditions of "soil," and that some such hypothesis would afford a clue towards explaining the many affections of exanthematous character which departed more or less from the true measles type. Clinically, many conditions were known as rötheln. These conditions differing widely in both intensity and symptomatology, the writer asked: "Are such affections due to the same contagion, assuming different degrees of force or intensity, and profoundly modified by different states of 'soil' and environment; or are they due to contagia specifically distinct, the one from the other?" In support of the hypothesis, attention was directed to many points in the clinical history of measles and so-called rötheln. These points were severally discussed under the following heads: Personal experience of the various forms of exanthemata differing materially from ordinary measles. The variation of symptoms found with measles. Immunity: does it depend upon intensity? Will a mild attack of measles confer immunity in the same degree as does a severe one? Second attack of measles. The modification of measles by environment and by different "soil." The mutual want of protectiveness between rötheln and measles: may it possibly depend upon degrees of intensity? Is the general type of measles less severe than formerly? Special reasons why the contagion of measles is placed under conditions which will apparently favor variation.

THE PERSPIRATION IN CHILDREN IN PHYSIOLOGICAL AND PATHOLOGICAL CONDITIONS (IN SCARLATINA AND NEPHRITIS).[8]

The perspiration in healthy children is chiefly influenced by the relative moisture and the temperature of the surrounding air, in inverse proportion to the former and in direct proportion to the latter.

The ordinary variations in atmospheric pressure have no noteworthy influence. The perspiration in healthy children is inversely proportionate to the age and the body temperature. Introduction of food and drink increase the perspiration. In scarlatina, in all stages, the skin perspiration is diminished. The most notable retention of water is in scarlatina just before the appearance of albuminuria and with the appearance of uræmic symptoms.

Affection of the kidneys has for a cause this diminution of the skin perspiration.

Increase of the moisture and lowering of the temperature of the surrounding air favors the occurrence of scarlatinal nephritis. Therefore, it is to be recommended to keep scarlatinal patients in dry and warm air. Warm baths increase the skin perspiration notably, while inunctions of fat diminish it. Therefore warm baths are to be recommended as early as possible for scarlatinal patients, while inunctions of fats are to be avoided.

NINETY OBSERVATIONS ON ACUTE ARTICULAR RHEUMATISM IN CHILDHOOD.[9]

This affection is less common among children than among adults. The influence of the seasons does not appear very clearly, but heredity plays an important part in its production. Two peculiarities are noted

with regard to localization: first, as in adults, its rarity in the hip-joint; second, the frequency in children as compared with adults, of manifestations in the vertebral column. General phenomena are commonly but slightly marked. This is perhaps due to their relation to the number and intensity of joint-affections. The thermometric curve, as with adults, is irregular, and bears a relation to the exacerbations and extensions of the lesions. Sweating and sudamina are observed; also hæmorrhages, and particularly nasal hæmorrhages. The urine presents no differences from that of adults. Anæmia is an almost inevitable consequence of the rheumatism of children, as that of adults. It surpasses that of any other disease, with the possible exception of malaria, and it leads not only to pallor, but to souffles in the neighborhood of the pulmonary artery and of the vessels of the neck.

Much the most frequent complication is endocarditis. It is very difficult to determine the precise moment when endocarditis begins, for it can only be diagnosticated when the souffle appears. It persisted in the great majority of cases until they were able to be out; nevertheless, in eight cases it became materially lessened, and in five it disappeared. In one of these last, resolution took place very slowly, and it was not until eight months that the child had regained its former state. Therefore one should not be in a hurry to make the diagnosis of a permanent lesion. Pleurisy must be cited among other complications. When it occurred, it was much more often in the beginning than in the course of the disease. Six cases presented a more or less abundant eruption.

SPASMODIC MOVEMENTS OF THE HEAD IN INFANTS.[10]

Five cases of rotatory spasms of the head in infants are reported. The author proposes the name of "gyrospasm" for this condition, but does not suggest that its etiology is different from that of other spasmodic movements in infants, such as nodding. In one case only was there associated nystagmus, and in this case the movement was confined to one eye. In another case there was convergent strabismus. Gyrospasm was first noticed in these cases at the ages respectively of three months, four months, five months, seven months and eight months. "Taken together, therefore, the cases do not support Henoch's view that dentition is a cause." Pertersen suggests that in most of the cases cerebral concussion will be found to be the determining factor, and observes that in adults severe concussion may give rise to rapid though temporary nystagmus. The prognosis is, he believes, good; but a recovery may be hastened by the administration of bromide of potassium in doses of from one and one-half to three grains thrice daily.

A MATERNAL GUILLOTINE. — The Boston *Herald* relates an actual occurrence which is interesting as an example of the entire disassociation of meaning and intent from the words actually used by an irritated person. The writer when shopping overheard the following remark made by a woman who was buying some handkerchiefs in a crowded store. Her little girl was idly twirling a box by the string, while waiting by her mother's side. The string slipped off. The mother saw it and snapped out: "You bad, naughty girl; I'll chop your head off."

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. OBSTETRICAL SECTION.

G. H. WASHBURN, M.D., SECRETARY.

REGULAR Meeting, Wednesday, March 22, 1893, DR. INGALLS in the chair.

DR. C. W. TOWNSEND read a paper on

PLACENTA PRÆVIA.[1]

DR. E. REYNOLDS: I think in dealing with placenta prævia, it is necessary to divide the subject, first, as to the degree of prævia, and then, as to the period of pregnancy at which hæmorrhage begins. Few things of serious import are more easily managed than marginal placenta prævia; its mortality, untreated, is not very high. Almost nothing is more creditable to an obstetrician than to get out of a central implantation with a living mother and child. Few emergencies are more dangerous. The question of treatment, apart from the greater urgency of the more complete prævias, rests mainly upon the period of pregnancy at which hæmorrhage occurs; more on the period at which the first hæmorrhage occurs than on the amount of hæmorrhage. When it occurs in the second third of pregnancy I think there can be but little question of judgment as to the treatment which should be employed. When hæmorrhage occurs at that period the dangers to the mother, which must necessarily ensue, to my mind, greatly outweigh any possible question of the survival of the child, which has not a very good chance if left to nature. I should unhesitatingly interfere in the second third of pregnancy so soon as I had the diagnosis established. When the hæmorrhage, however, first appears in the course of the seventh calendar month or even when six calendar months have been completed, I think the question of treatment is an extremely delicate and difficult one. The question is whether the case may be carried along until the child reaches the period of viability, with fair regard to the safety of the mother, and I think it must be determined largely by the circumstances of the patient rather than by any other consideration. If she is so placed that she can command the constant attendance of a physician, or if she is in a hospital where aid can be rendered at any moment, I think it is fair to carry her along so long as the hæmorrhages do not distinctly weaken her and raise her pulse. If she is in a situation in which she is distant from competent aid, is unable to command the time of any physician to such an extent that he will be safely within reach, I should prefer to sacrifice the fœtus; and I should do that as readily for moderate bleeding, with a well established diagnosis of placenta prævia at six months, or in the seventh month, as I should for moderately severe hæmorrhage. If it is a very bad hæmorrhage, of course we must interfere. A first hæmorrhage of one drop may be followed at any moment later by a hæmorrhage that will be promptly fatal within a few minutes. Of course with the circumstances of the patient must be included the degree of prævia; yet even a marginal placenta prævia in a patient remote from aid is a pretty dangerous thing to let alone. I think that question of interference in the course of the seventh calendar month of pregnancy is the most difficult question in the whole subject of placenta prævia.

[1] See page 612 of the Journal.

I want to speak of one case illustrative of that point, that I have recently had. I have seen a number of cases of placenta prævia, and I have never seen but one patient who has died of placenta prævia and that was this one. Last autumn I saw in consultation a lady, six and a half months along, who had had moderate flowing which had been checked promptly by putting her to bed. It had occurred, I think, twice. She was in good condition. On vaginal examination I thought I could feel the edge of a marginal placenta prævia, or perhaps hardly more than a low implantation, through the cervix. The flowing was very slight at that time. She lived next door to the doctor. Within one hundred yards there were two other thoroughly competent physicians. Her circumstances were such that they were able to make an arrangement by which one of the three physicians should be within call all the time, and I advised him to carry the case on until the child was viable, stating my opinion that if the lady was kept in her rooms, and in bed whenever there was any question of flowing, the chances were that she would go along until the child was in a condition of good viability, or perhaps to term. She went on about a month without losing a drop of blood. Then the physician was called to find her exsanguinated, arriving within a few minutes of the first appearance of bleeding. He immediately etherized, dilated, turned, and delivered a living child, had but slight postpartum hæmorrhage, and yet lost the patient within an hour. I still think at that period of pregnancy and under those circumstances, that is, where the patient could command constant care, it is only fair, in view of the value of the life of the child, to carry the case along to viability, or until something in the way of severe hæmorrhage urges immediate interference. I report that case as illustrating the fact that after a very slight hæmorrhage we are taking a risk for the mother for the sake of a child which will shortly be viable, and that, however slight the first hæmorrhage may have been, however high the implantation of the placenta, this risk is never absent. When the first hæmorrhage occurs after the child is viable, there is less question about the treatment. In such cases outside of a hospital, or without the most constant attendance of a competent physician, I should interfere, in the belief that here the undoubted risk to the life of the mother more than counterbalanced the risk to the child.

As to treatment when interference has been resolved upon, I think there is but rarely any choice, and that internal podalic version is generally the better treatment. In marginal cases of partial prævia, I am inclined from a moderate experience in the expedient, to prefer the performance of version through the undilated os by the use of two fingers, rather than dilatation and the whole hand, a tamponade of the lower uterine segment by the half breech and waiting. It is much more rapid and I think is, on the whole, a less severe operation to the mother. I have not lost a child in that way. I think that two things are to be spoken of further in connection with the treatment of a case that must be interfered with at once. The first is that the very moment the diagnosis is made, I think that the hand should be passed into the vagina, one finger passed into the os to nearly its whole length and the placenta detached from the margins of the os for a distance of two or three inches. In my experience that expedient is invariably followed by a considerable increase in the dilation of the os and by prompt, though temporary, arrest of flowing. It gives the patient a chance to recover a little from such loss of blood as may have occurred, and gives the physician time to make his preparations. Hæmorrhage may recur at any moment and the fact that it has stopped after the detachment of the placenta, should not be allowed to induce the physician to absent himself a moment from the bedside. Further, the great liability of postpartum hæmorrhage after placenta prævia and the great danger that follows slight additional losses of blood after moderate hæmorrhage has once occurred, should, I think, make it incumbent on every one who has to deal with a case of placenta prævia to use the most careful manual guarding of the fundus from the moment he begins his delivery, to have the fundus followed down the moment the extraction of the child begins, and have it guarded by the hand during every individual second that follows the delivery; without the omission of a single second, until he is convinced that the retraction of the uterus is sufficient to guard the patient against any likelihood of postpartum hæmorrhage. The hand should be held against the fundus and at any sign of softening of the uterus, rapid, light friction should be applied to the fundus through the abdominal wall. It is my experience in labor in general, that anticipation of postpartum hæmorrhage, does more to prevent loss of blood by postpartum hæmorrhage, than all the means of controlling postpartum hæmorrhage that are within the control of the profession, and I think it is very important in placenta prævia to remember the likelihood and great danger of *postpartum hæmorrhage.*

DR. KINGMAN reported

TWO CASES OF ACQUIRED COMPLETE ATRESIA OF THE VAGINA.[2]

DR. E. W. CUSHING sent the following history of a case, which may be of interest in connection with Dr. Kingman's paper:

Mrs. M., of Canton, Mass., about twenty-five years of age, entered the Charity Club Hospital in the following condition: There was a complete rupture of the perineum extending some two inches into the rectum; there was a large opening in the base of the bladder, and the vagina was apparently perfectly obliterated, as not enough space remained to pass a probe up towards the uterus. This condition was the result of labor some three months previously; the delivery had been effected with forceps with great difficulty. I first repaired the vesico-vaginal fistula and the perineum at one operation; the perineum united well, but in about ten days the bladder began to leak again. At a second operation I separated with great difficulty the anterior and posterior walls of the vagina, as far as seemed safe and possible. To do this required real dissection; if the woman had not previously had a child, I would not have believed that she had ever had a normal vagina. At length, however, I reached the cervix with an opening sufficient to admit the finger, and packed with iodoform gauze the channel thus formed; I then proceeded to close the vesico-vaginal fistula, which was much smaller than at the first operation. This time it united. The packing of gauze was renewed at intervals for some three weeks, when I again gave the patient ether, and working laterally with the finger and scissors, I was able to enlarge the

[2] See page 615 of the Journal.

vagina, and also to separate the adhesions in the anterior and posterior vaginal fornices, so that the cervix was liberated. The passage thus re-established was packed at due intervals with iodoform gauze, and the patient finally left the hospital in a good condition. She soon became pregnant again, and by my advice went to the Boston Lying-in Hospital, to apply for admission for an operation for premature delivery, owing to the contracted pelvis. I learned afterwards, indirectly, that although such an operation was recommended to her by the physicians of that institution, she did not appear in due season, but was finally delivered there at term.

SENDING PATIENTS AWAY FROM HOME.[1]

DR. E. N. WHITTIER: Mr. President, it is my privilege, through your courtesy, to express the high appreciation entertained by the Society for this timely presentation of a most important subject, at the hands of our distinguished associate, for to him more than to any one else in this country is due the large advance made in the treatment of tubercular diseases by the method known as "high altitudes."

I have been pledged from my earliest recollection to the expression of a favorable opinion, as to the results of a judicious selection of cases to be "sent away from home," particularly when such selection is combined with an accurate knowledge of the various health resorts: for as far back as the time when cod's livers were fat and frequent in the pure water of Casco Bay, I remember our hired-man in the garden back of the barn, trying out cod-oil, then in its therapeutic infancy and but little known to commerce; that on three separate occasions the family gathered at the bedside to receive the last words of one blanched with hæmorrhages. I shall never forget the sublime courage imparted by the promise of the physician, that though the distance was long, and the months of separation would be wearisome, a return to fair health could be assured by going away from home; the voyage to South Carolina was most distressing, the journey across the State most tedious, and a planter's house in Aiken the only place then affording sheltering care. A second winter completed the good work begun in the first, and the patient returned home free from all signs of pulmonary disease, to live many and invaluable years, yielding at the last to an acute disease bearing no relation to that, for which in early years so great anxiety had been experienced and for whose cure a measure then rarely appealed to, was resorted to and not in vain. It is for this reason I advocate careful study of the rules set forth by Dr. Knight, and would ask your cordial commendation of his insistence of the principle now well established, that by a wise selection of patients and places tubercular processes can be arrested and cured. It is of frequent mention that about 30% of the residents of Colorado are of tuberculous history. Dr. Solly states, however, that in his experience of seventeen years in that State he has known of but four cases of phthisis contracted there, a most remarkable comparison. The conclusions now reached are based upon the tabulation of results in nearly five thousand cases, at the hands of sixteen or seventeen of the most competent observers, here and abroad, and represent the most careful painstaking observations of cases, during the earlier stages of the disease, in advanced stages, through all the time they were under treatment, and for considerable time afterwards.

These results show the marked advantages, claimed by Dr. Knight in his papers on the high altitude method of treatment, as well as the fact that the sanitariums and closed resorts do not offer in any degree the inducement found in the open-air resorts. For the percentage of cases in closed resorts and sanitariums, is only ten, as compared with thirty-two per cent. in open-air resorts, for phthisis in all stages; while for the first stage of this disease the closed resorts give only twenty per cent. against sixty-two per cent. for the open-air method: the conclusions are irresistible. We can, therefore, maintain in practice, that there is abundant promise of good result, and of benefit commensurate to the large effort and sacrifice frequently and freely made.

Dr. Knight makes a strong point when he discusses the financial side of the question, the large expense incident to the process of sending patients away from home, and the necessity of learning before advising change of climate, whether or not it would be reasonable to expect the patient to follow such advice if given. To hold out to a patient the promise of cure by going away from home, when it is impossible to obtain the means to do it, is a refinement of thoughtless cruelty too often inflicted by consultants, neglecting to secure information, at hand, to guide them. I know that physicians sending their patients for advice and opinion, are sometimes made to feel not only that the consultant is too careless, but that he shirks the responsibility in all forms of any process which is in any sense a departure from an inflexible inelastic rule of sending away from home all whose physical condition offers hope of remedy.

DR. S. W. LANGMAID: I regret very much that I did not hear the whole of Dr. Knight's paper, but I have no doubt that I am familiar with what he has said in it from a knowledge of his previous papers, to which I heartily subscribe. I do not know that I can say anything in addition to what he has said. The only thought in my mind is in regard to the influence of altitude. Taking it in a large way, it has seemed to me that altitude has much to do with cure. One may obtain palliation without altitude; but, so far as my experience goes, cure has been accomplished ordinarily in those cases in which patients have been sent to some considerable altitude, like Colorado. This is generally accepted, I believe. Here, then, is an important factor in the selection of residence. Where cure can be hoped for, a region of high altitude may be selected even if all the conditions of the place may not be in accordance with the patient's comfort. Other considerations enter into the selection of a residence for those who are manifestly beyond the hope of cure; considerations of comfort, of distance from home and friends, etc. By formulating his views, in this and others papers, Dr. Knight has greatly assisted those who have the responsibility or choosing residences for their patients.

DR. F. B. GREENOUGH: I would like to endorse

[1] See page 609 of the Journal.

two practical points; one is the absurdity of sending patients in whom the disease is too far advanced to health resorts to die. In the old days people with tuberculosis were sent South and died like sheep. The other point is the absolute absurdity of sending a patient to Colorado or to any health resort who cannot buy bread and butter. It would be as absurd as to advise dispensary patients to buy woodcock and champagne.

DR. G. W. GAY: I think this is one of the most important subjects that could be brought up at this time. It was very forcibly brought home to my mind last winter, which I was obliged to spend on the Pacific coast. There one is brought in contact with this subject all the time. I think the most pitiable objects I ever saw were those far gone in consumption sitting on hotel piazzas trying to keep warm, and to look on the bright side of life. Many of these poor creatures would have been infinitely better off at home under any circumstances; therefore I think this subject cannot be too widely agitated, in order that properly selected cases may be sent away to these various health resorts. That infinite good is done in many cases everybody must bear witness. I had this forcibly brought to my notice last fall in the case of a young lady friend, who was examined by Dr. Knight and sent to Colorado. She was in a deplorable condition, with high temperature, quick pulse, constant cough and rapidly emaciating. It seemed as though the young lady could not live six months here. At Dr. Knight's suggestion she went to Colorado Springs, and was placed under the skilful care of Dr. Hart. It was with the greatest difficulty that she reached there. After arriving at her destination she had to stay in bed about three weeks before she could breathe with comfort. She remained during the winter and spring and in the summer went to some resort near by. The result was that she got perfectly well so far as any physical or objective sign could be detected. Rather against our advice, she has come back here for the winter. I think this is the most marked case of benefit from change of climate I have ever seen.

There is another practical point, which people should understand who go West, and that is, as to the kind of weather they are to experience there. They are apt to think that because the sun shines the year round it must be warm, and consequently they take thin clothing. They had better put their thin clothing at the bottom of their trunks, and have all their warm clothing on top, because the climate of the Pacific is peculiar. While in the sunshine one is comfortable without an overcoat, but if one goes into the shade he needs an overcoat. At San Diego I was fortunate enough to have a room on the sunny side of the house, and many an afternoon I sat writing with my window open and without a coat, while across the hall my neighbors had to have a fire. In the shade the climate is cold, in the sun warm. As to having hot weather, they may have it in the summer; they certainly do not in the winter or spring. Personally I never had so many colds, as while on the Pacific coast. I think that was because I was ignorant of the climate, and did not know how to dress.

The mental characteristics of the patient are important. Some patients are contented anywhere, others nowhere. The latter, I should say, had better stay at home. If they go West, whatever their surroundings, they will be homesick and unhappy, and derive little benefit from the change, whereas, those who look upon the bright side of things, would stand a much better chance under the same circumstances than the first class. Those are points that will be brought out more and more by such papers as Dr. Knight's. For my part I am very much obliged to him for presenting it to the Society.

DR. KNIGHT: I am very much obliged to the gentlemen for endorsing my remarks. I wish to say one word in regard to the patient Dr. Gay has mentioned. I do not remember the exact condition of the young lady, but I should not like to have the Society think that was exactly a picture of the case I would usually plunge into a high altitude. I do not remember what determined me to feel that that was the place for her, but ordinarily a very high temperature and very rapid pulse and rapid respiration would make me hesitate to send most patients at once to a very high altitude, but there was undoubtedly something about the case which made me feel that that would be the best place for her, and so it proved.

DR. EDWIN E. JACK reported

A CASE OF RECURRENT PARALYSIS OF THE OCULO-MOTOR NERVE.[2]

DR. G. L. WALTON: I do not remember having seen one of these cases. It has seemed to me they must be rare in this country, especially since a conversation with an oculist who has had a large experience in one of the ophthalmological clinics, and who said he did not remember having seen a case. On general principles and judging from the literature there would seem to me to be two classes of these cases. I can hardly believe that all those collected come under the same head. A patient, for example, who becomes comatose and dies, revealing on autopsy an exudation at the base of the brain involving the nerve, can hardly be classed along with the cases (rather more typical), which begin in infancy or early life and recur at more or less varying intervals until middle or advanced life with no effect on the general system, no other paralysis or any important symptoms between the attacks. It seems to me that in this class of cases we have something analogous to migraines and also analogous to the transient monoplegias, hemiplegias which we call hysteria, the typical hysteria of Charcot, in which there is a real paralysis of one or more extremities, which is not under the patient's control but of which we do not understand the pathology, analogous again perhaps to some of the transient paralyses occurring in organic disease where after death we do not find anything to account for the symptoms. I remember a patient with general paralysis who died in an attack of hemiplegia, where the post-mortem examination showed no definite localized lesion in the brain, to gross appearances at all events, to cause any such symptom. I understood Dr. Edes to suggest in a paper read last year before the Boston Medico-Psychological Society that there was in these cases perhaps a localized œdema, and it seems to me that is not an unreasonable theory. We see in hysteria in certain parts of the body œdema, swelling of the ankle or wrist, for example, which lasts a certain length of time and disappears. I have seen the leg so swollen that the skin would crack and the leg become superficially gangrenous, in a case of hysterical hemianæsthesia and hemiplegia of that side; typical hysterical

[2] See page 617 of the Journal.

symptoms persisted a number of years in this case and the patient was sent to the Home for Incurables, where she recovered completely. Now it would hardly do to call that functional, for there was a definite lesion, and yet it disappeared. I have myself advocated rather strongly in these cases of hysteria where there are definite paralyses, going back to Eulenberg's theory of disturbance of the vaso-motor system in migraine, although a good deal of contumely has been cast on vaso-motor theories. I cannot imagine anything else than a vaso-motor disturbance, however, which will give rise to paralyses that will suddenly disappear and suddenly recur or suddenly shift from side to side of the body. I cannot imagine a dynamic change working in this way. I can imagine also that there is localized œdema of the brain in some of the more lasting cases. Of course, it is all theory where nothing is found post-mortem, and one person's judgment is perhaps as good as another's in ante-mortem pathology. Probably some cases reported are the results of organic disease and perhaps have been confounded with these recurrent paralyses of functional, perhaps reflex character.

Dr. S. G. Webber: These cases are interesting, especially when grouped with other cases of recurrent or periodical paralyses. Speaking first of such cases as have been reported, I think I should agree with what Dr. Walton has said about the vaso-motor condition, that many of them are reflex in their origin, but it is not always easy to find the seat of the trouble which causes the reflex action. I do not remember any reported case where the condition of the eye was examined to discover whether there was any disturbance of vision, such as is found in so many cases of sick headache, which produces the sick headache, and it seems to me it would be worth while to make such examinations when the opportunity offers, to examine the eyes carefully to see if there is any refractive disturbance. I do not know why refractive disturbance should not cause motor as well as sensory trouble, why it should not cause paralysis of the motor oculi nerve as well as sick headache or, as in some cases, spasm.

The case of Thomsen, which came to autopsy, is interesting and instructive. Thomsen, I believe, reasoned that it could not be a disturbance of the peripheral nerve, that it must be a disturbance of the nucleus of the nerve. Some time afterwards the patient died and there was found a growth around the nerve. The fibres of the nerve were pressed apart by the abnormal growth. The nerve fibres on both sides the tumor were healthy and the paralysis was evidently due to congestion temporarily increasing the pressure. It is hardly possible that every case can be explained in that way. In fact this case by its rarity would be a proof that the lesion in periodic paralysis is generally not peripheral, not organic. The very singularity of this case would make it more likely that in other cases the paralysis is due to local congestions of the nerve centres. Most peripheral disturbances would destroy the fibres of the nerve, and there would be a more decided and absolute loss of power which would be persistent. The very fact of the periodicity and of the complete recovery in the intervals would exclude the peripheral origin. Any gross lesion near the nucleus could hardly be accepted as a cause, because if large enough to produce so much disturbance it would be likely to produce still more disturbance, and even a small growth near the nucleus would affect other functions if it did not affect the nucleus itself, and if the nucleus was affected by other than vascular changes we should have permanent symptoms which in many cases we have not. To be sure one class of these cases shows symptoms connected with the limbs and various other disturbances which must be due to gross lesions, but I am speaking of that class of cases in which there is simply temporary motor oculi paralysis without any other symptoms. There are probably two classes of periodic paralysis, one with gross lesions, one without. In the former there are other nerves affected and the disturbance is more permanent. I should rather favor the reflex vascular disturbance as the probable cause in cases truly periodic. There is one peculiarity in many of these cases which gives a little hesitation in fully accepting this and that is that after long continuance of the paralysis some of the symptoms become permanent, certain muscles, perhaps the superior rectus or the levator of the eyelids or muscles of accommodation remain permanently affected, showing that a permanent change has taken place, but this may be the result of repeated vascular changes.

I said that these cases were interesting with reference to other similar cases. I had a case of periodical aphasia once under my care. At first the patient was completely himself between the aphasic attacks. Later the attacks became rather more severe, lasted longer, and the patient between the attacks would miss words or use wrong words in talking, no more than some persons in apparent health would do; but as the attacks continued in frequency they became still more severe, and at length he was not able to talk properly between the attacks and not able to attend to business. He was put in an insane asylum. He died; and at the autopsy there was found more or less meningeal adhesion and some softening of the cortex, especially in the neighborhood of the island of Reil. Some of the cells of the brain had undergone fatty degeneration, and the small arteries were calcareous with degeneration of the cells, so that on cutting the brain the arteries were pressed down by the knife, and as the section was made the arteries projected as small twigs above the cut section and there was a little grittiness to them. The aphasic attacks were at first probably purely vascular. Of course later there was inflammatory change of the membranes and cortex as you find in general paralysis.

A peculiar case which I had and which was more of the nature of spasm was that of a man, seven members of whose family were similarly affected. The affection consisted of attacks of more or less difficulty in walking, chiefly stiffness, but when these attacks came on at night he would wake up in the morning unable to move. His whole body would be helpless. The attack would last until about noon when he would recover the power of motion. That was perhaps stiffness rather the opposite of paralysis, and it is possible the man may not have known the difference between contraction or rigidity and paralysis.

Five cases of general periodic paralysis have been reported by Consot; several of the five patients were of the same family. There was paralysis of all the limbs, the attacks recurring every day in some of the patients, in others at varying intervals from a week to ten or fourteen days. The attack lasted from five or six to ten or twelve hours, some longer. There was complete loss of power of motion and complete recov-

ery. The attacks began in comparatively early life; in some of the patients they continued till quite late in life. One patient had no more attacks after her first pregnancy. Westphal has reported a similar case of periodical paralysis in which there was complete loss of motor power in all the limbs with loss of electrical reaction which lasted a certain length of time and recurred, and in which there was complete recovery between the attacks.

Now these are very peculiar and singular cases and they seem to have an analogy to those that were reported as well as the cases of hysterical paralysis which Dr. Walton has referred to, and we cannot think of these cases of total paralysis as having any other source than the brain, that from some cause either by reflex influence, or by some other influence upon the circulation, there has been a vaso-motor disturbance which has destroyed the power of the cells to respond to the will. I suppose it might be called an inhibition of the motor power. I should be rather inclined to say it was a vaso-motor disturbance. It would be valuable and interesting if we could have more autopsies, but unfortunately we have not, and we are in the dark and have to grope about reasoning from analogy rather than from facts.

DR. P. C. KNAPP: I have been so fortunate as to see two cases in which I have made this diagnosis. The first case was referred to me by Dr. Wadsworth and is the one which he reported to this Society some six or seven years ago. The other case I hope to publish later. I would take issue with both Dr. Walton and Dr. Webber in regard to the pathology of these cases. In the first place, I question whether we can regard them as being analogous or akin to migraine, although Charcot has given the cases the name ophthalmoplegic migraine. I would agree with Mauthner in his conclusions that the difficulty is more probably with the oculomotor nerve after it leaves the nucleus. The fact that the condition is always unilateral, always recurring on the side in which it began in later attacks, speaks somewhat against the involvement of the nuclei. Furthermore, in the majority of cases the internal muscles of the eye are affected as well as the external, while in the nuclear palsies the accommodation and the movements of the iris are not usually affected. I must confess myself also sceptical in this as in many other affections in regard to the vaso-motor theory. We must not forget that in this affection there are only twenty-eight cases on record with three autopsies, but in every one of those cases there were distinct lesions found in the third nerve, either a tumor or inflammatory exudation, and in many of the other cases the clinical symptoms were such as to indicate some lesion in the neighborhood of the nerve. It seems to me, therefore, that we must confine ourselves to the limits of absolute knowledge without going into theoretical pathology, and absolute knowledge points as far as we have it to distinct changes within the nerve itself. In regard to the analogy and kinship to hysteria, that seems to me most remote, I do not know of a case of hysteria with the history of paralysis of the third nerve involving the external and internal muscles of the eye.

DR. JACK: I do not see how œdema can explain the persistence of the paralysis. Dr. Wadsworth's case, which seems to be so clearly connected with the otitis, cannot be explained in that way. One of the typical cases was in a tabes patient and it was considered that there was a connection between the two troubles. If this is true the paralysis in that case was certainly nonfunctional. It seems to me that the theories most distinctly in favor of the migrainous character of the affection are the accompanying disturbances.

Möbius thought that if there were a basal lesion the pain would not cease with the appearance of the paralysis. He therefore placed the origin of the pain near the nucleus. I would add to the reason which Dr. Knapp gave against the nuclear origin of the trouble, the non-involvement of the fourth nucleus and the completeness of the ptosis in most instances, the ptosis in known nuclear ophthalmoplegia being usually slight.

Cases analogous to these involving other nerves, the facial especially, have been reported. In one case there was in the different attacks an alternate paralysis of the facial and abducens.

Recent Literature.

Chirurgie des Voies Urinaires: Etudes Cliniques. Par le DR. E. LOURNEAU. Bordeaux: Feret et Fils. 1894.

Under the above title the author presents a varied assortment of clinical observations, together with his comments upon a number of cases of diseases of the genito-urinary organs. Many of these cases are sufficiently interesting in themselves; but they offer too little that is new or important to be considered valuable contributions to the subjects which they illustrate.

The observation which seems to us the most instructive is No. VII, which contains the reports of seven cases of chronic hydrocele, the cause of which in each case the author considers to have been urethral stricture — the latter being responsible for chronic inflammatory areas in the deep urethra and in the tail of the epididymis. One of these cases is very striking from the fact that hydrocele developed in the course of the formation of a stricture, disappeared spontaneously after an internal urethrotomy, recurred later as double hydrocele synchronously with the recontraction of the stricture, and again underwent spontaneous cure when the stricture was dilated.

The work suffers much from the diffuseness of the author's style in many places. A conspicuous example of this fault is to be seen in Observation III, which relates a case of the impaction of a bit of a pipe-stem in the urethra and bladder of a young girl. Six pages are occupied by the report of this case. All that is at all essential is contained in the space of a page and a half, the remaining pages being filled with such details as the visits of the mother and daughter to the doctor's office, the anger of the girl's father at the mysterious loss of his pipe, etc. These matters are, it is true, dealt with in a manner sufficiently entertaining, but scarcely appropriate to the serious consideration of the case *per se*.

The introduction of somewhat elaborate reports of such cases as those of a peri-urethral abscess occurring in the course of an acute gonorrhœa, or of a certain abnormality of the meatus urinarius, seems rather trivial.

The book would gain much if it were reduced to one-half its compass. We must confess that we do not find in it a *raison d'être* for so imposing a volume; nor do we think it will appeal strongly to the profession at large.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 21, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE PATHOGENY OF BRONCHITIS.

MOSNY, in a useful treatise on broncho-pneumonia,[1] recently published in the Charcot-Debove series, emphasizes equally with Netter, the microbian origin of this disease, and ascribes its pathogeny to four species of microbes:

(1) The diplococcus pneumoniæ, or Talamon-Frænkel lanceolated pneumococcus.

(2) A streptococcus which Netter and others identify with the streptococcus of erysipelas and of suppuration.

(3) The staphylococcus aureus and albus.

(4) The encapsulated pneumo-bacillus of Friedlander.

This writer insists that these are all common microorganisms normally existing in the upper air passages (bucco-pharyngeal cavity and nasal fossæ) of most people in health, and ready under the influence of predisposing causes to become virulent and morbigenous. We live, then, he says, in perpetual menace of pulmonary infections, of which our organism harbors within itself the cause; it is this category of infections which Bouchard has felicitously designated under the name *auto-infections*. Happily, the organism possesses ordinarily means of protection, which suffice to prevent the pullulation of the pathogenic agents and even to produce their destruction.

Claisse in an elaborate article in the *Semaine Médicale* (1893, p. 297) takes the stand that the microbian nature of the bronchitis is now demonstrated. Certain causes heretofore regarded as efficient, are to-day ranked among the predisposing causes; cold, for instance, only prepares the way for the microbian invasion. He takes, as the type of bronchial affections, those which occur in children, without alveolar lesion, and apart from any general disease. This type is seen in certain rapid forms of suffocative catarrh, so often fatal in infants.

The presence of the microbe in the bronchi manifests itself by both local and general effects.

[1] Broncho-Pneumonie, par E. Mosny, Paris, 1892.

The local effects have to do with the secretory reaction of the bronchial tree, which in certain conditions may bring about obliteration of the tubes, thus interfering with respiration. Bronchial obstruction is always an element of great danger, and doubtless gives to these respiratory infections of early childhood their principal gravity. But there is another pathogenic factor which also has its importance, as it has much to do with the general symptoms, namely, the toxicity of the bronchial secretions.

Beau, in a memoir published fifty years ago,[2] speaking of the bronchial catarrh of infants, observes that the products of bronchial secretion when swallowed, are the source of true poisoning accidents. Hayem, many years later in writing on bronchitis,[3] explains certain symptoms as due "to alterations of the blood by poisons secreted." The systemic intoxication thereby caused accounts for the febrile temperature, and in some measure for the dyspnœa.

Claisse, who has made a particular study of these bronchial auto-infections, divides the respiratory tract into (1) regions normally aseptic, (2) regions normally septic. The first are constituted by the bronchial network, the second by the mouth and naso-pharynx. The communication between the two systems is a wide one, hence the transition is not abrupt. There is an anatomical zone of transition constituted by the larynx, trachea and larger bronchi where there is a progressive decrease in septicity. Thus, there is a marked difference in septicity between the upper bronchi and the pharynx, and the finer bronchi normally contain no microbes. These passages, however, have a constant communication with the septic region, and hence the facility with which infective inoculations can be made. Claisse contrasts this anatomical condition with that of the liver and gall-bladder and the urinary bladder, aseptic viscera which are better protected from microbes, both by their situation and by sphincters. The greater frequency of bronchial infections over infections of the liver and urinary bladder is what we might expect from these anatomical differences. The bronchi are armed against infection by their system of vibratile ciliated epithelia expelling the figured elements, and by the microbicide quality of the adhesive secretion of their caliciform cells and glands. The lymphoid stratum of the mucosa constitutes a leucocytic infiltration resembling that of the pharynx, having an especial importance, when the epithelium is destroyed, through the phagocytic function of its lymph cells. The lymphatic glands also play an important rôle in the defence of the organism. The upper air-passages are endowed with reflex sensibility, enabling them to throw off by expectoration divers noxious substances. The medium-sized bronchi, less exposed to infection, are less efficaciously armed, though possessing a muscular coat which helps expel mucus and foreign bodies. The ciliated epithelium disappears at the extremity of the bronchial tree. The secretory apparatus, the cartilaginous rings and the muscular

[2] Beau: Journal de Médecine, 1843, p. 146.
[3] Hayem: Thèse de Paris, 1869.

fibres are here lacking; reflex sensibility has disappeared; on the other hand, absorption is more active, being favored by the thinness of the epithelial layer. Hence, it is apparent that the finest bronchi are poorly defended against the penetration and stagnation of septic products, and are especially adapted for the absorption of toxines.

We have not space for the clinical picture which Claisse has drawn of capillary bronchitis, and the arguments by which he explains the general symptoms in accordance with his theory of systemic intoxication. The well-known syndrome certainly markedly resembles that of some forms of uræmic or ptomaine poisoning rather than that of simple pulmonary obstruction; note the myosis, the frequent typhoid prostration from the onset, the multiform cutaneous (purpuric or erythematous) manifestations, the extreme oliguria, and the fact that the fulminant bronchial infection is not always accompanied by the boisterous symptomatic cortége of suffocative catarrh. There may even be absence of cough from the first. The autopsy shows the bronchi engorged, in places eroded of their epithelium, stuffed with an exudation containing modified epithelium, leucocytes and the microbian agents of infection. The liver is often found fattily degenerated, and the spleen fatty.

Claisse affirms that the hyper-acute bronchial infections of infants at the *Hospice des Enfants Assistés* are habitually streptococcus infections. This microbe attains in the disease-focus a preternatural virulence, and when inoculated in guinea-pigs produces a fatal septicæmia, without reaction at point of inoculation.

What are the causes which favor the microbian invasion? "We may," says Claisse, "suppose the bronchial tree to be injured in its resistance, epithelial or lymphatic, by cold or some other agency which modifies the mucosa. There is no longer a sufficient defence against the infection. The microbes obtain a lodgement and multiply; triumph over the divers means of resistance already mentioned; and spread or are carried in the air to the fine bronchi where they meet with little opposition; there they elaborate their poisons without stint."

The bronchial lesion is then the necessary starting point of the infection.

Claisse has artifically provoked bronchitis in animals by different methods. In a first series he produced aseptic lesions by intratracheal injections of dilute sulphuric acid or ammonia. The animals (healthy hares) were killed in twenty-four hours, and reparation of their lesions was nearly complete. In a second series he injected into the trachea of hares a few drops of cultures of the streptococcus and staphylococcus. At the end of twenty-four hours the animals were killed, and no lesion was discoverable. A third series was subjected first to the action of the aseptic caustic, then, at the end of an hour, to the injection of the microbian culture; at the end of twenty-four hours the animals were killed and were found to be the victims of an intense bronchitis.

These experiments were designed to imitate conditions occurring in nature where lesions of an irritative or erosive nature (physico-chemical traumatisms) are the antecedents of the bronchitis. It is known that the inhalation of gases, irritant by their high or low temperature or chemical properties, also dust, perhaps of some kinds of pollen, the elimination through the bronchi of certain toxic substances as alcohol and iodine, etc., may usher in attacks of bronchitis. Doubtless many microbes (as those of measles and whooping-cough) are able by their natural virulence, in many subjects, to immediately overcome the resistance of the bronchi.

Claisse has made some interesting experiments to elucidate the toxicology of bronchitis. We can only sum up the results which, together with considerations before advanced, have led this writer to the conclusion that the symptomatology of the bronchial infections is dependent largely on systemic poisoning by the toxines elaborated by the specific microbes.

Portions of the infected bronchial tract are broken up in sterilized water and filtered through porcelain. The filtrate when injected in hares produces very marked toxic effects, among which are hyperthermia and dyspnœa.

Streptococci taken from the same bronchial exudate are sown in bouillon; this bouillon is filtered through porcelain and injected in hares, producing precisely similar constitutional effects.

Benign forms, when the general phenomena are slight and the symptoms of local reaction conspicuous, manifest the preponderant resistance of the organism and the triviality of the lesions; while the grave forms betray the insufficiency of the organism in the struggle and the profundity of the intoxication.

MEDICAL NOTES.

CHOLERA. — The cholera still prevails to a considerable extent in Russia, Odessa particularly being infected. Hungary has been officially declared free from the disease.

INFLUENZA. — Newspaper reports from the Continent state that the influenza is widespread and general, though of a mild character. There are said to be 10,000 cases of the disease in the Province of Rhine Hesse. Throughout the United States there continues to be a spread of the disease, many cases being reported from all quarters, usually of a mild and short course.

SUCCESSOR TO SIR ANDREW CLARK. — Prof. J. Russell Reynolds, M.D., has been elected to succeed Sir Andrew Clark as President of the Royal College of Physicians. He received seventy-five votes. Dr. Samuel Wilks of Guy's Hospital received seventy-two votes.

MR. ANTHONY COMSTOCK AND GYNÆCOLOGICAL TABLES. — The action which Mr. Anthony Comstock, recently brought against the manufacturers of gynæ-

cological tables for sending indecently (?) illustrated circulars through the mails has been dismissed by the Commissioner at Albany.

A Severe Penalty. — An Italian physician has just been tried for refusing to visit patients ill with the cholera, and sentenced to twenty days' imprisonment, to pay a fine, and is enjoined from practising his profession in any way for three months. During the previous epidemic of cholera the peasants were accustomed to shoot and stone physicians who attempted sanitary improvements or to give medical aid. Between the law, which says *must*, and the people, who say *shall not*, physicians have a hard time in Italy during cholera epidemics.

A Remarkable Prescription. — The following prescription has appeared in the column of therapeutic notes in two esteemed medical contemporaries:

FACIAL NEURALGIA.

℞ Dover's powder.
Sulphate of quinine, . . aa . 3i.
Ext. of valerian, q. s.
M. Pil.
Sig. Four daily, seldom fails.

The New Orleans Lepers. — The condition of the nine lepers confined in the hospital at New Orleans is said to have become a matter of public attention in that city. The building is reported in an almost untenable condition, unprotected from the weather and insufficiently heated. The eight men and one girl are expected to wait upon themselves and provide their own food upon a small weekly allowance, which admits of nothing more than the necessities of life.

The Vienna Food Exposition. — An international food exposition is to be held in Vienna next spring, to which our Government has been invited to contribute. While no special appropriation is available for the purpose, the Department of Agriculture has taken an interest in the exhibit, and directed its representative in Central Europe to do all in his power to aid American exhibitors.

Human Sausages. — A story comes from Saxony of a most attractive character. A soldier having purchased a ten-pfenning sausage found in it the tip of a human finger-nail and bone. The vendor was brought to trial, and testified that the finger was cut off by the chopping machine and while he went to staunch the wound his assistant came in and completed the making of the sausage meat, in which he incorporated his master's finger.

BOSTON AND NEW ENGLAND.

The New England Cremation Society. — The annual meeting of the New England Cremation Society was held in Boston, December 19th. Bishop Lawrence was the chief speaker, and gave as his opinion that cremation, as a means of disposing of the bodies of the dead, is reverent, proper and healthful. As showing the progress of public opinion with reference to cremation we may mention that the remains of the Dowager Duchess of St. Albans, who died on December 2d, and Dr. Bradby, formerly Master of Haileybury College, were cremated recently, in accordance with the terms of their wills.

Small-Pox in Boston. — During the last week there have been four new cases and one death from small-pox.

Small-Pox in Brookline. — A case of small-pox occurred in Brookline December 16th, which is traced directly to the Morrison family in Boston.

Small-Pox at Methuen. — A case of small-pox has occurred this week at the Methuen almshouse. The man had recently come from Boston.

A Physician's Bequests. — The will of the late Dr. Lucius F. Billings of Barre, bequeaths his medical library and surgical instruments to the Worcester County Medical Society. On the decease of Mrs. Billings, $5,000 is bequeathed to Harvard University, to be kept as a permanent fund for the medical department, the annual income of which is to be used for scholarships for the benefit of poor but deserving medical students.

Hydrophobia in Connecticut. — A considerable epidemic of hydrophobia exists at Westville, Conn., among dogs and cows. All the cases are traced to the flying visit of a strange and rabid dog some four weeks ago.

Influenza in Connecticut. — Many cases of influenza are reported from New Haven, Norwich and Middletown, Conn., while many smaller places report their share. The cases are all said to be mild, though one town is said to have many cases of the grip, while "colds and incipient pneumonia are numerous."

NEW YORK.

Discussion upon Dr. Biggs' Report on Tuberculosis. — At the meeting of the Board of Health held December 13th, the report of Dr. Biggs on Tuberculosis came up for discussion; and Commissioner Cyrus Edson offered the following recommendations:

"(1) That a circular be prepared for distribution setting forth the danger of contagion from tuberculosis.

"(2) That physicians be required to report all cases of tuberculosis within seven days of the time when such sick person comes under observation.

"(3) The medical sanitary inspectors should, as part of their duty, investigate cases of the disease reported, and take specimens of sputa for diagnostic purposes, as is done in cases of diphtheria. Upon the verification of the diagnosis, the inspector should visit the physician reporting each case and request him to fully instruct his patient, and the person with whom he is in contact, concerning the nature of the disease and the danger of its transmission."

The following resolutions were also adopted:

"*Resolved*, That this Board urge upon hospital authorities of the City of New York the importance of separation, so far as possible, in the hospitals of this city of persons suffering from pulmonary tuberculosis from those affected with other diseases, and urge that

proper wards be set apart for the exclusive treatment of this disease: and, be it further

"*Resolved*, That the Commissioners of Charities and Correction be recommended to take such steps as will enable them to have and control a hospital to be known as 'The Consumptive Hospital,' to be used for the exclusive use of this disease, and that, as far as practicable, all inmates of the institutions under their care suffering from tuberculosis be transferred to this hospital."

The Board also ordered that the disinfecting corps disinfect places where evidence of infection exists, whenever in the opinion of the Chief Inspector for Contagious Diseases it shall be necessary.

APPOINTMENT TO THE BUFFALO STATE HOSPITAL FOR THE INSANE. — Governor Flower has appointed Dr. Wm. S. Tremaine, of Buffalo, manager of the Buffalo State Hospital for the Insane.

DEATH FROM HYDROPHOBIA. — Cornelius Minton, of Fair Haven, N. J., a lad fourteen years of age, died of hydrophobia on December 9th, after a two days' illness. He was bitten by a rabid dog on October 20th, while riding a bicycle, and the wound, which was slight, was cauterized; but no other precautionary measures were taken. It is said that two other individuals were bitten by the same animal.

DR. H. W. SPENCER. — Dr. Henry W. Spencer, formerly of New York, died at his residence in Paris, France, in November, at the age of eighty-six. In 1858 he was appointed United States Consul to Paris, and his house there became a famous rendez-vous for his visiting fellow-countrymen. During the Empire, he gave a number of handsome entertainments, and at these, American artists and medical students, however straitened their circumstances, were always most welcome guests.

Miscellany.

HOT BATHS IN JAPAN.

AN interesting account of use of hot baths by the Japanese is given by Prof. W. K. Burton, in a recent number of the *China Medical Missionary Journal*. Every Japanese of every rank in life takes his bath daily, and in water at a high temperature. The private and public baths vary only in size and arrangement, enormous tubs, square or oval in shape, with large copper tubes passing through them, in which charcoal is burned to heat the water.

"In the public baths it used to be the universal custom for men and women to bathe together, and the baths were commonly open to the street. Of late years, out of deference to foreign prejudice, the baths in the towns have been closed in, and there is always a division between the women's and the men's bath, although it is of the flimsiest nature. It is sometimes merely a bamboo laid across the bath at the surface of the water. In the country, and specially at all places where there are medicinal baths, promiscuous bathing is still common, but there is never any evidence of indecent thought or feeling."

The general time for taking the bath is after the work of the day is done, but those who have leisure bathe several times a day. The temperature seems astonishingly high to one who has not tested it. "Anything below 110° F. is considered too cold, anything over 120° F. unpleasantly hot, though in some cases this temperature even is exceeded." The bather, after laving himself with the hot water, and pouring some on his head, enters the bath and sits immersed in the water quite up to his neck for from two or three minutes to a quarter of an hour, according to his inclination and the heat of the water. There is no ill effect upon the health of those who bathe so often in this hot water: and the general healthiness of the Japanese who live among sanitary conditions in many ways defective, is considered greatly due to this habit.

When Japan was first opened to the world, and the people began to take advice of western nations in all things, the foreign physician strongly condemned the practice as bad; and "a regulation was issued that the public baths must not be heated above a comparatively low temperature. The great discontent of the people led to an investigation by physicians, both Japanese and foreign, with the result that except in cases of those suffering from weak heart, the custom was pronounced harmless."

"It might be supposed that the habit of public bathing would lead to the communication of infectious diseases, the more especially as, in some of the public baths and the hotel and tea-house baths, the water is not changed as often as might be advisable. All that can be said is that investigation has so far failed to detect such communication of diseases, and that, if there is occasionally a solitary case, the evil is much more than counterbalanced by the general improvement in health that results from the cleanliness gained by general hot bathing, which could not be indulged in by the poorer classes were it not for the public baths."

The charge for the use of the public bath is one cent. The many hot volcanic springs are much used for the baths. The most famous of these is that of Netsu-no-yu (literally fever bath) or Kusatsu. The springs of this town have been in use for more than a thousand years, and their repute is indicated by an odd proverb that "even Kusatsu cannot cure love." The highest value of the bath is in the treatment of syphilis, leprosy and skin diseases. The temperature of the bath at its source is 160°; but the water is cooled before using to baths of three temperatures, the hottest being 128° F., at which heat it is actually used. The water contains free hydrochloric and sulphuric acid to the extent of one-quarter per cent. of the whole volume, and about three volumes of sulphuretted hydrogen per thousand, and one part of sulphide of arsenic in one million parts. The effect of all these after about ten days' treatment is to produce "blisters about the scrotum, between the legs and under the arms, resulting in the characteristic 'Kusatsu walk,' the patients moving slowly along, with legs stretched wide apart and the arms held well away from the body." The pain of bathing in this state is such that for the two hottest baths the patients undergo a sort of semi-military drill under a master.

"About half an hour before bathing time a trumpet is sounded, and the bathers begin to arrive. They take their places around the bath, and take turns in vigorously churning up the water with broad boards. This

exposes the water to evaporation and cools it to the temperature mentioned above. As the time for bathing approaches, the bathing-master, in a white dress, takes his place amongst the bathers. He gives a signal, and every bather takes a large wooden ladle with a short handle, bends down and begins to pour water over his head. This is to prevent the likelihood of congestion from the excessive heat of the bath. The pouring continues for five minutes. And then there is a second signal, at which all stop for a rest of three minutes. During this time, those who have been most affected by the treatment wrap thin cloth bandages around the parts most affected, as this reduces somewhat the torture of the parboiling process. At the end of the three minutes, the signal to enter the bath is given, and very slowly the bathers lower themselves, taking about thirty seconds before they are completely immersed. And now begins the most extraordinary part of the whole affair. It is a sort of a chant on the part of the bathing-master, with an answering chorus from the bathers, the whole thing intended to encourage them in bearing the pain. The chant of the master, freely translated, is somewhat as follows:

"'If you are all ready enter the water.
There are three minutes.
There are only two minutes more.
Persevere a little longer.
There is only one minute more.
Persevere only a very little longer.
Get out of the water *slowly*.'

"To each of these sentences, chanted in a strange manner, the hundred or so of bathers answer from the bath with a sound that is between a shout and a wailing cry, and that can be heard all over the town. The order to get out of the bath is obeyed, but there is no slowness about the movement. Each bather leaps and scrambles from the bath with an agility that shows how hard he has found it to bear. Nearly a hundred enter the bath at once, sitting just as closely as they can, and the bathing goes on for more than an hour, five times a day. The usual course is about a month, and, after it is over, the bathers generally proceed to another hot-spring village where the waters have the effect of very quickly healing the skin."

THE ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

ROME, MARCH 29 – APRIL 5, 1894.

PROF. E. MARAGLIANO, M.D., of Genoa, Secretary-General of the Eleventh International Medical Congress, makes the following announcement through Dr. A. P. Clarke, of Cambridge, Mass.:

In consequence of the adjournment of the Congress, Articles I and II of the Statutes have been altered as follows:

ART. I. The Eleventh International Medical Congress will be inaugurated in Rome on the 29th March, 1894, and will close on the next following 5th April.

ART. II. Papers to be read before the Congress should be announced not later than the 31st January, 1894. The title should be accompanied by a very short *précis* of the paper and by the conclusions; the latter will be printed by care of the board, and distributed among the members.

Papers announced after the 31st of August, 1893, will be marked in the Provisional Programme with an asterisk.

The Provisional Programme will contain also those previously announced papers which have been published in scientific papers after the adjournment.

The railway companies have established that the reduction of fares should be available from the 1st of March till the 30th of April, 1894.

The travelling tickets of membership and railway passes will be sent by the Secretary-General's Office to each member enrolled before the 14th of February, 1894.

The first edition of the Provisional Programme is going to be printed, and will contain details concerning the Congress and a list of all the papers announced till November 15, 1893.

It should be well to remember the following articles of the Statute:

ART. 2. All physicians are admitted to have a part in the work of the Congress, provided that they have satisfied the conditions of inscription and obtained the required ticket of membership.

ART. 3. The doctors of other sciences who, for their special studies, should have an interest in the work of the Congress may be enrolled, with the duties and rights of the members of the Congress who are doctors of medicine, being entitled to partake of the work, either by reading papers or by having a part in the discussion.

ART. 4. The admission fee to the Congress is fixed at twenty-five francs – one pound sterling; it entitles to a copy of the report of the Congress, which will be forwarded to the members as soon as it is published.

ART. 17. The persons, who, not being comprised in the Article 3, are interested in the work of a Section, may obtain admission by consentment of the President of the Congress.

Such persons will receive a special ticket, and will pay the admission fee like the other members, being entitled, however, to a copy of the Report of the Congress.

The persons thus admitted to the Congress may speak neither in the general sittings nor in the sittings of the sections to which they are not enrolled.

ART. 18. The students of medicine may be invited or admitted by the President to attend the sittings, but only as hearers.

They must obtain a special ticket which will be granted them without payment.

Members may apply to the Secretary-General's Office for railway passes for their wives and adult members of their families; the latter may be enrolled on payment of a fee of ten francs.

Medical gentlemen and all persons who wish to take part in the Congress are requested to give their names as soon as possible, writing for this purpose to the Secretary-General of the Eleventh International Medical Congress, Genoa.

Fees should be paid by post-order or draft to the order of the Treasurer, Prof. L. Pagliani, M.D., Director-General to the Office of Public Health, Home Department, Rome.

THERAPEUTIC NOTE.

SUB-CONJUNCTIVAL INJECTION OF CORROSIVE SUBLIMATE.[1] — Dufour, after making use of sub-conjunctival injections of corrosive sublimate in over ninety patients, concludes that it is the best treatment for the following five varieties of ocular inflammations: (1) in purulent ulcers and suppurative keratitis; especially when pus is present between the corneal lamellæ; (2) in deep keratitis from local causes; (3) in deep exudations, with the development of cells in the vitreous, which almost surely leads to phthisis bulbi; (4) in sympathetic ophthalmia; (5) in even non-syphilitic choroiditis in the early stages. The solution used varied in strength from 1 to 1,000 to 1 to 4,000. The most to be recommended is one of 1 to 2,000, which is easily tolerated and of sufficient strength.

Amesbury	10,920	1	1	—	—	—	—	—

Deaths reported 2,149; under five years of age 868; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fever) 341, acute lung diseases 504, consumption 284, diphtheria and croup 166, typhoid fever 44, diarrhœal diseases 29, scarlet fever 28, measles 24, whooping-cough 18, cerebro-spinal meningitis 18, malarial fever 8, small-pox 4.

From scarlet fever New York 5, Philadelphia and Boston 4 each, Brooklyn and Cambridge 3 each, Milwaukee and Chelsea 2 each, Cleveland, Fall River, Somerville, Northampton and Medford 1 each. From measles New York 15, Brooklyn 4, Milwaukee 3, Philadelphia and Northampton 1 each. From whooping-cough New York 6, Philadelphia 5, Brooklyn 3, Boston, Washington, Cincinnati, Cleveland and Taunton 1 each. From cerebro-spinal meningitis New York 5, Washington 4, Lowell 3, Cleveland 2, Brooklyn, Worcester, Springfield and Chelsea 1 each. From malarial fever New York 6, Cleveland and Nashville 1 each. From small-pox New York 4.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 9, 1893, TO DECEMBER 15, 1893.

Leave of absence for four months, to take effect about January 6, 1894, with permission to go beyond sea, is granted MAJOR ALFRED C. GIRARD, surgeon, U. S. A.

FIRST-LIEUT. ALLEN M. SMITH, assistant surgeon, granted leave of absence for four months, to take effect on or about January 4, 1894.

The leave of absence granted MAJOR PETER J. A. CLEARY, surgeon, on surgeon's certificate of disability, is extended four months, on surgeon's certificate of disability, on condition that he report in person to the commanding officer, Army and Navy General Hospital, Hot Springs, Ark., on or before December 11, 1893, for treatment therein.

Leave of absence until February 22, 1894, is granted MAJOR JOHN BROOKE, surgeon, U. S. A.

FIRST-LIEUT. BENJAMIN L. TEN EYCK, assistant surgeon, is assigned to station at Fort McIntosh, Texas, for field duty in the department of Texas.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 16, 1893.

C. A. SIEGFRIED, surgeon, detached from U. S. Training-ship "Richmond" and granted four months' leave.

J. A. HAWKE, surgeon, detached from Widows Island Hospital and special duty Portsmouth, N. H., and to the U. S. Training-ship "Richmond."

M. H. SIMONS, surgeon, ordered to Widows Island Hospital and to special duty at Portsmouth, N. H.

R. C. DEAN, medical director, ordered as President, Board of Medical Examiners, Washington, D. C.

A. A. HOCHLING, medical director, detached from Board of Medical Examiners and wait orders.

MICHAEL BRADLEY, medical director, relieved as President of Board of Medical Examiners and ordered as member of the Board.

SOCIETY NOTICE.

NORFOLK DISTRICT MEDICAL SOCIETY. — A meeting for Scientific Improvement will be held at the Norfolk House, Roxbury, Tuesday, December 26, 1893, at 7.45 P. M.

Communications: "A Case of Acute Infection, simulating Acute Yellow Atrophy of the Liver," Samuel Crowell, M.D.

"Puerperal Eclampsia, with report of cases," H. D. Arnold, M.D.

Coffee at 9.30.

JAMES C. D. PIGEON, M.D., *Secretary.*

HARVARD MEDICAL SCHOOL.

EVENING LECTURES.

The lecture on the "Structures and Functions of the Uterus" by Dr. Charles S. Minot, in the course of free evening lectures at the Harvard Medical School, which was announced for Wednesday, December 27th, will be delivered instead on *Tuesday evening, December 26th*, at 8 o'clock. Dr. Minot's second lecture will be, as announced, on Wednesday evening, January 3, 1894.

RECENT DEATHS.

ELBRIDGE GERRY WHEELER, M.D., M.M.S.S., died recently in Middlefield, Mass.

JOHN RENTON, M.D., M.M.S.S., died in Boston, December 15th, aged seventy-four years.

BOOKS AND PAMPHLETS RECEIVED.

Charaka-Samhita. Part VII. Translated into English and published by Avinash Chandra Kaviratna. Calcutta: D. C. Bass & Co. 1893.

New York County Medical Association, State of New York; Register of Members; Manual of Information. New York: Published by the Association. 1893.

Lecture.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XXII.

DISEASES OF THE JOINTS.

We begin to-day with diseases of the joints. I need not say that they are very common. Why they are so common seems to depend on two causes. In the first place, the parts around the joints are the centres of bony growth, epiphyses, consequently they are changing and only partially formed up to adult life. That would explain a good deal the tendency to disease in children. Again, in adult life, as in children, they are always centres of motion, always subjected to friction, always subjected to strains, to overuse; and they are the working centres, so to speak, of the bony frame, on which all the wear and tear comes, — causes certainly why, in susceptible persons, they so easily become the seat of disease.

SYNOVITIS.

Take the simplest form of affection about the joints which concerns only the synovial sac, — synovitis. In the simple acute form the progress is about as follows: The patient after a blow or sprain feels a slight lameness in the knee-joint, we will say. There is pain on flexion and in putting weight on the joint. Very soon a slight puffing on each side of the patella. This expands soon afterward across the bottom of the patella under the patellar ligament, increasing symmetrically, forming an ovoid and finally fluctuating swelling, and lifting the knee-pan up from the joint. While this is taking place, of course the synovial sac is removed away from its position around the bones. The muscles and fascia which are attached and prolonged into it lose their firm grip and bearing upon the bones themselves; and the joint becomes weak, and moves from side to side; and although it may not be the seat of great pain, yet the patient feels insecure, and is in constant danger of falling if he puts his weight on it. As the fluid increases the pain generally diminishes very much. During this effusing stage there is heat about the joint; and this continues during the acute stage; but after the fluid has been all poured out; after a few days, the heat and pain pretty much cease. The weakness of the joint remains. The swelling is very marked and characteristic. The patella together with the quadriceps extensor is lifted up from the front of the femur; and the result is what is called floating patella, and increased insecurity in using the quadriceps extensor muscle.

This disease may have various terminations. If properly treated and in a good subject, this fluid may be wholly absorbed again in a short time; in a few weeks, not in a few days. It goes away slowly, lingers last, naturally, at the bottom of the sac; and when it is nearly gone can still be detected by making the patient strip and stand upright and comparing the two knees; it is found that there is a manifest puffing below one patella, which does not exist on the other side. As this fluid goes down, it is apt to leave some thickening of the sac itself; and after the sensation of fluid is absent, there is still a little doughy feeling about the joint. In the perfect restoration of the part this finally disappears, and the knee becomes as it was before; but in order to become as it was before usually several months are consumed. What is more apt to take place is that the fluid is absorbed to a certain degree; and then the latter portion of it is indolent; the sac becomes slightly thickened like an inflamed pleura, and finally slight fibrous thready adhesions are formed across from one side of the synovial sac to the cartilages and the bones; and what is called fibrous anchylosis results. If now this goes on, finally the fluid is wholly absorbed. These threads shorten and become firmer; and what is called false anchylosis, a stiff knee, stiff by fibrous attachments, is the result.

On the other hand, acute synovitis may pass into the chronic form. In that case the patient frequently has recurrent attacks; has his acute synovitis; has it restored to a certain degree, and then the joint puffs up again; fluid re-forms; and the fluid is slow in going away the second time, if it can be noticed to go away at all. The reason is that successive inflammation of the synovial sac renders it incapable of absorption, and the knee becomes bathed in an indolent fluid of serum and perhaps some fibrin; it is not absorbed and forms the condition called chronic synovitis; sometimes called dropsy of the knee-joint.

The treatment of acute synovitis to be best should be immediate. Unfortunately the patient does not generally apply to the surgeon or physician until the disease has existed some days, and effusion is already well-formed. Immediate confinement in bed or on a sofa should be insisted on; the limb put on a hamsplint so that the joint may be restricted in motion and yet the front of the knee-joint left uncovered so that it may be treated. At first it should be treated with cooling and evaporating lotions during the early inflammatory stage; later with more stimulating applications like blisters and tincture of iodine; and finally by pressure; and pressure and firm bandaging will usually complete the cure. This all takes several weeks. Afterwards the patient should be instructed to wear a flannel bandage a number of weeks; to use the limb with caution; carry a cane; and be careful not to strain the recently healed parts, so that any other effusion may take place. This usually suffices to cure an acute synovitis in the healthy subject.

The chronic synovitis, on the other hand, is extremely obstinate of treatment; and although we rest it; put it on a splint; apply blisters, iodine, etc., yet the fluid sometimes does not go away. Under these circumstances the judicious application of continued pressure is of great benefit; and this should be applied in one of two ways. In the old way, — still a very good way, — by putting on dry compressed layers of sponges, wetting them and making firm compression on the whole synovial sac. After this has done its work and is beginning to loosen, re-apply. In this way a strong uniform pressure is got over the sac, and the result is to gradually absorb the fluid by compression.

Another method, which is more ready and perhaps as good, is to apply around such a joint a rubber bandage which can be put on and the patient strictly confined to bed. That can be readjusted from time to time, and firm pressure made on the joint.

Still there sometimes remain obstinate cases of dropsy of the knee-joint, which are indolent, painless, free from fever and irritation, with no signs of absorp-

[1] These are unwritten lectures printed from the stenographers' reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

tion. In such a case as this, tapping of the joint may be done with advantage; and aspiration having been used, the joint can be pumped off by the vacuum, and pressure put on. If this measure proves insufficient and fluid afterwards re-forms, a second time we may tap and draw off a portion of the fluid, and inject into the joint some irritating preparation: tincture of iodine, a preparation of ammonia, a weak solution of carbolic acid, or something of that kind. Absolute alcohol has been injected with a good deal of benefit. This lights up an inflammation; converts an old chronic dropsy into a pretty lively synovitis for the time being; and after that has subsided, we put on pressure, and by subsequent bandaging lead to the absorption of the fluid.

In a person not strong we always have a dread that an acute synovitis, if not promptly cured, may lead to something worse; and that something worse is the change in the synovial sac described by Brodie as pulpy degeneration of the synovial membrane. The change takes place in the inner lining of the synovia, where it becomes thickened and roughened; and softens and undergoes a change somewhat like that undergone in the arteries in atheromatous disease. Bony plates are not formed; but ulceration of the surfaces; fatty degeneration and formation of flakes of fibrin; and such a change in this membrane that it is impossible for it ever to wholly recover. In these cases we find the young subject with a permanently altered joint as to its usefulness. The natural outlines of the joint are lost. The patella is no longer distinct. The sulci on either side cannot be made out. The shape of the joint is still entirely symmetrical, alike on both sides. If it is alike on the two sides it means disease in the synovial sac; if on one side more than the other, it means disease outside the synovial tissue, or else inside of the bone. The joint becomes spindle-shaped; the muscles above and below waste to a certain degree; the shape of the joint is lost. It is doughy; not hot to the touch, particularly; slightly painful, and remains in an indolent state. It cannot remain in this condition without some subsequent change; and the next change which takes place is that the effusion which was present in the joint gradually degenerates, and finally, incapable of absorption and subject constantly to friction and motion, and also subject to the influences of a feeble constitution in the patient, the fluid becomes changed into pus, and suppuration in the joint takes place. Now occur fever and chills and sweats and pain, all the phenomena of hectic. Finally the joint begins to lose its symmetrical appearance; swells on one side or the other; reddens; becomes acuminated; thins and bursts; and we have suppurating disease of the knee-joint, with a sinus leading into it, and the constant discharge of pus.

ULCERATION OF CARTILAGE.

We have another form of disease of the joint, called ulceration of cartilage. By that we mean decay of the cartilage.

The cartilage is an extremely lowly-organized body, nourished mainly by imbibition from the neighboring vessels and tissues. Its nutrition is never at a very high point. It easily falls into decay, and anything which affects either surface of the cartilage from the sides where it gets its nutrition, cutting off the supply of blood and the proper absorption of fluids into it, may lead to its decay: hence decay or ulceration of the interarticular cartilages, or the articular cartilages of the bones may arise, on the one hand, from the diseased synovia bathing it in a purulent secretion, and preventing its nutrition on that side; or it may arise from the disease beginning in the bone itself, whereby its nutrition on the side where it clings to the bone is cut off by occlusion of the vessels. In the first place, it is due to suppurating synovitis; and, in the second place, to disease of the cancellous tissue of the epiphysis of the femur or tibia; and frequently that, also, is of a tuberculous origin. Tuberculous disease, cheesy degeneration in the cancellous tissue of the head of the bone, soon affects the overlying cartilage, cuts off its nutrition, and leads to its ulceration. The result is, that as this diseased condition goes on in the feeble subject, that the cartilage loses its lustre and becomes yellow and dull, flattens off; a portion decays and drops into the joint. If the disease is going on on both sides, erosion takes place rapidly; and in the advanced state we find only shreds of cartilage lying about the bone, and the cancellous tissue of the bone already exposed, and rough and carious.

So far, then, with the exception of tubercle, every change we have described is in the joint and symmetrical, and outside of the bones themselves. All these changes, then, for example, would be accompanied by no change of shape of the bones whatever, and, were we to judge by the bones alone, we should not say that the joint was diseased in the slightest particular.

I will speak now of the other series of changes which begin in the bones. When tuberculous degeneration or any change begins in the epiphysis of the femur between the two condyles, it leads to a congestion, and then to inflammation and effusion of false products into the cancellous tissue. This gives rise to dull, aching pains which are persistent in character, to elevation of the temperature in the joint itself, and to the usual symptoms of hectic. The most peculiar change which takes place, which may be noticed by the outside observer, is the expansion of the bone itself; and the end of the femur visibly grows, enlarges, and broadens under observation, so that from being normal it widens out, until it is immensely enlarged on one side or both, sometimes more on one side than on the other, frequently more on the inner than outer condyle, until there is a large bulging of bone over the inner side of the condyle of the femur. This means bone disease, an ostitis going on in the cancellous tissue, a softening and caries taking place there, generally from a tuberculous deposit. The pulpy degeneration of the synovial membrane, which follows in the scrofulous subject, in acute or chronic synovitis, and the ulceration of cartilage, which is the next stage in the diseased process, and which is, in consequence of the cutting off of the nutrition of the cartilage, eventually leading to suppuration and change in the joint, and finally to disastrous disease — all these forms of disease have been called, among the laity, by the common name of white swelling. White swelling, in popular parlance, means chronic synovitis affecting the sac, the cartilages and the bone, generally of strumous origin, and finally resulting either in anchylosis or abscess. The reason of the name was probably because it is a swelling of the joint which does not change its color. It never reddens until the acute process has burst through the sac into the cellular tissue. It is a pasty, pale, œdematous, soft tissue,

which retains the imprint of the finger about the joint, has lost the true shape of a joint, is rather free from acute heat or inflammation, and is in this chronic strumous state which will end, probably, in suppuration, ulceration of cartilage, abscess in the joint, caries, anchylosis, if cured; excision, or amputation if not cured.

Still another change, a very curious one, takes place. After the sac is altered, these diseased fluids poured out, cartilages eaten away, bones become carious, still inside the sac are shut-up pus and decayed products; if acute abscess does not take place on the outside, the joint still retaining its contents to the last, by and by another change begins to be observed in the knee. It is spontaneous dislocation of the head of the tibia back of the femur. The disease has gone so far, it finally attacks the ligaments, loosens them; and the power of the long muscles pulls the tibia backwards and dislocates it almost entirely behind the condyles of the femur. In such a joint as this you find a peculiar shape beginning to develop in the front of the joint. The outlines originally lost and indefinite become more distinct. The patella stands out, the condyles of the femur stand out. You will see, on close observation, that the tibia is no longer on a line with the femur, and is dropping back; and the condyles and the patella are projecting out over it at a sharp angle. This change goes on further and further; and in very old, crippled subjects, who have had this disease a very long while, instances are found where the tibia is absolutely dislocated backwards into the popliteal space, the limb shortened, and the femur thrown entirely in front of the lower bone. Usually it does not go so far as that.

If a moderate and partial dislocation, it is still capable of spontaneous cure. After a term of years, without the occurrence of any external discharge of pus, inspissation of pus takes place, the formation of fibrous adhesions, the formation of bony adhesions, and finally, cure results, with a partial dislocation and a firm, bony anchylosis.

This bony union is called true anchylosis, but is not necessarily accompanied by dislocation.

What are the symptoms of this graver class of diseases? We have seen how insensibly in the bad subject they shade off one into the other, usually pursuing a line of well-marked steps or stages of gradual degeneration of the part. We have said it is quite easy to recognize an acute synovitis. The swelling is great, fluctuation is considerable, the disease is painful, the cause is quite evident, the patient is fully aware of what is taking place and the diagnosis is practically made with great facility, and a mistake perhaps is seldom made. Not so with these insidious stages of chronic synovitis, for the symptoms are slight and obscure, and they continue for months, perhaps, before the attention of any one is called to them. One great reason for this is that both in the knee and in the hip they occur largely in young children, too young to tell their symptoms, and indifferent, as children always are, to bodily suffering, providing they can keep about without having to lay up, and play around with their companions under the emulation that always exists at that age. Children are very peculiar in this respect. They of course never simulate disease; never have hysteria or mimesis. They do not pretend to have what they do not have. It is only by sharp observation that you can find out in the little child that something exists which is pulling him down. In the knee-joint, for example, if the disease begins as pulpy degeneration and ulceration of cartilage, slight limping; favoring of the limb; bending of the knee; not carrying it quite straight; favoring it by walking on the toe; occasional attacks of fever and pain; starting pains at night. These last are the most characteristic signs of articular disease at all ages. They occur from the spasmodic contraction of the muscles after one falls asleep; and they occur also after amputation, making a painful jumping of the stump, after the limb is gone. The control of the muscles is lost in sleep. A spasmodic action of the muscles occurs, and the child wakes from pain, and falls asleep again. This occurs from diseases of joints; those affecting the synovia, the cartilages and the bones; and it does not occur usually in the simple forms of synovitis; and does not occur in the series of joint diseases which are hysterical, or mimetic. The signs then of this condition are insidious. We have a little limping, a little bending, yielding of the foot, a little change of shape, slight attacks of fever, frequent starting pains at night, and if we look at the joint it is somewhat altered in shape. Still more insidious are those changes where tuberculosis begins in the bone itself and expansion takes place in the condyles of the femur and the femur grows out on either side; and the child also limps slightly, bends the leg slightly, and has a certain amount of pain. You will frequently see children at the out-patient departments who run along with a slight limp, without good motion of the joint. Examining the two ends you find a great expansion on one side, not present on the other. At a later stage when suppuration has taken place and abscess is about to form, the symptoms become extremely severe and intense up to a certain point, and then are promptly relieved on the bursting of the abscess itself.

So much for the diseases of children and youths and young adults. Now the old people have their peculiar diseases of the joints which are very characteristic. We know that most of them are ascribed to rheumatism or gout, and with justice; but besides these there exists in the old a form of chronic arthritis which has sometimes been described as senile hip disease. The hip disease of old people is a matter of months, or years. The leg slowly shortens; the shape of the part changes; the joint still moves to a certain degree, but is stiffened; there is constant pain and lameness; and the patient, although accused of having had a fall that they may never have had, manifests all the signs of shortened femur, and goes about with increasing symptoms of hip disease, during the remainder of life. They are essentially cold inflammations; and the changes which take place are those of softening and absorption, rather than of acute suppuration. On the other hand, the very large class of diseases in the joints of old people which are due to gout or rheumatism are marked by very peculiar and easily recognized symptoms. The chronic rheumatic arthritis, or rheumatoid arthritis, in elderly people, is characterized first, by what is called a dry joint; the joint creaks and snaps on motion. This is especially true of the knee. The patient sometimes may be heard in the house walking down the stairs, while the patellæ snap upon the front of the femur. Similar creaking and rubbing takes place in the hip; in the bodies of the vertebræ; or in other joints. The shoulder becomes roughened and cracks on motion. This change is due to gouty

deposits on the articular surface of the joint itself. The joint surfaces become roughened; bony growths take place; fringes of little osteophytes grow about the articular surface; and creaking and rubbing take place which simulate exactly the crepitus of a fracture, no injury, however, having occurred. The patient being at an age to have this disease, we may diagnosticate this bony affection as chronic rheumatic arthritis. The joint is dry; rubs and grates; motion is restricted; anchylosis does not always take place; but restriction of motion to a very marked degree takes place, so that finally the patient becomes unable, perhaps, to get the hand up or behind the head, but can still make the to and fro motions in the joints. The motions of the knee and hip become restricted. These patients go on through life and die in this condition, lame, stiff, disabled; but the disease does not reach any higher grade of destructive process. Occasionally nature makes another change, which is very remarkable; and after they have been rough and crackling sometime the knee gets smoother and works better, and eburnation or ivory-like polishing of the surface takes place. The cartilage is gone; the bone is smooth and hard and rubs against another surface without the intervention of cartilages; and a species of smooth polishing down, without much synovial assistance, is made, and the patient moves about pretty well.

NEURALGIA OF THE JOINTS.

It is rather hard to say what it is. I believe it is almost always due to some unsuspected and unrecognized diseased condition of the bone itself, in the neighborhood of the joint. For example, a person too far advanced in life, and too active and of too many interests in this world to be suspected of wanting to lay up, complains of constant lameness in the knee. It is always located in one spot; shows nothing outside; you can feel nothing; appreciate nothing; no swelling, heat or change of outline, but an everlasting boring pain in the inner condyle when he gets tired; which obliges the patient after a half day's work to come home and rest his leg on a sofa, when the pain gradually subsides. It is probably due, so far as we can make out, to gouty changes in and about the joint itself; and just as in the arthritis deformans, so about the femur and in the larger joints, occasionally, gouty deposits take place, which are the seat of pain; these are probably chalky deposits, which are not sufficient to throw the joint out of position; but are the subject of constant painful friction, after the patient has long used the part.

A very large class of supposed diseases of the joints are due to an hysterical condition. They generally begin in the young and susceptible subject; not always a female, but often females; in consequence of a real injury. The patient gets hurt a little, not much; but she does not get well. When the time has passed for the effects of the bruise or slight synovitis or blow to be cured; when you think you can take the knee-joint and move it; and she says she cannot stand upon it; and cannot move it herself; and you can detect no ostensible disease whatever, you have got to suspect that the disease is in the mind, and not in the joint itself. It is what is called hysteria, a very false name. It has nothing whatever to do with the uterus. It is better called mimesis or simulation; not always conscious simulation. The patient may be perfectly honest, and self-deceived, on account of this peculiar mental tendency; weakness of will; the imaginative faculty, which is in excess. They get into a condition when they believe that the joint is diseased; that they cannot stand on it; that it is going to kill them if they get on it; and the longer this delusion exists, the more helpless becomes the joint. Finally, in such cases, unless relief can be given in some way, the patient, who cherishes this illusion, takes to her bed, and becomes what Dr. Channing described as the bed case; and nothing gets her up, except something which appeals more strongly to her imagination, than the surroundings in which she is. If there is a fire and the bed gets on fire, she will get up and go out. If influences of a hypnotic or spiritual kind are brought to bear, she may be immediately cured. If she can be shocked to get up, or induced to get up, she may be cured; but unless her will can be in some way got hold of, she does not make that effort; and the limb remains, what is called, an hysterical joint. Brodie, who practised among the wealthy and indolent classes in the latter years of his life, says hysterical joint disease was very frequent; and a majority of cases of joint disease he saw in the young were purely mimetic, and not real. In these cases the difficulty comes in making the diagnosis. We all know that organic disease may be behind these manifestations. Patients thought to be hysterical may be found to have internal cancer. We must be as sure as possible that the diagnosis is correct; and exhaust every means to try to find it. Try such a limb with the electrical current; test it carefully as to its temperature; have careful watch kept in the patient's sleep, to see whether she ever has those painful, nightly shrieks, which are almost pathognomonic of disease of the joint, and do not occur in the simulated variety. When the joint keeps the same temperature and shape and appearance, and the only change about the leg is that fatty degeneration is taking place in the muscles with wasting; meanwhile, the patient looking and remaining in perfect health; keeping a good complexion and a pretty good color, and only yielding to this peculiar condition of the joint; we may then be pretty sure that it is due to a misplaced effort of the mind; want of will, error in the imagination. It is a species of insanity, and should be treated with charity; but the cure will be brought about by mental treatment, and not treatment of the limb itself. Such a patient should be encouraged in every possible way to get up and try to put the weight on the limb. One may perhaps induce them to do so by the aid of crutches; massage and gymnastics are useful. Passive exercises may be given by other persons while the patient is lying down; and finally, perhaps, the patient may be persuaded to resist against the hand of the rubber, and make motions herself. If she once finds out that she can do that, the cure commences. Electricity is of great assistance. In addition to this, diversion of the mind; if the patient can be carried out of doors, amused; led to forget herself; and brought on from stage to stage, until she can be cured. More depends, I am inclined to think, in the treatment of this class of cases upon the personal magnetism of the individual, than anything else. Some people have the power of impressing those with whom they come in contact; of preserving always a certain belief and confidence in their assertions; and finally lead the patients out of their beds, and on to their feet, so that they walk. The most unfortunate thing which can happen is to remain at home and be

surrounded by a set of sympathizing friends, who believe in the reality of this false disease; who encourage every supposed pain and ailment; who shrink from anything being done; and unless the patient can be removed from such surroundings and started anew, frequently a cure is almost impossible. These cases, as I say, should be treated firmly; but they should be treated charitably; for they are practically and really a disease of the mind, and should be treated like other mental affections. Most of them, sooner or later, get well. Sometimes they take a year or two, sometimes some years. Occasionally one remains permanently through life; and such instances, of course, are very painful, because as time goes on it is evident that there is no disease; because the patient does not alter; no change in the joints; no abscess; no anchylosis; no formation of cancer; no pulpy degeneration; and the patient remains bedridden, but perfectly well.

HIP DISEASE.

Hip disease is one of the more marked diseases of the joints. It most frequently comes in children, fortunately, because in children it is capable of cure; and in adults it is not; unless the spontaneous stages of the disease have been gone through and the diseased condition terminated by the time puberty comes on; so far as my experience goes, the patient never gets well if the age of puberty is passed, and the active changes of hip disease go on; they last then through life, or until they destroy the patient.

This disease is supposed to originate in two different ways. Undoubtedly it does, like all the forms of which we have spoken, originate in two ways; beginning in the synovial sac, or in the head of the bone itself. It may begin as a chronic synovitis, with pulpy degeneration of the synovial membrane and ulceration of the cartilage, from cutting off of nutrition from that side of the cartilage; or it may begin as a tuberculous deposit in the head of the femur, and from want of nutrition from the inner side, lead to erosion of the cartilage; abscess, and all the phenomena of hip disease.

The symptoms which present themselves first are, usually, that the child begins to throw out the foot of the affected side a little more than the other side, as it walks. The limb is apparently lengthened. The child limps a little as it walks. It does not complain of much pain. No changes have taken place about the joint which give any characteristic appearances from the outside. As the disease goes on a little further, more pain is manifested; inability to walk with any freedom; and, after a while, the position of the limb and foot changes, and apparently a little shortening takes place. About this time the child usually becomes very sick, and an acute fever supervenes, with intense pain in the joint; the child lies in bed with the limb drawn up towards the abdomen to relieve and relax the part. The parts all about become shiny and thin and change in shape. The fold which exits normally between the buttock and the femoral muscles is lost. The hollow in the groin becomes filled up, so that the diseased side is full and flat; and, in addition, intense nightly starting pains with hectic; rise of temperature; sweats, chills, etc.; and then sudden and immediate and perfect ease. The child turns over, begins to laugh, feels better, wants to get up. The explanation is, that the earlier stages, marked by such extreme suffering, were those of an abscess distending the synovial sac to the point of bursting. Finally it bursts; pus pours out into the cellular tissues; the pain ceases; all symptoms are relieved, and there is a great remission in the course of the disease. This remission, however, is not of long duration; and after the child gets up it is soon found that dislocation of the femur takes place; the foot is turned in opposite the other; shortening of one and a half inches occurs. Another attack of fever comes on. The child goes to bed; is sicker than before; the hip becomes shiny; abscess bursts and the pus escapes externally. Relief of symptoms again follows. The child gets up and goes around with a stick or crutch, with dislocation on the dorsum; inverted foot; and the disease goes on through its other stages, which are chronic caries; and if cure can occur, finally, drying up of the abscess, and bony anchylosis on the dorsum of the ilium, with the head fastened in its new and false position.

STRANGULATED HERNIA.[1]

BY GEORGE W. GAY, M.D.
Surgeon to the Boston City Hospital.

It is to be hoped that a report of the following cases of strangulated hernia may draw the attention of the younger members of the profession to the importance of giving to these patients *early* relief, and also to the necessity of rapid operations under certain circumstances. Another important lesson which one learns, before he has had very much to do with these cases, is that in many instances the vitality of the patient is exhausted to a much greater degree than is indicated to the ordinary observer by the general symptoms and appearance.

A Case of "Compound" Inguinal Hernia.

Mr. S., aged thirty-seven years, was operated upon at the City Hospital in 1878, for a recent hernia, which was attended by urgent symptoms indicating danger of strangulation. Eleven years later an effort was made to obtain a radical cure of the rupture by operative measures, but without success.

On April 18, 1893, this man came to the hospital in a buggy, walked into the accident room, and letting down his trousers showed what has been very aptly termed a "compound" hernia, by which is meant a protrusion of a portion of the intestines through the skin. The patient gave the following account of the accident: Twenty-four hours before coming to the hospital, while lifting a heavy weight, the cicatricial tissues at the site of the previous operation gave way, thereby letting the bowel protrude through the rent in the skin. He got into a car, rode home, went to bed, and remained there without any treatment whatever until the following day, when he got up, dressed, and rode to the hospital with a friend in an ordinary wagon.

Upon examination, about four inches of the small intestines were seen protruding from a small opening in the skin in the right inguinal region, between one and two inches in diameter. The bowel was distended and covered with a thick layer of dirty, grayish lymph. There were no signs nor symptoms of strangulation, a

[1] Read before the Boston Society for Medical Improvement, November 13, 1893.

condition that would probably not occur as readily from the constriction of thin, attenuated skin, as it would from the pressure of dense, unyielding fasciæ and tendons.

There was no vomiting, and the pain was only moderate. The belly was not distended, nor was there other evidence of general peritonitis. In short, the man was in very good condition.

The patient was profoundly etherized, the exposed gut was cleansed as thoroughly and carefully as possible, and after enlarging the opening in the skin, an effort was made to replace the protruding bowel. This proceeding required the combined manipulations of two pairs of hands for several minutes for its accomplishment, owing to the coughing and straining of the patient, who was very strong and muscular.

The lower or outer pillar of the external ring was absent, but a fairly successful effort was made to close the large aperture in the abdominal walls by uniting the inner pillar to the deep fascia below with silk sutures. The external wound was partially closed, and dressed with antiseptic compresses and spica bandage.

Little shock followed the operation. He vomited occasionally for two or three days, for which calomel was given in small doses. The bowels moved freely on the third day, and the convalescence was tedious and uneventful. The wound suppurated freely as was to be expected, but there were no complications. He was discharged from the hospital in eleven weeks, wearing a truss over a small granulating surface.

Considering the exposure and irritation of this patient's intestine, it is surprising that he did not develop general peritonitis. The external causes would seem to have been ample to produce such a result. We may express our ignorance upon this point by saying, that his tissue or his system was in a favorable condition to resist the onset or extension of serious inflammatory processes.

Several years ago a girl was admitted to the hospital with a large rosette of intestines protruding from a rent in the abdominal walls. The accident was due to the sudden rupture of an abscess. The bowel was covered with recent adhesive lymph, which matted the coils more or less firmly together. Dr. Cheever carefully cleansed the mass, separated the adhesions, and replaced the protruding structures. No untoward result followed.

Intestinal Resection for a Strangulated Inguinal Hernia. Death in eleven days.

Mrs. P., aged fifty-two years, entered the City Hospital April 6, 1893, with a strangulated inguinal hernia upon the right side. The rupture had existed fourteen years, and had been controlled by a truss till within a year. Symptoms of strangulation had been present for a week, and consisted of vomiting, constipation and pain in lower abdomen. A tumor the size of a hen's egg was situated over the right inguinal canal. It was free from impulse, and was irreducible. Considering the duration of the symptoms, the patient was in fair condition. The pulse was frequent, but of pretty good strength. The vomiting was stercoraceous. No delirium nor stupor.

The sac was opened quickly, and a perforation half an inch in length was found at the seat of the tight constriction at the internal ring. Three and a half inches of the small intestine, which was purple, thickened and not glistening, were excised. The bowel was closed by end-to-end coaptation with two rows of continuous silk Lembert sutures. Operation lasted about three-quarters of an hour. Only an ounce and a half of ether was required. Shock was moderate, from which she rallied well.

With the exception of some diarrhœa, the patient was very comfortable the next day. Two days later, she was taking food without difficulty; there was no vomiting nor pain. Everything went on favorably for over a week, except that on the fifth day the temperature dropped to 96.4°. Wound united by first intention, and the sutures were removed on the seventh day. There was no tenderness, nor distention, nor other local signs of peritonitis at this time. On the ninth day pain in the belly came on with vomiting and tympanitis. The wound opened, and its edges became dark and sloughing. Exploration revealed extensive adhesions everywhere among the intestines, but no pus nor fæces could be found. The urine, which was examined and reported normal when she entered the hospital, now contained albumen, and hyaline and granular casts.

The patient gradually sank, and died eleven days after the operation, from peritonitis and nephritis. No autopsy was made, and hence the condition of the intestinal wound is not known.

This is the third case of intestinal resection done by the writer during the past few years. The first patient lived a week, and died from peritonitis. The second patient, a feeble old woman, recovered in a surprisingly short time, but died several months later from an operation for the removal of an ovarian tumor. She had no further intestinal trouble, and her death was due to shock and exhaustion consequent upon a laparotomy of moderate severity. No autopsy could be obtained in any of these cases; hence we are in the dark as to the exact condition of the intestinal suture.

Strangulated Inguinal Hernia. Patient in collapse when brought to hospital. Quick operation: Recovery.

Mr. M., aged fifty-six years, entered the City Hospital April 23, 1893, in a state of collapse. An inguinal hernia had existed upon the left side a year, for which he had never worn a truss. It had been strangulated a week, and profuse stercoraceous vomiting had persisted for three days. The extremities were cold; he was pulseless at the wrist, and had hiccough. The superficial arteries were calcified. Urine contained albumen, and hyaline and granular casts.

The patient was surrounded with heaters, well covered up, and brandy freely injected under the skin. A very little ether was given, the sac was quickly opened, and the bowel found to be covered with a thick, dark layer of lymph, mottled in places, threatening sphacelus. The constriction was divided, the bowel placed just inside the wound, which was packed with baked gauze. This was done to give exit to the intestinal contents, should occasion require it. The operation lasted but a very short time.

The patient rallied very slowly from his most desperate condition. The vomiting persisted for five days, gradually diminishing in amount and frequency. He was fed and stimulated by the mouth and rectum. At the end of a week the hiccough and vomiting had ceased, and there seemed a chance for his recovery. The wound was closed with sutures in five days after the operation, and it was healed completely in five weeks. Although the rupture returned before the

patient left the hospital, yet the rings were so large that strangulation in the future would seem to be impossible. He was ordered a truss, and told to wear it during the remainder of his life.

This man had wonderful powers of endurance and of recuperation, yet it may fairly be claimed that his recovery was due in no small degree to the mode of treatment which was adopted. The method was fully described in a paper presented to this Society ten years ago,[2] and consists of the following essentials:

Just enough ether is given to control the cutaneous sensation; scarcely more than the primary effects are requisite. In other words, the anæsthesia is light and frequently interrupted, the patient at no time being profoundly unconscious. The operation is best performed in the warm bed, the body being well covered, surrounded by hot bottles, kept dry, and moved as little as is necessary. The operation is to be done as quickly as possible, and no time is to be wasted in trifling refinements of technique. It goes without saying, that hæmorrhage must be controlled in the speediest manner compatible with the patient's safety. The sooner the necessary dressings are applied, and the person is arranged in his bed, and left alone with his nurse, the better are his chances for recovery. In three cases of gangrenous hernia operated upon by me, while the patient was in a state of marked collapse, I have deliberately opened the bowel, as one would open an ordinary superficial abscess, with one stroke of the knife, and have then divided the constriction by carrying the herniotome into the lumen of the intestine. This very unscientific method was adopted rather than to risk a long, tedious, and hence dangerous dissection in a mass of gangrenous and extensively infiltrated tissues, in which all of the ordinary anatomical landmarks were obliterated by the prolonged morbid processes. Two of these patients lived a fortnight. The third, an old man at the time of the operation, is alive and well, and is earning his living as a printer, now, several years after his serious illness.

This method of relieving strangulation is manifestly justifiable only under the most desperate conditions, such as those which have been described above, and under no other circumstances should it be resorted to, or thought of.

A case of very large omental hernia is here alluded to because of an unusual complication, namely, hæmorrhage. A man, twenty-five years of age, had never worn a truss upon a rupture in his right inguinal region, although it had troubled him for ten years. Had been operated upon for strangulation some years ago. Present symptoms, vomiting and pain, were of twenty-four hours' duration.

On opening the sac, about six inches of small intestine was found entangled in a large mass of adherent omentum. The bowel was readily returned after a free division of the constriction had been made, but the omentum was returned with great difficulty, owing to the numerous firm adhesions. While dividing some of these dense bands upon the inner side of the mass, an enormous omental vein was wounded, giving rise to a profuse hæmorrhage. As is frequently the case in wounds of large veins, it was impossible to control the bleeding with forceps. It was readily done, however, by packing the wound with sterilized gauze, which was removed piecemeal from the third to the fifth day, without recurrence of the bleeding. The patient made a good recovery in five weeks, and left the hospital wearing a firm pad and spica bandage.

Another case of strangulated hernia lately operated upon is of interest by reason of the obscurity of the origin of the symptoms. A young man was sent to the hospital by Dr. Boland, with the appearance of approaching collapse; general abdominal pain, tenderness and distention, fæcal vomiting of three days' duration, cool extremities, congested skin, and pinched features. There was evidently general peritonitis. For fifteen years he had had a rupture in the left inguinal region, which came and went readily according to the position of the body. Had never worn a truss. Present symptoms began five days before entrance to the hospital.

In the left inguinal region was a soft, painless tumor the size of an almond. It was not tender, nor was the skin reddened or indurated. The bunch could be moved about in all directions, and felt very much like a lymphatic gland. The question naturally arose as to the relation of this apparently insignificant tumor, and the grave symptoms, as related above.

An exploratory incision showed that the little bunch was a mixed hernia, composed of omentum, in which was entangled about an inch and a half of small intestine. The constriction, which was very tight, firm, and located high above the internal ring, was freely divided with the herniotome, and the contents of the sac were easily returned to their proper place.

The patient rallied slowly, and the convalescence was tedious, owing in part to an attack of septicæmia, as indicated by chills, fever, parotitis, and a sloughing condition of the wound. He recovered, and left the hospital in seven weeks, wearing a pad and bandage.

This case leads me to mention three others in which I have been called upon to operate, for the reason that the symptoms did not subside after the hernia had apparently been reduced. The first case was that of a middle-aged man, with a strangulated hernia in the right groin of about twenty-four hours' duration. It was reduced by his physician at night without undue force. Upon the following morning, the symptoms not having subsided in the least, the abdomen was opened just above the inguinal canal upon the right side. A knuckle of small intestine was found to be tightly constricted by the neck of the sac, situated above the internal ring, and freely movable. It had been reduced *en bloc*, but there were no signs of injury from the taxis. The intestine, while deeply congested, showed no indications of mortification or other lesion. The constriction was divided from above. The patient died from shock and exhaustion in about twenty-four hours.

A patient of Dr. Goss, an elderly man, had a strangulated inguinal hernia upon the right side. Moderate taxis applied by the patient himself caused the tumor to disappear several hours before summoning the physician; but the symptoms, pain, restlessness and vomiting, persisted. At the end of twelve hours an ordinary herniotomy was done. The constriction was reached with difficulty by carrying the finger high up through the canal and rings. It was divided, the bowel brought down, examined, and found to be in good condition. Union by first intention followed, and the patient made a quick recovery.

The third case was that of an old man, seen with Drs. Reed and Gavin. Shock, prostration and vomiting were urgent. An operation revealed a tight con-

[2] Vide Boston Medical and Surgical Journal, October, 1883.

striction high above the internal ring. The bowel was in fair condition, but the patient died in about twenty-four hours.

It is a noticeable fact, that the constricting band in these four cases was located above the internal inguinal ring, and with its contents was very movable, thereby explaining the ready disappearance of the hernia. These cases serve to emphasize the fact, that the only reliable indication of the success of taxis, is a marked change in the symptoms for the better. If they do not show unmistakable signs of improvement within twelve hours after an apparent reduction, the probabilities are, that the obstruction is not removed, and that operative measures are called for to ascertain beyond a doubt the exact condition of the structures involved. Intestinal obstruction, complete enough to produce vomiting, cannot be relieved too early. The prostration resulting from this calamity is always serious, oftentimes insidious, and not infrequently deceiving the surgeon as to its severity. The recuperative powers of the patient are often reduced to a much lower state than are indicated by his general appearance and symptoms. Hence the danger of delay. The risks of an operation are as nothing compared to the perils of a strangulated bowel. The sooner obstruction is relieved, the safer the patient.

In conclusion, I can only say what has already been better said many times before in relation to the treatment of strangulated hernia. If the symptoms are urgent, waste little time upon efforts at taxis, as they seldom succeed under these circumstances. The tissues, already more or less damaged, are rendered still more incapable of repair by the manipulations. While the application of cold, and pressure by means of weight and elastic bandages, raising the foot of the bed, etc., may succeed occasionally in reducing a rupture, yet, as a rule, more harm than good follows their use, owing to the difficulty in making a proper selection of cases, and also to the fact that valuable time is lost in making the experiments. Be chary in the use of opiates before and after taxis, and after operation, lest they mask the symptoms, and lull the attendant's suspicion, until the patient is beyond relief.

If a rupture, real or suspected, is accompanied by vomiting, herniotomy, as a rule, is not only justifiable, but it is demanded. Operate early. If the patient be not in good general condition, operate quickly, and avoid shock and prostration. In desperate cases do as little as possible beyond dividing the stricture at the primary operation, and complete the work later, when the patient has rallied sufficiently to justify it. If in doubt as to the reparative powers of the damaged tissues, pack the wound with sterilized gauze for a few days, or until the point has been decided by the natural course of events.

Husband the patient's resources in every possible way. Save time, and avoid shock. Preserve the animal heat, and keep the body dry. Disturb the patient as little as possible by moving. Avoid all unnecessary manipulations inside the peritoneal cavity, as they increase shock. Stimulate and nourish by the skin and rectum. Let the anæsthesia be light, and often suspended. And, finally, never lose sight of the fact that the keystone to the operation is a thorough division of the constricting band.

THE editor of the Russian *Grazhdanin* has been sentenced to ten days' imprisonment for defamation of military surgeons.

ON CERTAIN DANGERS ATTENDING THE USE OF ATROPINE, AND THE EMPLOYMENT OF A NEW MYDRIATIC.[1]

BY HASKET DERBY, M.D.

IN his recent text-book of ophthalmology Professor Fuchs uses the following language:

"The mydriatics may bring about an inflammatory attack (of glaucoma) in an eye predisposed to the same; and this is true not only of the powerful mydriatics, like atropine, but also of homatropine and even of cocaine.

It is therefore better to always inquire into a possible predisposition to glaucoma, before applying a mydriatic in the case of an elderly person."[2]

Priestley Smith includes duboisine in the above list.

Attention was first called to the unfavorable effect of mydriatics, or rather of belladonna, in acute glaucoma, by Mr. Wharton Jones, more that a generation ago.[3] I am not aware however that he alluded to the possibility of its favoring the production of increased pressure where this might be impending. I believe the two cases I reported to the American Ophthalmological Society in 1868,[4] one occurring in my own practice and the other in that of the late Dr. Althof, of New York, to have been the first published instances of glaucoma supervening directly on the instillation of atropine. At about the same time, although the fact subsequently came to my knowledge, von Graefe published in his *Archiv*[5] a short observation bearing on this same point; giving no cases, but stating his own experience, and advising the avoidance of the instillation of atropine in chronic glaucoma.

These views met at first with little favor, but they are now generally entertained. Probably the most accepted theory of the causation, or rather acceleration, of the outbreak of glaucoma through mydriatics is that they interpose an obstacle to filtration by pressing the thickened, peripheric portion of the iris from the ciliary processes, towards and against the cornea, thus increasing the narrowing of the filtration angle. "When the filtration angle is already dangerously narrow" says Priestley Smith in his recent excellent treatise on the pathology and treatment of glaucoma (p. 132), "the thickening of the iris base, which accompanies dilatation of the pupil, may suffice to complete the blockade."

If this view be true it must apply to all mydriatics without exception, and it is in fact known that all those in common use have accelerated the onset of glaucoma. In consequence of this we hesitate to employ them on patients who have passed middle age, at any rate for the investigation of refraction, certainly in no case to use them without some preliminary examination.

For therapeutic purposes atropine is undoubtedly the mydriatic in most general use. While its benefits are unquestioned, the occasional disadvantages it entails are by no means to be lost sight of. I shall never forget once instilling two or three drops of a half-percent. solution in the eyes of a boy of thirteen, of seeing him after the lapse of an hour stagger as he left the office, and of being sent for the evening of that day, to find him with a flushed face, great dryness of the fauces, and possessed by hallucinations, all of these symptoms passing away in the course of the night.

[4] Transactions for 1868, p. 35.
[5] A. F. O., Bd. xiv, Abth. ii, S. 117; see also A. F. O., Bd. xv, Abth. iii, S. 123, note.

In addition to what has already been detailed, atropine is known in certain cases to cause slight general excitement, with increased frequency of the pulse; a bitter taste in the mouth; a peculiar form of conjunctivitis, where its use has been long continued; and not to be at all borne by certain individuals, who manifest a peculiar susceptibility to its influence.

The discovery of a mydriatic free from the above dangers and inconveniences, would mark a distinct advance in therapeutics, and facilitate examinations of the eye, whether of refraction or for purposes of exploration. Such an agent, it is claimed, has been found in scopolamin, an alkaloid furnished by the roots of the scopolia atropoides. It is contained, with hyoscin, in the hyoscyamus niger or henbane, but differs materially from hyoscin in a chemical point of view.

A recent article published by Raehlmann (Kl. Monatsblätter für Augenheilkunde, Jahrg, XXXI, S. 59) drew attention to this new mydriatic. It is more active than atropine, being used in about one-fifth the strength of that agent, a solution of from one to two parts to a thousand being the one usually employed. It acts with efficiency, its first effect on the pupil being in most of my cases visible at the end of five or six minutes, and full dilatation secured in from twenty to twenty-five minutes. Mydriasis lasts several days, but seems to be less prolonged than that due to atropine. Dr. H. H. Haskell, ophthalmic interne at the Massachusetts Charitable Eye and Ear Infirmary, has had the kindness to observe the results of the application of a one-fifth-per-cent. solution of scopolamin in a series of seven cases, and the figures are here appended. The first column gives the age, the second the number of minutes that elapsed before any effect was perceptible, the third the minutes required for maximum dilatation, and the last the number of hours that elapsed before the pupil became again normal.

9	8	40	51
8	16	35	60
17	10	21	72
12	9	30	80
9	10	25	60
20	10	20	80
12	12	40	90

Unlike atropine the effect of scopolamin on the cerebral cortex is to paralyze rather than to irritate, and the frequency of the pulse is not increased but diminished. This has been proved by experiments on animals. It is said to cause no nervous excitability, and not to affect appetite.

The advantages claimed by Raehlmann for scopolamin over atropine are as follows:

(1) Dryness of the throat occurs only after excessive use.

(2) Its application can be prolonged without causing irritation, and it may even be substituted for atropine when the latter is no longer borne.

(3) It is better adapted to the treatment of certain inflammatory affections, particularly those connected with hypopyon, than is atropine.

(4) It causes no increase of intraocular pressure, has even been used with relief to pain in cases of acute glaucoma.

If experience corroborates these facts, the new remedy may well supersede atropine. The last advantage claimed is one of the utmost importance. If we have indeed, in the case of scopolamin, a mydriatic which is unlikely to cause an increase of intraocular pressure, in an eye predisposed to the same, the theory of the action of this class of agents must be revised. In that case we must abandon the supposition that excretion is checked by crowding the iris up against the filtration angle, and recur to the former hypothesis that atropine diminishes filtration by contracting the vessels, thus thickening their walls and diminishing transudation.

Raehlmann's article is based on observations made with scopolamin hydrochlorate. For four weeks past I have used the hydrobromate, the only form of scopolamin I have been able to procure, and which was furnished me by T. Metcalf & Co. As far as I can judge with so limited an experience the effects are similar. Since commencing with it I have used no atropine.

Clinical Department.

REMARKABLE EFFECTS OF DIVULSION OF THE URETHRA.[1]

BY JOHN HOMANS, M.D.,
Surgeon to the Massachusetts General Hospital.

IT is very seldom that a surgeon has an opportunity to examine the urethra immediately after divulsion. Such an opportunity has lately been afforded me, and I bring the specimen for the Society to see.

The patient died from the combined effect of hæmorrhage into the cerebellum, hæmorrhage into the bowel, tuberculosis of the mesenteric glands, abscesses in the prostate, and the etherization and operation done on the day of his death. The case was an extremely interesting one in every aspect, but more particularly in its pathological appearances.

The patient was a single man, twenty-five years old, who had led an irregular but very active life for several years, and had taken no care of himself. Some abscesses in the perineum and scrotum had either opened spontaneously or had been opened about a year before his death; and this fact together with a history of gonorrhœa and occasional purulent discharge from the urethra, had given rise to the belief that a tight stricture existed, and that the urethra had ruptured behind it, causing abscesses and sinuses.

When I saw the patient early in October, 1893, he was quite emaciated and very pale. He was extremely unwilling to have any instrument passed, and it was with the greatest tact that I was able to persuade him to let me pass a small one. I tried several, and nearly all of them brought up in false passages, only one went through. Finding these false passages and seeing the sinuses old and healed, only confirmed me in my belief that there was a tight stricture. At the same time the young man said that he had no trouble in passing water, but his attending physician said that urine came at times through the sinuses. In this he was mistaken. There was an acquired phymosis with much thickening of the prepuce, and considerable thin pus between the prepuce and the glans. If I could have persuaded the patient to let me pass a medium-sized instrument, my belief in the existence of any very narrow stricture would have been dispelled.

The patient lived six days after I first saw him. His pulse was always weak, and he developed a most

[1] Read before the Boston Society for Medical Improvement, November 13, 1893.

intense headache. The pain was terrific, absolutely unbearable, and was accompanied by a spasmodic twitching of both sterno-cleido mastoids. His favorite attitude was with his hands folded behind his head, or with his head and shoulders bent forward, lying curled up with his back very much rounded.

After etherization, I laid open the sinuses in the scrotum, perineum and buttocks. Two of them were symmetrical and were found to spread out beneath the skin, as tubercular abscesses do. None of the sinuses communicated with the urethra; they were curetted and packed with iodoform gauze. A small bougie was then passed into the bladder, and the urethra divulsed with Bigelow's divulsor. The points of most resistance were near the glans and in the membranous portion of the urethra. There was no bleeding. A large-sized elastic catheter was easily passed into the bladder, and was tied in and connected by a rubber tube with a bottle. But little urine was secreted after the operation. Eight hours later the patient died. The autopsy showed clearly the causes of the pallor, weakness and headache and the effects of the divulsion.

Dr. Whitney reports that the calvaria was thin and its inner ridges and markings extremely prominent, recalling the appearances in the skulls of very old people. In the right hemisphere of the cerebellum was an area of red softening occupying the central portion for its entire thickness. The area was rather pyramidal in shape, and its greatest area was about one inch square. The blood was dark red in color, and was evidently of quite recent origin (probably within a week). About six inches above the ileo-cæcal valve was an irregular ulceration, about three-quarters of an inch in diameter, which was well into the muscular coat. The lymphatics were distended with an opaque cheesy material. The glands at the root of the mesentery were enlarged from the size of a pea to that of an orange, and on section contained abundant creamy pus with cheesy periphery. The intestine below the ulcer was filled with dark tarry blood. In the prostatic portion of the urethra were several holes, capable of admitting a sound, which passed into the prostate and from which yellow pus could be squeezed. The prostate was completely riddled with abscess formations. To sum up: Red softening of the cerebellum; tuberculosis of the mesenteric glands and tubercular ulcer of the intestine; abscesses in the prostate and about the perineum and anus; recent rupture of the urethra from divulsion. Any other changes in the viscera, if present, were masked by the fluid injected by the undertaker.

The appearances of the urethra in the recent state were as follows: At a point two and a half inches from the meatus, and extending two and five-eighths inches downwards, is a clean cut, or tear, parallel with the axis of the urethra. This cut or tear (linear) extends through the mucous membrane and through the submucous tissue, an eighth of an inch in depth. In the alcoholic specimen you see at the side of this cut, a shred of membrane (possibly mucous membrane, probably not), but I am not sure that this was there when the autopsy was made; it may have been made in the slitting open the urethra. In the membranous portion is a clean cut or tear on the floor of the urethra, one inch long and extending to the prostatic urethra, but not into it. The prostatic urethra and the prostate gland are riddled with holes and abscesses of long standing. At first sight this seemed to me rather too extensive a splitting, as the result of the passage of the divulsors, but the more I have studied it and thought about it, the more I am convinced that it was a most excellent result and could not have been obtained in any other way. There was absolutely no hæmorrhage, nor an ecchymosis. The cuts were as straight and clean as if made by a knife and not ragged and there was no bleeding as there would have been with a knife. There were two strictures, one in the pendulous portion of the urethra, the tightest, and one in the membranous portion. If the urethratome had been used there would have been considerable bleeding and the division of the stricture would have been no more satisfactory, though the incision in the urethra would probably have been shorter.

On the whole, I regard this linear splitting of the urethra, without hæmorrhage, almost the ideal treatment for stricture of the urethra, and if divulsion often effects such a bloodless and thorough division, I regard it as perhaps the best method of treating a stricture, at least a deep-seated one.

ŒSOPHAGOTOMY, WITH HEALING BY FIRST INTENTION.[1]

BY ABNER POST, M.D.

THE following case of œsophagotomy presents some features of interest, especially in its recovery. The patient was a little girl twelve years of age who on her birthday received as a present a bright new silver twenty-five cent piece, which was a larger sum of money than she had had at her own disposal before. In her excitement she put it in her mouth, and accidentally swallowed it. For the first day after the accident she was unable to swallow anything. On the second day the coin evidently shifted, and she was able to swallow liquids. At the end of the second day she was brought to the hospital. I saw her late the next forenoon. She was evidently in pain; and when I approached her, she screamed, and grasped her throat by both hands. It was impossible even to touch her without anæsthesia, and the next day was appointed for the operation. The next morning she persuaded her nurse that she was able to swallow, that the coin had passed down; and I was so informed, so that I did not see her till late that forenoon, when I asked to see her swallow. She took but a single swallow, grabbed the throat with both hands, and made that characteristic painful deglutition which is so well-known with difficulty in the œsophagus. I was obliged again to postpone the operation until the next day, which was the fifth since she swallowed the coin.

When she was etherized an attempt was made with the coin-catcher to catch and extract the coin. I succeeded in locating it, but did not catch the coin. The bristle probang was then passed; it came up showing that the bristles had spread irregularly, and that the portion of the probang where the bristles had been thinnest had caught in the coin. The instrument was passed again, but no force that I dared apply would stir the coin. The probang came up with a little blood, and it was evident that œsophagotomy was necessary. The child being already on the table, the head turned to the right exposing the left side, which was made prominent by placing a rolled sheet beneath the

[1] Read before the Boston Society for Medical Improvement, November 13, 1893.

neck, it was then possible to feel the coin from the outside at a point midway between the cricoid cartilage and the sternum. An incision was made along the anterior border of the sterno-mastoid which was loosened, and with the vessels beneath was pulled outward with a spatula; the depressors of the hyoid, which were pretty wide, were loosened at the edges and pulled inward. The sterno-mastoid had been pulled to the outside, the trachea gently pulled to the inside, and the omohyoid depressed, so that there were three spatulæ, one pulling in, one out and one down. Very little manipulation with the trachea in the region of the œsophagus liberated a few bubbles of gas, which were explained later by seeing that the coin had begun to penetrate the walls of the œsophagus so that it was just visible. The œsophagus was then incised by a small tenotome tracing the position of the coin, which could be made out very plainly. The coin was then seized with forceps and extracted. The coin was firmly grasped by the œsophagus, firmly held on two sides, if one may speak in that way of a circular object, and when it was extracted the median line was thoroughly discolored by sulphuretted hydrogen, while the two parts on the sides that had been grasped by the œsophagus were left comparatively bright. There had been practically no loss of blood. The record places the loss of blood at less than one-half drachm. The parts were then allowed to resume their natural positions, and the external wound was closed at the top and bottom, leaving the middle portion freely open, and the child was sent back to bed. There was no vomiting.

When I visited the ward the next day the child was up, dressed and playing about the ward. To my surprise I found that she had already been fed with cracker soaked in milk, and that none of the food had appeared through the wound. From that day until she was discharged there was absolutely no leaking. It was, then, an œsophagotomy which closed by first intention. So far as I have been able to find, this is the only case on record in which so successful an issue has been reached.

In trying to explain this good fortune, I think it lies in great measure with the child. She presented a neck which seemed to have been formed by nature for the operation. It was a little long, entirely devoid of fat, and the connective tissue very slight, so that the muscles were separated with a minimum of traumatism. No vessels were cut, so there was no blood to prevent immediate union.

I think this must be the only œsophagotomy that has been done with simple aseptic precautions. So far as I know, after the skin was cleansed there was nothing that should be called antiseptic that entered the wound. The instruments were sterilized by heat; the dressing put on afterwards was gauze that had been baked.

In the majority of cases the wound does not close under two weeks. This child must be one of the youngest on whom the operation has been performed. Dr. Leroy McLean, of Troy, N. Y., reports the case of a child of sixteen months. In that case the recovery is said to have been "rapid and complete." Dr. George W. Gay has operated on a child of three and a half years.

The little girl is here to-night. She has only the scar to show. She is good enough to let us see how slight a scar can result from so serious an operation. She now eats food of all descriptions without difficulty.

PREGNANCY IN THE LEFT HORN OF THE UTERUS, SIMULATING EXTRA-UTERINE PREGNANCY: LAPAROTOMY.

BY F. W. JOHNSON, M.D.,
Gynecologist at the Carney and St. Elizabeth Hospitals, Boston.

Some months ago I saw in consultation Mrs. M., twenty-two years of age. Menstruation (which had always been regular) had been absent for three months. During this time she had had more or less pain in the left ovarian region. At times the pain was sharp and cutting, causing her to wince and cry out. I saw her about 12 M. The family physician was called the evening before. He got a history of flowing of only a few hours' duration. "Nothing" had passed from the vagina. Great pain, at times cutting like a knife, was complained of in the left ovarian region. There was marked sensitiveness on pressure over the left ovarian region. Patient was restless, and had an anxious expression. Pulse, 120; temperature, 101°. There had been no chill. Ether was administered, and nothing was detected by the finger inside the uterus. He told her it was probably a case of extra-uterine pregnancy. When I saw her the above-mentioned symptoms were present. She had flowed some during the night and forenoon, but had passed nothing except blood from the vagina. She was pale and restless, and vomiting was present. The abdomen was distended, and so sensitive that palpation revealed nothing. Vaginal examination revealed an enlarged uterus, with an ill-defined, sensitive swelling extending from the left horn. Pulse, 130; temperature, 103°. There had been no chill. Morphine had been necessary to relieve the severe pain.

At 2.30 the abdomen was opened. Nothing except an enlarged uterus, with the left horn enlarged, and an enlargement of the left tube close by the uterus was found. With the sharp curette, a quantity of placental tissue was removed from the left horn.

Convalescence was uneventful, and she was discharged in four weeks.

She is now four months pregnant. The symptoms in this case pointing to extra-uterine pregnancy were certainly as well marked as in some of the cases where I have removed a fœtus either from the tube or the abdominal cavity.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., BOSTON.

ANATOMICAL CHANGES UNDERLYING OCULAR DISTURBANCES OF CEREBRAL SYPHILIS.

Uhthoff[1] reports the anatomical changes of the eyes and optic nerves of 17 cases of cerebral syphilis which resulted fatally in the Berlin hospitals.

In two cases there were intra-ocular changes; in one, irido-choroiditis, with very noticeable vascular changes (peri-vasculitis) in the retina; in the other, a gummatous formation in the iris. The optic papillæ, nerves, chiasma and tracts were involved in 14 of the 17 cases; in several the anatomical changes found *post-mortem* had not given rise to any disturbances of function.

[1] Bericht über die 22te versam. der Ophthal. Gesell., Heidelberg, 1892.

"Choked discs" were found in three cases (once unilateral); optic neuritis in two; simple atrophy of the papillæ in three. In six cases no ophthalmoscopic changes were discovered.

In the orbital portion of the optic nerve were found perineural changes varying from simple hydrops of the sheath to an intense descending perineuritis, and interstitial neuritis with secondary atrophy; also simple descending atrophy. The intracranial portion of the optic nerve showed pronounced gummatous degeneration, severe perineuritis and slight perineuritic changes. The chiasma was affected in a comparatively large number of cases. In one case the optic tract in its entire length was converted into a gummatous mass. In eight of the 17 cases there was third-nerve affection, twice bilateral. The sixth nerve was paralyzed in two cases. The trigeminal nerve was involved in three cases, in one of which neuro-paralytic keratitis occurred.

THE OPTICAL TREATMENT OF CONICAL CORNEA.

Mackay[2] estimates the refraction of the apex or any other more desirable portion of the cone in conical cornea by means of retinoscopy done through stenopaic discs with central circular apertures of three to five millimetres, using the disc with the smallest aperture, through which the glow can be recognized and its motion followed. He cites two cases. In the first case, the best glass selected by the trial with test types and lenses alone resulted in R. — 3.00 D., sph.; L. — 9.00 D., sph.; R. V. $= \frac{6}{24}$ parts; and L. V., $= \frac{6}{36}$. By retinoscopy through a three millimetre aperture, the refraction of the summit of the cone proved to be R. — 13 D., sph. ⌒ — 6 D. cyl. axis hor.; L. — 15 D., sph. ⌒ — 8 D., cyl. axis 130°. Vision with practically these glasses, through the same opening, proved to be R. V. $= \frac{6}{12}$, L. V. $= \frac{6}{18}$; and J.1 from 8 to 20 inches R., J.2 from 2 to 10 inches L. The interpupillary distance was carefully measured, and a pair of spectacles prescribed having the posterior surface coated with an opaque black varnish, leaving clear central areas of two millimetres in diameter. With these she eventually obtained four letters of $\frac{6}{9}$ with the left eye, and was most grateful. In the second case, with an opaque summit, he was able by the same method to determine the existence of nearly twelve dioptres of myopic astigmatism near the visual axis, and to improve vision from "fingers at one metre" to $\frac{6}{36}$.

IRITIS AS A SYMPTOM OF BRIGHT'S DISEASE.

Schapringer[3] reports a case of iritis which he deems to have been due to a nephritis from which the patient suffered. The eyeballs were extremely sensitive to the touch; there was intense photophobia, well-marked œdema of the conjunctiva, but not associated with any congestion of that membrane. The cornea was clear, but the aqueous humor slightly turbid. No precipitate on the posterior wall of the cornea. The iris was discolored and dull, and the pupil contracted. The optic disc was slightly swollen; its outlines were indistinct. The retinal veins were enlarged and tortuous. In the region of the yellow spot there was a faint indication of white discoloration in two or three spots. Under treatment the eyes improved, and were well in six days. The white spots in the macula region disappeared. The patient died in about six weeks' time.

WOLFE'S OPERATION.

Weeks,[4] in the report of the restoration of the eyelids in a case of severe burn, presents a tabulated report of 37 cases collected by him of the transplantation of skin without a pedicle (Wolfe's operation) for the restoration of lost tissue in the eyelid; from which it appears there was no sloughing in fourteen cases, or 37.8 per cent. Partial sloughing occurred in eight cases, or 40.6 per cent. Complete sloughing occurred in eight cases, or 21.6 per cent. The final result was good in 18 cases, or 48.6 per cent. Sutures were employed in 23 cases; of these cases there was partial or complete sloughing in 18, or 78.25 per cent.

No sutures were employed in 14 cases; of these, partial or complete sloughing occurred in five cases, or 38.5 per cent. No sloughing occurred in nine cases, or 61.5 per cent. The maximum shrinkage, where reported, was reached in four months (four cases). The amount of shrinkage is reported to range from 50 to 80 per cent.

OPHTHALMOMETRY.

Lautenbach,[5] in an article upon ophthalmometry, as to what the Javal instrument will do and what it will not do, comes to the following conclusions: The ophthalmometer will not give the refraction, nor will it give the total astigmatism except when this is confined to the cornea; or any knowledge as to whether there is or is not lenticular astigmatism. It will give the axis and degree of astigmatism when this is corneal; practically he finds that it gives the axis in 88 per cent.; and the amount of the astigmatism in 45 per cent. It reveals a knowledge of diseased conditions of the eyeball when the disease is of such a nature as to interfere with the nutrition of the cornea or increases or decreases the ocular tension. It will, in connection with other methods, enable a calculation to be made of the lenticular refraction and astigmatism as well as the depth of the eyeball.

SIMPLIFIED DIAGNOSIS OF OCULAR PARALYSIS.

Wegmann,[6] in an article upon the differential diagnosis of paralysis affecting a single extrinsic muscle of the eye, formulates the following rules:

Rule 1. — Paralytic squint manifests itself in the direction of the affected muscle.

That is to say, covering one eye with a red glass in order to differentiate the images, if the test object, the light of a candle, is carried to the right and the images then separate, the affected muscle would be either the right external rectus or the left internal rectus.

Rule 2. — The paralysis is to be found in the muscle of the eye whose image keeps in advance during the test movement; the image lagging behind belongs to the sound eye.

Rule 3. — In case of paralysis, the recti of the vertical meridians cause crossed diplopia, the obliqui homonymous diplopia.

After it has been thus determined whether the paralysis lies in the vertical recti or the oblique, it only remains to apply Rule 2 to determine the particular muscle affected.

Rule 4. — The faulty image will show such a position to the correct one as the eye would assume if

[4] New York Eye and Ear Infirmary Reports, January, 1893.
[5] Ophthalmic Record, December, 1893.
[6] Op. cit., February, 1893.

acted upon in a normal state by the muscle now paralyzed.

Rule 4 is not, as will be readily seen, necessary in order to simply make a diagnosis.

THE USE OF PRISMS.

Maddox,[7] gives the following maxims to be observed in prescribing prisms:

(1) Never order them unless indications for their use are unmistakable.

(2) Never order them simply on account of an anomaly in the behavior of the eyes under various tests, unless there is asthenopia, headache, tendency to diplopia, or giddiness, possibly relievable by them.

(3) Do not judge by one test, but by the "finger," "rod" and "card" tests, and if specially indicated by the relative convergence test also.

(4) Remember that considerable latent deviation in distant vision is more important than in near vision (though the latter is not to be ignored), and that moderate divergence in near vision is physiological.

(5) Always more or less under correct with prisms.

SYMPATHETIC OPHTHALMIA.

Schirmer,[8] in a comprehensive article of more than two hundred pages, has gone over the whole question in regard to sympathetic ophthalmia. The article is timely, as Deutschmann's theory is not nearly so fully accepted now as it was upon its first publication. Sympathetic inflammation is again differentiated from sympathetic irritation. The latter has two well-marked characteristics; there is no inflammation, and the influence of the injured eye stops short upon its enucleation.

In regard to the cause of sympathetic inflammation, our author divides all reported cases into two groups: (1) cases in which the tunics of the eye have not been perforated; (2) cases in which the tunics have been perforated. All the reported cases of the first group are gone over from whatever cause; and our author does not admit that the resulting sympathy of the second eye was anything more than sympathetic irritation in any case, with the exception of three cases of choroidal sarcoma with no perforation of the tunics but with a well-marked irido-cyclitis and its complications. In these cases Schirmer thinks the sympathetic inflammation probably due to the irido-cyclitis, which may have been due to endogenous infection through the presence of organisms in the system at large, and that the presence of a tumor provided specially favorable conditions for such an infection, and that a migration of the infection from one eye to the other was then reasonable. In considering the second group of cases, he shows that all the cases which excited a true sympathetic ophthalmia either had at the time or had in some past time had a uveitis, thus confirming the assertion of von Graefe that an inflammation of the uveal tract was a necessary factor in the production of all cases of sympathetic inflammation.

In most cases an interval of three weeks intervened between the injury and the inflammation of the sympathetic eye; in a few cases the interval was less than this by two or three days; and in two reported cases in which the interval was only fourteen days, our author considers the evidence not conclusive.

Inflammation has appeared in the second eye after the removal of the injured eye many times. It may occur at any time within three weeks; and in a few cases the interval has been even a few days longer. In two cases the eye was removed within a day or two after a severe injury, which caused a severe and somewhat persistent orbital cellulitis, and sympathetic inflammation began in one case after five weeks and in the other case after seven weeks, and was attributed in each case to the transmission of the infective inflammation from the orbital tissue. Two cases of sympathetic inflammation after evisceration are reported; but as the outbreak occurred within the period in which it may occur after enucleation, they do not prove that evisceration affords less safety than the entire removal of the eye.

An optico-ciliary neurotomy has been followed a considerable number of times by sympathetic ophthalmia. It is well established that reunion of the optic and of the ciliary nerves may take place, and even in one neurectomy in which the optic nerve to the extent of fifteen millimetres was removed, sympathetic inflammation began four weeks after the operation. It is probable, however, that the operation diminishes the risk to the other eye.

Our author advances the following facts as opposed to the theory that irritation through the nerves is the cause of sympathetic ophthalmia. Irido-cyclitis in the exciting eye is an essential condition. In the vast majority of cases this irido-cyclitis is of bacterial origin. Mechanical irritation of the ciliary nerves even associated with intense pain, as in glaucoma, does not induce the disease. A transmission of such a nerve influence along the optic nerve is inconceivable when, as is often the case, the nerves are completely atrophied. Finally, when a sympathetic irritation is produced by a nerve influence, it is cut short by enucleation.

The bacterial theory of the disease would account for all these facts. There is little reason, however, for supposing that the ordinary pyogenic coccus is the organism in question, and until we learn the tests for detecting the presence of the specific germ of this disease, we cannot definitely determine its method of transmission. A direct migration from one eye to the other seems probable.

For treatment our author formulates the following rules: An eye which is blind, and which is in a condition to excite sympathetic inflammation, should be removed, without waiting for any sign of sympathetic inflammation. If sympathetic inflammation has already broken out, the exciting eye, if blind, should be removed. If the sympathetic inflammation breaks out while the exciting eye retains some vision, the exciting eye should not be removed, for sometimes the second eye is entirely lost, while the exciting eye recovers more or less vision, and permanently retains vision. It is possible that both eyes may recover useful vision. From the clinical records the best treatment, aside from enucleation of the exciting eye, appears to be, sweating, mercurial inunction, warm compresses, darkness, atropine, and absolute rest of the eye. Operative interference to aid vision should be postponed as long as possible.

PURULENT OPHTHALMIA.

Hindl,[8] in an abstract of a paper upon purulent ophthalmia from the standpoint of its specific microbic cause, gives, among others, the following conclusions:

[7] Ophthalmic Review, February, 1893.
[8] Von Graef's Archiv., vol. xxxviii, Part 4, 1892.
[8] Ophthalmic Record, August, 1893.

(1) That all cases of purulent conjunctivitis are of microbic origin, and due to Neisser's gonococcus.

(2) That all cases originate from a gonorrhœal focus, by devious paths often, and not always traceable.

(3) That those parts of the conjunctival sac having a cylindrical, or a modified cylindrical epithelium, namely, the palpebral portions and that of the fornices, are the seats of election of the micro-organism.

(4) That the location of the gonococcus on the mucous membrane is first super-epithelial, then inter-epithelial, and still later sub-epithelial, and all combined.

(5) That its special habitat is within the pus cell, yet it is also extra-cellular as well as intra-epithelial.

(6) That the associated inflammation of the adjacent lid-tissues is due to the lymphatic absorption of the ptomaines of the microbe.

(7) That the compact stratified epithelial layer of the scleral conjunctiva and cornea is very resistant to the attack of the gonococcus.

(8) That ocular complications are due to pressure-necrosis, producing an infection atrium through which the streptococcus, and may be the staphylococcus, find ready entrance to tissues with greatly impaired physiological resistance and often rapidly destroy them; resulting in perforation of the cornea, intra-ocular infection and loss of the eye. This is a secondary infection.

(9) That the therapeutical indication is the mechanical removal or destruction of the gonococcus with its ptomaine, and that if this is done early and thoroughly in the weeping stage, the period of acute inflammation will be cut short and the ocular complications avoided.

(10) That it is well, in the incubative stage, even without positive evidence of a gonorrhœal origin, to regard with suspicion all cases of severe monocular catarrh, and especially so in the female, irrespective of age or condition, and to treat them as if due to the gonococcus. . . .

(11) That, of all local remedies, nitrate of silver is the most potent and at the same time, least irritating microbicide we possess. It prevents complications and can be used in sufficient strength to destroy the gonococci without risk of injury to intact ocular tissues and that solutions of greater strength than two per cent. are unnecessary.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, November 13, 1893, the President, Dr. C. F. FOLSOM, in the chair.

DR. G. W. GAY read a paper on

SOME CASES OF STRANGULATED HERNIA.[1]

DR. D. W. CHEEVER: I understood the reader to say that opium after taxis, and previous to operation, might mask the symptoms. I should like to add to that, that its effect is even more dangerous and insidious, as concealing what we ought to do, if it is given, as it often is, by the physician before taxis is attempted. I have seen in private practice a good many patients who had strangulated hernia so comfortable under the influence of opium that they were not willing to be operated upon. Now this is a very serious state of things. The surgeon who is called to a case and finds capillary stasis on the surface of the abdomen, on the hands and about the nails, who finds the cool skin and flickering pulse, and that peculiar pinched look which is so characteristic of strangulation, who finds a bunch and has heard the history, cannot hesitate to think that operation is imperatively and immediately required. But the patient is very comfortable; his friends are naturally averse to having anything done; and all this may enforce a fatal delay. This is occasionally due to the subcutaneous injection of morphia, which has been given to such an extent as to mask those symptoms which are the only ones that can be appreciated by the patient and his friends. As an illustration of what quickness of operation will do, I should like to mention one case that I think was relieved perhaps as quickly as cases ever are. I take no special credit to myself for the occurrence, but I wish to put the credit where it belongs — upon the very sensible views of the patient, who was a woman of middle age. I saw her about two o'clock in the morning. She had been aware of the existence of a hernia, but had been perfectly well up to nine o'clock the evening before. At that time she went to the closet, had a somewhat constipated stool, during which she felt the hernia slip and come down. Pain, colic, nausea, etc., supervened immediately. She went to bed, and within a short time sent for assistance. She was in a lodging-house. I asked her if she was willing for me to telephone for an ambulance and take her to the hospital immediately. She said she was. The operation was over, and she was warm in bed and pretty well out of ether before daylight; and therefore the strangulation had existed only three or four hours before it was entirely relieved. Now the point I wish to make is this: that this was a feeble old woman with atheromatous vessels, rather a poor type of patient; the bowel was hardly showing the signs of constriction, and, of course, the operation was in every way the most favorable, and I never saw a case recover so quickly. Not the slightest bad symptom followed the operation, and she got about much sooner than any other person I ever saw. This shows what can be done under the best circumstances if people will submit.

I also wish to add my word to the very deceptive condition of these patients as to bearing any long operation. Instances have occurred a good many times in which, after prolonged etherization in these abdominal operations, the patient has suddenly given out, the heart and lungs have given out together, the bronchi become filled with mucus; sighing, gurgling respiration comes on; the operation is suspended, and death promptly follows. I have seen this occur several times. It is entirely unlooked for by one who has not seen it before. It is always unexpected and unlooked for by the etherizer unless he has had a large experience; and I would emphasize the point that the surgeon's mind must be almost as much on the anæsthetic as on the site of the operation itself. Now, in cases in which patients are considerably reduced, the question comes up whether we had not better allow them to go with an artificial anus, rather than do any prolonged operation. Most cases of artificial anus get

[1] See page 637 of the Journal.

well. I mean to say that they not only recover from the immediate danger of the strangulation and live, but they finally close the opening — at least that has been my experience with cases of artificial anus in the groin. I am aware that in cases in which colotomy has been done, what may be called rather ventral openings than openings low down in the groin, have been made, they often do not close, and require subsequent operation; but I think that a considerable percentage of cases of artificial anus that follow ruptured hernia finally close themselves; and in all times it has often been the case, when patients have had the bowel burst from mortification and abscess, that they have recovered finally, first going through the tedious stage of artificial anus. If this is so, I think we ought to be very careful about subjecting the patient to a formal resection of the bowel unless he is in a fresh and good state. If the patient is a strong man with a rupture down only a few hours, and if, on drawing out such a piece of intestine, you find it ecchymosed as result of taxis, if the bowel has lost its shiny appearance, there is a probability that these spots are going to slough. In such a case, if you have made up your mind that it is better not to return the bowel, it is wiser to draw it out, cut out the injured portion, make a clean resection, and such a patient will often get well. But if the strangulation has existed a long time, it is wiser sometimes to make an artificial anus than to resort to the other. Here comes in another very important point. The modern surgeon is very properly tempted to add the operation for a radical cure to the operation for strangulation. It is excellent if the patient can stand it; but it means prolonged handling and shock, and it seems to me that sometimes the combination of these two operations is not wise for the patient. In the treatment of these cases, it is a matter of judgment how much you think the patient can stand, how much he had better have done to him, how quickly it had better be done, and what are the best chances, not for curing the hernia, but for saving life.

In connection with this subject I should like to mention a case I had last week, not of hernia, but it has a bearing on methods of treatment. The patient was a strong man who was a hostler; a strong, powerful young man accustomed to be about horses, and who in an incautious moment got kicked. The horse kicked him across, not squarely, so that the corks and the mark of the shoe showed in the thigh. It was a glancing blow, and the thigh was not broken; but the foot in going across came pretty firmly upon the cord and the upper part of the scrotum, not the testis. The patient had a varicocele for which he had done nothing. The blow landed to a considerable extent over this varicocele. He immediately became sick and faint and nauseated. Ecchymosis of the abdomen took place, and he was brought to the hospital. He had not a previous history of hernia, but the appearance of a rupture caused at the moment existed; the upper part of the scrotum was black with the extravasation of blood running up to the inguinal ring; and as far as you could feel was an oblique mass as large as the thumb, the shape of a hernia; and of course it was impossible to say what it was inside. I told him, under the circumstances, he had better take ether, and have an incision made for the fear that he might have a hernia. It was entirely a hæmatoma from ruptured varicose veins which bled profusely, and had to be tied thoroughly, and the injury to these and the subsequent ligatures, I think, were the cause of sloughing of the testicle, which he will probably lose. This is the second case that I have seen of rupture of the spermatic veins. The other occurred to a delicate young lad who was playing ball, not foot-ball. Suddenly he turned pale, felt faint, and laid down and said something had given way about the inguinal canal. He was brought to my office in the evening. I examined him, and found a large swelling about the site of the ring. Then I insisted on an incision. Ruptured spermatic veins were found. There was no varicocele. The veins were ligatured, and he made a prompt recovery without any injury to the testis. Perhaps other gentlemen have met with these cases, but to me they were rare.

Dr. J. Homans: I think that the most embarrassing thing in these operations is to determine whether or not the intestine is viable. If it is not, you don't want to return it; if it is, of course you do. If you do not return it, you want to make up your mind whether to resect it, or to attach it to the ring, if it is not already sufficiently attached, and open it. Last summer I had a case of strangulated hernia in a lady about fifty years old, who was brought down from Rutland, Vermont. After opening the sac I examined the bowel and thought it had a fair chance of living. I returned it, and she got along very well for four or five days when the bowel gave way, and she died of peritonitis. In that case I made an error of judgment. The question of doing a radical operation for the cure of the hernia, at the same time that you relieve the strangulation, must be settled by the condition of the patient. If the patient is in excellent condition I think it might very well be attempted; if the patient is feeble the less handling you do the better. There are other strangulated hernias besides those of the bowel and omentum. As a general rule when I operate on a strangulated omental hernia I remove the omentum, — sometimes I have removed a number of pounds of it, particularly at the umbilicus. I saw a case of strangulated hernia at the hospital about a year ago, where the contents of the sac were exceptional. I was called in the night to see a woman about thirty-five years old who was four and a half months pregnant. She had a swelling in the left inguinal region over the crural ring which I took to be an ordinary femoral hernia. I opened the sac which contained a good deal of fluid. To my surprise there was no bowel, but there was the left Fallopian tube with its fimbriated extremity, and about four inches of the tube, strangulated. It was difficult to replace this tube after I had enlarged the opening a little because it was like a piece of string, perfectly flaccid and it doubled up. However, I did return it, sewed up the ring, and the external wound, and the woman recovered. She was confined at term without trouble. She had had symptoms of hernia off and on for a number of years, and my theory is that as the uterus grew in size it got up to such a point that the Fallopian tube came opposite to this hernial opening and dropped into it. If she had not been pregnant I think it very likely that the hernia which occurred would not have contained the Fallopian tube.

Dr. C. B. Porter: It seems to me that there is amongst the profession and amongst writers on the subject a certain amount of confusion with regard to the nomenclature of hernia, that is, calling an incar-

cerated or irreducible hernia, strangulated hernia. It was only a short time ago (in the Edinburgh *Journal*) I saw six cases of strangulated hernia reported. No detailed account was given, but it was said that they all reduced themselves under the internal administration of one-fourth of a grain of extract of belladonna. Evidently there was a mistake in nomenclature. Those were irreducible for the time being, but not strangulated hernia. In strangulated hernia there must be attending the hernia constitutional symptoms like nausea, vomiting, pain, colic, colic in the abdomen, pain at the seat of the constriction and generally constipation. Those in a more or less marked degree having existed a longer or shorter time, mark the condition or make the condition which is considered a strangulated hernia. Given those symptoms in a mild degree, palliative measures it seems to me might be considered perfectly proper, as the application of ice, putting the patient in the exaggerated Trendelenberg position. I have been able to reduce what were previously irreducible hernia, but not strangulated at the time, by putting the patient in the Trendelenberg position, and any one who has operated in that position knows that the tendency is for the intestines to fall towards the thorax and to drag upon the part which has become incarcerated in the internal ring and the patient is in the best possible position for the reduction. If the symptoms are marked, — marked vomiting, colic, — if they have existed any length of time I think any surgeon would hesitate to resort to palliative interference. The first thing is to relieve the constriction; then comes the question, and that is very important to decide, as to what shall be done with the contents of the sac. Those contents are either omentum or gut. If the omentum is strangulated it should be tied off in sections, that is, it should be dragged down until healthy omentum is found, tied off in sections, the gangrenous part cut away and the rest returned to the abdomen. If not gangrenous it may be returned without ligatures. There remains to determine whether or not the gut is viable, — the most important thing in connection with the operation. If there is any doubt I think the best method is to treat either by artificial anus, by excision or by retaining the gut in position, the constriction having been relieved. The constriction having been relieved, if it is doubtful what the condition of the gut is, it seems to me better that it should be packed in the wound and there retained until it is determined whether it is viable. If it is not viable, then an opening should be made into the gut and an artificial anus established, if the patient is not able to stand any further operation. In connection with the establishment of artificial anus I wish to mention some cases in contradistinction to what Dr. Cheever has said, "that the cases of artificial anus usually cure themselves." The first two cases of intestinal suture I ever did were in cases where there had resulted an artificial anus from inguinal hernia, which did not close. There was a constant discharge of fæces from the inguinal opening. The first case was that of an old woman. I relieved the intestine and brought it out until all the ulcerated part could be found. I used the Lembert suture; suture of the intestine was done, the intestine put back into the abdomen and complete recovery followed. Some years afterwards I saw the post-mortem specimen. The other case I saw in Lynn while there in consultation upon another case. I found a man in bed in a pool of fæces; he was reduced to the lowest extremity of flesh, and he said to me: "Dr. Porter, if there is any hope whatever of being cured I should like to have an operation." He said: "This is the first time that a glimmer of hope has been given." I said: "If I were in your place I should want to make the trial." He came to the hospital and a successful operation was done. With reference to the establishment of artificial anus, it must be remembered that the small intestine is more frequently the location of a hernia than the large, and that if the artificial anus is especially high up malnutrition follows and sooner or later some operation must be done, so that if the patient can endure the operation after dividing the stricture, it seems to me wise to do an exsection at that part; but an artificial anus should be established if the patient cannot endure exsection and enterorrhaphy. If the patient has strength to endure exsection of the diseased tissue and the enterorrhaphy, that is the next thing to consider; and in connection with that it is most important to be sure to get beyond the gangrenous portion. Kocher has removed five feet and Koeberle six feet of intestine successfully, so that the loss of a few inches more of intestine is not of moment, but it is of great moment to get to healthy tissue, that which has not been subjected to constriction at all and the intestine should be dragged down until that tissue is found, then enterorrhaphy made; and I believe an enterorrhaphy by continuous suture can be very rapidly made. I do not think that Senn's plates, Abbe's rings or Murphy's button for closing the intestine should be used under these circumstances, because the opening must be made much larger in order to reduce the intestine into the ring. The enterorrhaphy having been made, then comes the question as to what shall be done, whether the intestine shall be returned immediately into the abdomen or watched. There is a great difference of opinion with regard to what shall be done by those who have had the largest experience. Mickulicz says the suture having been made, the intestine should be dropped back into the wound in the groin, that no attempt should be made to close the wound in the groin, that if the intestinal suture is not competent, that then if the wound is open, if the intestine gives way the extravasation of fæces will be towards the wound and there is no danger. There are others who say that that should not be done, that the intestine should be kept outside and the suture watched, just as the intestine should be watched if it is a little doubtful, there being no constriction, and there is another German writer, Hahn, who says it is better to make an opening in middle line having sutured the intestine, leaving it there, close the inguinal opening and keep it there packed in gauze until sure of the suture and then return and close the abdominal wound. I believe it is better to keep the intestine in view if you are not sure of the viability of the intestine and the competency of the suture, otherwise it should be dropped in. I have never kept one outside yet. I have never had occasion to regret dropping an intestine back but once. That was a case of pyosalpinx where the intestines had been adherent to the tumor and torn in the operation. It should have been kept in the wound and an artificial anus established. It did not occur to me that the peritoneal coat was not intact. Where the patient is able to endure it after relieving the constriction I should say do a radical operation; if the patient cannot endure it an artificial anus should be established and left to be treated subsequently.

DR. BROKAW, of St. Louis: I am a little diffident about making remarks upon this subject. I am sorry I did not hear the beginning of the paper, but from the remarks that have been made I catch the drift of the discussion. Personally I speak from a rather limited experience. I have had more or less experience, however, in the matter of intestinal surgery. One or two thoughts occur to me. One remark by Dr. Porter in regard to the matter of aid sutures particularly interests me. When Senn commenced his work in experimental intestinal surgery which had every promise of electrifying the surgical world, I was at work on an intestinal suture, the ring which I devised being the segmented rubber ring filled with catgut. My idea was that the absorption of catgut would take place and that the segments of rubber tube would pass away. Experience on the dog is very satisfactory to the inventor, but every experience has led me to believe that all the aided sutures are not what the inventors claim for them; possibly an exception might be made in the case of gastroenterostomy where the aided suture or ring would answer very well. I have abandoned all the methods. I have tried all except Murphy's button. In the matter of their application to strangulated hernia where you have gangrene, it occurs to me that they are out of place; they necessitate a larger opening than is necessary simply to relieve the constriction. Again, the question comes up, Shall we do anastomosis at once or wait? I think that no experience in the matter of herniotomies will be of sufficient weight at present to dictate to surgeons in general what shall be the procedure in each and every case. I think there is a law fitting to each and every case, and I don't think that we can apply any specific rules covering all cases. I think that each case should be governed by the conditions that are present. I have seen gangrene of the intestine take place where there were very few symptoms; I have seen gangrene of the intestine take place in a very short time with very pronounced symptoms. What shall we do when confronted with such a problem? I think we shall have to rely on our own judgment and not on the experience of others. As to anchoring the intestine and waiting, I believe that is a very good idea, but unfortunately I am a little at sea to know what to do in some of these cases. I call to mind an unpleasant experience in which after anchoring as I supposed fairly securely, I found about four feet of the intestine outside of the partially open wound. Various devices have been called up, such as strapping a glass cap over the wound so that only a limited amount of intestine could be forced out. But it will break away the anchoring sutures in almost every instance if great care is not exercised. I am rather inclined to believe that while experience of individual operators is valuable, yet that each case as the emergencies arise is to be met in the most intelligent manner possible. I am rather in favor in cases where there is any doubt about the condition of the patient of not doing a radical operation such as resection at once. When I have done a resection in cases where the individual was at a low ebb or in a bad state of collapse, my operation has amounted to nothing more than a surgical exercise, and I therefore think that to relieve the constriction, place the intestine in the best position within the wound, drawing the integument a little over the intestine, using one or two or more sutures, making latticework as it were with the integument and anchoring the intestine in place is the best we can do in most of the cases. If you subject a patient to the operation of resection that takes time. I am a great advocate of doing all the operations of abdominal surgery in the shortest possible space of time. I think many of the bad results are not so much due to the operation as to the anæsthetic. That question does not come in here particularly. I want to say while I have done a fairly large amount of experimental work, with some work on the human subject in this field, I have abandoned and I am frank to admit it and take back all the recommendations of aided sutures, rings, plates, etc., I made early after publication of my work on intestinal anastomosis, and I now condemn absolutely the use of the intestinal plates and aided sutures of any kind whatsoever. You can accomplish just as much and almost as rapidly with the interrupted or the continuous Lembert suture, and you can have an opening quite large enough so that when subsequent contraction takes place, which follows rapidly, a failure in the ultimate result does not follow. You can make an anastomosis with an opening in the bowel two and a half to three inches. If you use a plate you have to introduce within the lumen of the intestine a mass of foreign matter which has to come away, and very frequently parts of it are retained for quite a little while. I have seen a rubber tube come away five or six weeks afterwards, and in gastroenterostomy I have had patients vomit parts of my ring; but taking the so-called absorbable rings, for instance Abbe's ring, that does not hold the parts together I think nearly as well as the simple suture. When you come to Senn's plates it may or it may not be absorbed; they cause kinking and are liable to bring about late obstructive trouble. Stricture is bound to follow. I hope that Murphy's button will prove more than a makeshift. I hoped that my rubber segmented rings would be of value to every surgeon, but I have become convinced that the unaided method by simple suture is the best suture in the hands of experienced abdominal surgeons — the aid sutures for the beginners and unexperienced. I do not believe we can set down definite rules in this matter of herniotomy, and I think each case is to be governed by the circumstances.

DR. M. H. RICHARDSON: We should always bear in mind the possibility of strangulated hernia in acute intestinal obstructions, even if no tumor can be felt at the usual seats of hernia. A few days ago I saw a case of acute intestinal obstruction at the New England Hospital, in the service of Dr. Mary Smith, due, as I supposed, to the sudden closure of a cancerous stricture. After Dr. Smith had exposed the intestines and had examined them from the jejunum to the sigmoid flexure without finding the cause of the trouble, a small segment of the small intestine was discovered in the internal ring; — it was a case of strangulated hernia with total obstruction discovered only by laparotomy and complete turning out of the contents of the abdomen. There was not the slightest reason for suspecting such a condition except on general principles. In my opinion the best treatment for a gangrenous hernia is, first, that which gives the best promise of life to the patient, and secondly, that which restores the lumen of the intestine; therefore, if the patient's strength is good, I believe in the performance of an excision with suture. This operation ought not to last more than one hour; — if the patient's strength does not admit of this, I think an artificial anus should be made. I have

never seen a case in which anastomosis seemed to me the better operation either in acute or in chronic obstruction. Conditions do, of course, exist both in chronic and in acute obstructions in which an anastomosis is indicated, but this operation as I understand it — never having performed or seen it — seems to me as complicated and difficult as end-to end suture. I believe the surgical profession is coming to this opinion that, when possible, immediate excision and end-to-end suture is the best thing. If this cannot be done safely, I think the next procedure in gangrenous hernia is to make an artificial anus. The subsequent resection is comparatively safe, not only because it may be done deliberately with full preparation of the patient and the bowel, but because the peritoneum becomes more tolerant. I remember very well the first operations for the closure of intestinal fistulæ that were performed in this community. I refer to the cases of Dr. Porter in which excision and suture of more or less of the circumference of the bowel was followed by immediate and most gratifying recovery. Recovery has followed all the secondary excisions and sutures that I have made myself; even in cases of resection and suture for acute conditions the results have been encouraging, though the prognosis is more unfavorable in the latter. Instead of leaving the bowel entirely outside, or of fastening it in the wound, the device which I have described elsewhere of protecting the line of suture by means of gauze seems to me to offer a very safe remedy for the dangers of end-to-end suture.[2] The only danger to a patient strong enough to stand the operation is in extravasation and general peritonitis. In two of my cases of complete resection and suture there was a small escape of fæcal matter some days after the operation. This was promptly drained by the gauze I had placed over the stitches, and no harm resulted. A small fistula remained — such as we see in appendicitis — which in each instance cured itself.

DR. E. H. BRADFORD: In confirmation of what Dr. Porter said as to the danger of starvation from artificial anus I can contribute one unfortunate case. It was that of ordinary strangulated hernia in a feeble woman. Resection was not done. The woman recovered from the operation and lived ten days. At the autopsy it was found that the patient had died of starvation, owing to the short upper portion of the intestine. If resection had been done the patient might have died from shock, but if she had survived that, she would not, at least, have died of starvation.

DR. GAY: Dr. Homans brought up two points upon which I want to say a word. The first relates to removing large quantities of omentum. In some cases that is successful, but we had one case at the City Hospital that was unfortunate; a large portion of the omentum was removed; the patient recovered from the operation, but as time went on, the stump of the omentum formed adhesions, which produced internal strangulation and rupture of the intestine, for which we had to do laparotomy, and the result was fatal. Another condition I have met with, is in the case of old women with enormous umbilical herniæ, which have become strangulated. You open a hernia of that sort and find the adhesions very extensive and firm. In one case of that sort I simply found the constricting ring, divided it freely, closed the wound, and left everything as it was before. She made a quick and satisfactory recovery.

DR. ABNER POST presented a

A CASE OF ŒSOPHAGOTOMY.[3]

DR. M. H. RICHARDSON: I am very much interested in the subject of operations upon the œsophagus, and I am very glad to see this case. The application of the principles of asepsis to this procedure as recommended and practised by the reader is timely, for in our operations upon the œsophagus we may be still clinging too much to the methods of pre-aseptic days. I have always left the œsophagus open, letting the wound close gradually by granulation. If I have another case of this kind without suppuration I shall close the œsophagus at once, leaving the external wound open. I believe the dangers of suturing immediately the œsophagus depend more upon the closure of the external wound than upon the closure of the œsophagus itself. In regard to the treatment of foreign bodies in the œsophagus I speak from a very limited experience, — the experience of most surgeons must, I think, be limited. I have removed foreign bodies from the œsophagus by incision twice: — once by gastrotomy,[4] and once by external œsophagotomy.[5] The former case recovered and the latter died. An external œsophagotomy for stricture was also fatal.[6] I have had better success in opening the pharynx than I have had in external œsophagotomy. I recall three cases in which I have successfully taken out the side of the pharynx for malignant disease. In two of them I removed also the tonsil. The pharynx was left partly open in all the cases. The principle is the same as in external œsophagotomies as to the dangers from sepsis: in pharyngotomy there is greater reason for leaving the wound open from the more complicated movements in deglutition and from the proximity of the larynx. (One of these cases is briefly described, with the specimen — a round-celled sarcoma — on page 320 of the *Boston Medical* and *Surgical Journal* for March 31st, 1892.) From the impacted foreign bodies the patients ran great risk, though one had remained near the cardiac orifice eleven months. The location of the foreign body is of great importance. Below the clavicle a short distance the œsophagus comes in contact anteriorly with the heart or the aorta; lower down it is in close relation with the thoracic aorta, and on the left side with the pleura; the only place in which perforation would not be followed by immediately fatal or very serious results is the posterior wall. It takes a very short time for a foreign body like a coin to erode the aorta or to set up a pleurisy or a pneumonia. I think the dangers from external œsophagotomy under the aseptic conditions which Dr. Post describes are very slight.

It seems to me that this operation for the removal of foreign bodies is not justifiable until gentle efforts at extraction have been made through the mouth. When pointed bodies are impacted the use of the coin-probang may be dangerous, because after the probang is fast it cannot be withdrawn without either dislodging the body or breaking the instrument. Forcible attempts at dislodgement are extremely hazardous, and no instrument should be selected, therefore, that may not be under perfect control. In one of my cases the probang got hooked in this way under a tooth-plate, and the surgeon was obliged to use enough force to

[3] See page 642 of the Journal.

[6] Loc. cit., January, 1892, page 58.

break off the metallic end. This part was afterwards discharged by the rectum. On the other hand, in the case of a plate of teeth which had been impacted in the œsophagus at the level of the clavicle eleven months, I used the coin-probang with the greatest ease and success.

The last case of foreign body in the œsophagus that I have seen was in an insane person who had swallowed a teaspoon. I removed the spoon by external œsophagotomy, and the patient died two days afterward. We were unable to find the cause of death, but it is probable that the sharp edge of the silver spoon had cut through the œsophagus. In impacted foreign bodies, exploration should be made early; we should not wait for such symptoms of erosion as pleurisy or pneumonia or septic absorption. In opening the œsophagus above the clavicle we may explore with the finger to a point just below the arch of the aorta, and more or less intelligent use of instruments may be employed, even if the foreign body is lower down. If the impaction is at the cardiac orifice, the stomach route may be used successfully, as in my first gastrotomy and in the cases reported later by Bull and Phinney.

Dr. Brokaw: I have nothing to add of particular interest except one point in regard to the use of probangs and various instruments, particularly the coin-catcher. I am rather afraid to use them after an experience I had a year or two ago in the case of a child who had swallowed quite a large piece of bone. The piece of bone lodged very firmly and I tried everything to dislodge it. I used the coin-catcher and it caught on the sharp edge of the bone. I removed it not without some effort. Quite a profuse hæmorrhage followed. The question arose, What am I going to do if the hæmorrhage keeps on? The hæmorrhage was terrific. He would vomit the blood, and he bled so furiously that I was very much afraid that I was going to lose the patient. What vessel of size I had hurt I did not know. The mucous membrane probably was the origin of the bleeding. I think the use of these mechanical measures for removing a body whose exact location, shape and character we do not know, is like catching fish; we do not know what kind of fish we have on the hook. I think the operation of œsophagotomy should be done more frequently than it is. There are three points where the impaction can take place; at the junction of the pharynx and the œsophagus, then one and a half inches below that and at the cardiac end of the œsophagus. At those three points we have normally some constriction. Of course if the body is well down it is impossible to reach it from above very readily and by making an incision we at least gain the difference in space from the teeth to the beginning of the œsophagus where most frequently, fortunately, the impaction takes place. I wish to congratulate Dr. Post on the success he had. Having recently looked up the literature, I know of no case where immediate union by suture occurred or where it was attempted to suture the œsophagus at once. I see no reason why it should not be done. It requires an aseptic suture and that the sutures be placed with the very greatest accuracy so that there shall be no possibility of leakage; and I believe in these cases it is unwise to feed too early after such operations.

Dr. D. W. Cheever: My contribution will be chiefly historical. In 1868 I revived the subject here by looking up cases, and by operating on two cases, and it is quite interesting to note that previous to 1868, although a great deal of good surgery had been done in the world, yet the operation of œsophagotomy had been done but twenty times in the history of medical literature; the first time in 1760 or 1770, and up to 1868 twenty cases were all that were recorded; and since 1868 one hundred and forty odd cases; so that the latest tables give, I think, one hundred and sixty or one hundred and seventy cases in all. It is curious also to note the fact that the percentage of mortality is the same that it was in those first twenty cases, that it remains obstinately at 25%; that one in four die from the operation of œsophagotomy. The reason of the deaths is the lateness of the operation. If the operation is done early it is almost sure to save the patient. Demarquay, some thirty years ago, made a large number of experiments in France, on dogs, and the results show that foreign bodies impacted in the œsophagus tended to produce inflammation and abscess after the third day, that the third was the latest in animals, — in which inflammatory processes are slower, whose systems are more tolerant than ours, — that the third day was the latest that a foreign body could remain in the œsophagus without provoking inflammation that was sure to end in abscess, and abscess that was destructive of life, frequently. Among the first twenty cases I recorded, four died; and in all of these abscess had occurred. The lung and pleura had been perforated, the aorta had been perforated once, and posterior mediastinal abscess had occurred in another case; and in one case caries of the vertebræ followed and the patient survived a while, but finally died from this. So now, although the operation has become popular, the mortality has not decreased; and I think it is only because it is not done early. The last case I had was about a year ago. My delay, I think, added to the fatal result. My delay was a very foolish one. The patient came to the hospital and was a half-demented, feeble person, an epileptic; his description of himself was very imperfect. He was regarded as probably an hysterical patient; and not seeing any of his friends and not realizing at the moment what might have taken place, I let a day go by. Then some of his friends came and gave an intelligent account, — that the man was found in an epileptic fit, and that he had a set of false teeth, and when picked up part of the teeth were gone. Then I realized that there might be something in the œsophagus. Meanwhile he was sitting up in bed, and swallowing liquids with tolerable facility. On passing the whalebone probang with the ivory knob, at the depth of nine inches from the incisors I came upon a hard substance which was the plate and six or seven teeth attached. The location was below the nipple, nine inches from the incisors. It was rather a question what I had better do, whether I could recover it through an opening in the œsophagus, or had better imitate Dr. Richardson's manœuvre of opening the stomach and getting it from below. I did œsophagotomy, and was a long time extracting the substance. There was no hæmorrhage, but it slipped and slipped, and finally I extracted it. The patient did pretty well for a day or two, but gradually sank and died in the course of the first week. I never saw the œsophagus unite by first intention. I belong to the old school which does not sew it up. I never gave the patient anything to eat in the first twenty-four hours, but nourished by the rectum. It is not always that the wound leaks. It may not unite, but does not leak always. In operations in the pharynx, possibly the

muscles of the pharynx are more apt to overlap and close in the act of swallowing, at any rate, operations done on the pharynx from the outside do not leak. The œsophagus is more apt to leak, but they all recover. I see no objection to suturing the œsophagus if the external wound is left open. The dangers are of leakage, deep cervical abscess, mediastinal abscess, and death if this occurs and is not promptly recognized. I should think if the œsophagus is sutured and the wound left open, it might be an advance in the *technique* of the operation.

DR. J. HOMANS: I should like to mention a case where a quarter of a dollar was retained four and a half months. The little girl was brought to the hospital some ten years ago. The coin came up at once on the bristle probang. It was very black, as all coins are which have been retained in the alimentary canal. The child had been able to swallow fluids, and no serious trouble had resulted from the presence of this foreign body.

DR. C. B. PORTER: I wish to say a word in reference to two cases under my care. One was at the hospital two or three years ago. It was that of a woman who six weeks before had swallowed the better part of an artificial plate for teeth. The teeth were not on the part swallowed. It was quite readily removed by the coin-catcher. Another case was that of a man who came and said he had swallowed his whole set — two teeth on each side. I tried to catch it with the coin-catcher, but it slipped and went into the stomach. He said he would keep watch, and if symptoms developed he would let me know. About six months after that I received a paper stating that this man had recovered the plate and the four teeth. The teeth had become separated from the plate, and he had passed them per anum and was happy. That is a pretty large body to pass; but I remember as long ago as I was a student under Professor Wyman, of Cambridge, I spoke to him about the passage through the alimentary canal of foreign bodies, and he said never despair of anything after it has once got down. He told me of a case of a man who swallowed a large-sized jack-knife with the blade open, which passed successfully by the rectum, passing through without wound.

DR. G. W. GAY: I have done œsophagotomy four times. The most satisfactory case was for the removal of a cent from the œsophagus of a child three and a half years old. She had carried it several months. During the last month she grew very thin, and got so that she could not swallow anything. Chloroform was given. The patient recovered. The second case was that of a plate of false teeth. It was removed after five days. The man died of exhaustion and shock. Another instance was for a fish-bone, which recovered very promptly. I once opened the œsophagus in order to pass a probang through a cancerous stricture into the stomach, upon which I could pass the Simond's tube. The lower opening was located upon one side of dilatation in the œsophagus, so that no effort of either Dr. Mixter or myself could get a probang through the stricture. That was successful, and the patient lived several months. Another case is interesting from the fact that the symptoms were so slight, and the patient could swallow so well, that I was misled and missed the opportunity of doing the operation at the right time. The woman had got a little piece of wood into the œsophagus. She died, and the autopsy showed an abscess in the anterior mediastinum, which contained a small sliver. Another case, which happened in the practice of Dr. Garceau, of Roxbury, is interesting. A woman swallowed a small bone, which lodged in the œsophagus. The doctor passed a sponge probang, and pulled out a bone about an inch long. The patient was not relieved by the operation. I saw her the next day. The question arose as whether the bone had caught in the walls of the œsophagus and had been broken and a part been left. She was old and feeble, and I thought we had better wait. The next morning the lady got out of bed, while her attendants were out of the room, and dropped upon the floor dead. The autopsy revealed rupture of the left auricle of the heart. There was no fish-bone nor other foreign body in the œsophagus.

DR. POST: The fortunate result, I think, occurred in spite of the fact that the operation was so long delayed, and the few bubbles of gas, the commencing emphysema, showed that the operation was delayed as long as it ought to have been, and that symptoms were just beginning which would very likely have led to less favorable ending if interference had not taken place. The coin-catcher made a most uncomfortable sensation as I passed it. I hit upon the coin with it, but did not engage it; but the coin seemed so firmly fixed that the thought went through my mind that if I had caught it with the instrument and failed to extract the coin, it might have been extremely difficult to disengage the instrument itself. The œsophagus was not sutured. The only sutures were in the upper and lower ends of the external wound, leaving the middle of the wound perfectly free, with the intention of giving a free exit to alimentary substances or to any discharge.

DR. JOHN HOMANS read a paper on the

REMARKABLE EFFECTS OF DIVULSION OF THE URETHRA.[1]

Recent Literature.

Outlines of Obstetrics. A Syllabus of Lectures delivered at the Long Island College Hospital. By CHARLES JEWETT, A.M., M.D., Professor of Obstetrics and Pediatrics in the College, and Obstetrician to the Hospital. Edited by HAROLD F. JEWETT, M.D. Philadelphia: W. B. Saunders. 1894.

This little volume is, as its title implies, a syllabus of Dr. Jewett's lectures at the Long Island College Hospital, and is primarily intended as an assistance to the students of that college in their assimilation of their obstetric course, and is certainly admirably adapted for that purpose. It is not sufficiently full to be of value as an independent source of information to the practitioner. We have no doubt that many a busy physician would be enabled, by a perusal of this book, to find many weak points in his knowledge which ought to be brushed up by a study of a more extended work. To the specialist it possesses much interest, since it enables him to gain an accurate idea of Dr. Jewett's position on the many points of interest in obstetrics with a minimum loss of time.

ANNUS MEDICUS, MDCCCXCIII.

THE medical year now closing, though unmarked by any events of special or unusual importance, has been an interesting one in many ways. The new work in medicine and bacteriology has been along the line of therapeutical application of present theoretic knowledge, rather than of new discoveries. The theory of blood-serum immunity has claimed much attention, and promises good results in the not far distant future. The fear of another cholera epidemic led, during the winter and spring, to important sanitary action on the part of national and municipal governments; and the result of the improved hygienic condition of many large cities has shown most conclusively that the real treatment of epidemic disease is prevention. The medical profession has suffered great loss by the deaths of Jean Charcot and Sir Andrew Clark, both of whom died suddenly in the fulness of their intellectual powers.

EPIDEMICS.

The Cholera Epidemic this year was in marked contrast to that of 1890 and 1892. There was not the invasion and steady progress across Europe as in those years, but a relighting of the various centres of disease left smouldering during the winter; and in every place affected this year the disease was light and easily controlled, or virulent and general, just in proportion to the amount of cleaning up which had been done during the months of freedom. Never was a better example of this truth of the preventive value of cleanliness and vigilant isolation than in the city of Hamburg. Last year's terrible epidemic taught the lesson; and this year, owing to the improved sanitation and purified water-supply, the total number of cases was only a few score. The epidemic was chiefly European, and was not a new incursion from India as last year. By February it had pretty nearly died out all over Europe; and even Russia was declared free from the disease, though there is strong reason to believe that there was unavowed cholera present in St. Petersburg all winter in spite of the great cold, which reached a minimum of 13.5° F. lower than has been recorded for one hundred and thirty-eight years. In Podolia and the Volga provinces there were nearly a thousand cases during January and the first half of February.

On March 18th cholera appeared in a decided form at Odessa, and was suspected to be increasing in St. Petersburg, though denied by the Government. Throughout the Russian provinces it made steady gain, not along any definite route, but appearing simultaneously in many places. Astrakhan, Moscow, Nijni-Novgorod, Kieff and Podolia were first and chiefly infected. Shortly afterwards cases made their appearance in Austria and southeastern Hungary and in Galicia, where it was brought from Podolia. By the middle of April, all the southern provinces of Russia and the neighboring frontiers, had a largely increasing number of cases, many of them fatal. At this time the disease, which had been casually reported from Lorient near Brest in France, assumed serious proportions; and simultaneously cases occurred in many places in southern France and at a few points in northern Italy. Up to the middle of May, Russia bore the brunt of the epidemic, Podolia especially having a large number of cases. In Austro-Hungary it spread slowly along the river tributaries, chiefly with isolated cases. On May 27th the first case was reported from Hamburg; and the same week Marseilles, La Rochelle and Toulon became infected.

The most serious outbreak of the year now made its appearance in Mecca, which had been free from disease during the spring. The pilgrimage to the Holy City began the last of May, and by the end of June over 32,000 pilgrims had passed through Suez; and by the middle of June it was estimated that there were over 100,000 persons gathered at the Sacred Mount ready to start for Mecca. The first case of cholera occurred June 8th, and the number grew rapidly. Between the 16th and 20th there were 830 deaths, the next day 455, and by the following day 1,000. A few days later the disease broke out at Jeddah. In three weeks there were 5,000 deaths. The return pilgrimage began the first week in July; and by the middle of August the epidemic had come to an end, with a death-roll of some 10,000 persons. The quarantine established at El Tor for returning pilgrims served a most useful purpose. There were 135 cases and 91 deaths only, and the disease was not carried past into Egypt.

By the middle of July cholera had appeared in Spain, in some twenty towns in France, and in several Italian cities. In Naples there were 90 cases the last week in June; but the Italian Government declared there were none, and no precautions were taken in any way. Not content with this, it officially suppressed dispatches sent by foreign representatives and newspaper men. In August the disease broke out in Palermo; and both here and in Naples there was a serious epidemic, with many hundred cases before it ceased.

In Russia, July and August saw a continued in-

crease in every part of the country, the total number of cases reported from January to September being 62,107, with 24,284 deaths, as against 433,643 cases and 215,137 deaths in the corresponding time in 1892. The epidemic was not only smaller, but less severe, there being one-seventh as many cases, but only one-ninth as many deaths. Germany remained practically free from the disease; a few isolated cases at Berlin, Stetten and Hamburg being all there were.

In Antwerp the disease appeared July 28th, and ran a moderately severe course. In Holland some thirty-four places were infected. In Spain the cases were few in any one town, but nearly fifty centres of disease were reported during the summer.

In England the cholera gained a foothold at Hull and Grimsby in the middle of August, and a considerable number of cases with many deaths occurred. Isolated cases were reported from London, Liverpool, Leicester and several midland towns.

The sanitary regulations, elsewhere referred to, issued by our own government in the spring, and especially the detailing of special inspectors for the chief European ports, to supervise the disinfection of emigrants and baggage before sailing, undoubtedly saved the United States from an invasion of cholera. On August 4th the steamer *Karamania* arrived at New York from Naples, having lost three steerage passengers during the passage. She was quarantined, and the passengers kept under surveillance. Twenty-two subsequently were sent to the hospital with true Asiatic cholera, and three of them died. August 29th two deaths occurred in Jersey City from acute diarrhœal diseases, which bacteriological examination showed to be Asiatic cholera. These cases had not been in contact with the immigrants on the *Karamania*, and no cause was found for the occurrence. No other cases occurred in either city.

SMALL-POX has been widely distributed during the year. On the Continent it was nowhere epidemic, but in England it has been exceedingly prevalent and widespread. In London, especially, the disease assumed serious proportions. In February there were over fifty cases a week, and during March and April the number was still very high. From January 1st to June 1st there were 1,450 cases and 86 deaths in London alone, a mortality of nearly six per cent. During the summer there was a falling off in the number of cases, which reached the lowest point early in September, when there were only two or three a week. The last of October saw an increase, and during November there was an average of fifty cases a week. Over all the rest of the island — especially in the Midlands, in Manchester, Birmingham, and Lincolnshire and Yorkshire — there was a seriously large number of cases.

In this country the disease has been reported from nearly every State east of the Mississippi River, showing widespread centres of infection and an insufficiently protected population. New York has naturally had the largest number of cases, but there was a serious outbreak in western Pennsylvania in March. In Reading, Pa., a city of 70,000 inhabitants, there have been 678 cases with 18 deaths between January 1st and December 11th. Chicago has reported many cases since October. In Boston there were two cases stopped at quarantine in May. October 30th several cases occurred in various parts of the city, traced to a case which was allowed to land from the Cunard Steamer *Catalonia*. This series of cases was followed by a second group traced to one family, which, however, had no connection with the steamer cases. In all there have been 26 cases and 4 deaths. In considering the question of protection by vaccination and revaccination it is important to give due weight to these facts.

TYPHUS FEVER was reported from many districts in Europe, but no serious epidemic occurred. In New York there was another outbreak of the disease very much after the fashion of a year ago. On December 29, 1892, several cases of typhus fever were discovered in a block of cheap tenement-houses in one of the lower wards of the city; and within the first week of January, this year, 53 cases were reported. The epidemic while confined to New York City was not without serious menace, for it continued well into June before it subsided. Several nurses and attendants were infected and died. The total number of cases up to June 10th was 466, with 192 deaths, a mortality of 41.2 per cent. This is a more serious record even than that of last year, when there were a few over 194 cases and 29 deaths. This rapid increase in typhus fever in New York during the last few years makes all the more important and timely the new quarantine regulations and more strict supervision of immigration.

YELLOW FEVER continued its devastation at Santos throughout the first half of this year, which is now the third year of continuous epidemic disease there; scattered cases occurred at various southern ports during the summer, but without gaining foothold. At Brunswick, Ga., the disease appeared in July with a few mild cases, and there were occasional cases during August. In September the disease suddenly became epidemic, lasting until November 23d, when ice formed. A quarantine camp was established, and so efficiently maintained that the disease was confined entirely to Brunswick and Jesup. In all there were 1,001 cases and 53 deaths, 409 of them whites, one Mongolian and 12 blacks.

INFLUENZA. — In the spring and early summer there was a mild outbreak of influenza in Italy and some other parts of Europe; but, generally considered, there was no pandemic, as there was last year. During the last two months many cases have been reported from England and Germany, especially on the lower Rhine and in Hesse. In this country the disease is said to be starting up in many places, but in a milder form than in the last two epidemics.

The whole continent of Europe, and particularly Russia and France, suffered greatly from the cold during the winter, the mortality from cold alone being

greater than for many years. An unusual and prolonged drought during the spring and early summer destroyed the crops and caused great hardship. In parts of France and Italy no rain fell for three months, and the farmers were obliged to kill their cattle for want of water to give them.

QUARANTINE.

The narrow escape of the country from an invasion of cholera in the autumn of 1892, the continuance of epidemic cholera in Russia during the winter of 1893, and the occasional occurrence of cases in different parts of Europe claimed the attention of sanitarians and public health officials, and forced the consideration by Congress of the unsatisfactory position of our quarantine regulations as well as of the imperfect equipment and variable, uncertain and unscientific administration at some of our ports of entry. The importance of securing co-operation from our immediate neighbors to the north and south, and the necessity of regulating the passenger traffic of the great ocean transportation companies became from one week to another more and more evident. Congress was memorialized by several of the large and active medical organizations in the cities of the Atlantic sea-board. It was hoped that some legislation might be secured creating a National Health Bureau by which quarantine might be administered or at least supervised for the whole country. In the month of February an act was passed by Congress granting additional powers and imposing additional duties upon the Marine-Hospital Service. This act abolished the old National Board of Health; gave power to the President to prohibit immigration in whole or in part; authorized him to detail any medical officer of the Government to serve in the office of the consul at any foreign port; affirmed the duties of United States consular officers in regard to the cargo, passengers and crew of vessels sailing for our ports; and authorized the Secretary of the Treasury to remand an infected vessel arriving at any port not provided with proper facilities for its treatment, at its own expense, to the nearest national or other quarantine station where suitable accommodations and appliances were provided for the necessary disinfection and treatment of the vessel, passengers and cargo.

Though not what was desired by those most competent to judge and most conversant with sanitary questions as affecting the country at large, it was all that could be obtained from Congress, and the most and the best was made of it. A conference of health officers from the Atlantic and Gulf ports was held at Washington in March, at the invitation of Surgeon-General Wyman of the Marine-Hospital Service. Some of the best medical officers in the Marine-Hospital Service were detailed to serve in connection with the consular offices at European ports, where their work — notably at Hamburg and Naples — was invaluable. This provision, supplemented by the intelligent co-operation of most of the Steamship Companies, and the judicious vigilance of the health officers at our ports of entry, was attended by the happiest results. Not only did the country escape an epidemic, but hardly a case of cholera found access within our borders.

Apart from the prevalence of extraordinarily fine weather during the summer of 1893, the fact that Western Europe and the United States escaped a serious epidemic outbreak of cholera is a striking tribute to the advances made by Sanitary Science in recent years.

MEDICAL LEGISLATION.

Medical legislation in the United States, this year has had its usual history: many good bills have failed to pass, and, as in compensation, some very bad ones have also been defeated.

With a view of keeping Canadian pleuro-pneumonia out of the United States, the Secretary of the Treasury instructed collectors of customs on the northern frontier that neat cattle may enter the United States from Canada only at Buffalo, N. Y., after passing the inspection prescribed by the Secretary of Agriculture.

In Massachusetts the law providing for the registration of deaths by physicians, in connection with the obtaining of a burial permit by undertakers, has been amended so that in cases of still-born children and those dying immediately after delivery, the same form is required as in other deaths, and a penalty is provided for making false statements. A law was passed providing that "sweat shops" shall be licensed and superintended by the police, and that in cases of danger from infectious diseases or vermin, the State Board of Health shall take charge and control. A bill was passed requiring local boards of health to notify the State Board of the existence in their districts of any disease dangerous to the public health. Hereafter plumbers must be licensed, and must pass an examination. The examining boards consist of the chairman of the local board of health and the inspector of buildings. It will be no longer possible for any ignoramus to practise plumbing, but the practice of medicine is still unrestricted.

The Michigan State Board of Health unanimously decided that consumption is a dangerous, communicable disease, and must be reported by physicians and householders to the several health boards.

In New York a bill was passed providing for the levying of a special annual tax for the support of the insane. The tax of one-third of a mill, imposed by the bill is expected to yield about $1,350,000 each year. The New York City Board of Health took similar action in regard to tuberculosis to that of the Michigan State Board.

The legislature of Ohio passed a law regulating the practice of veterinary surgery, and requiring an examination before allowing any one to practise upon horses. Ohio has no medical practice law.

In Pennsylvania the legislature passed a bill establishing a medical council and three State boards of medical examiners, corresponding to the three so-called schools. The boards are to be appointed by the Gov-

ernor, and their work is to be supervised by the medical council, consisting of the Lieutenant-Governor, the Secretary of Interior Affairs, the Superintendent of the State Board of Health, with the presidents of the boards. Applicants will be required to have studied medicine for four years.

In Tennessee an act was passed to prevent the spread of communicable diseases, providing that the local health authorities shall be notified of all cases or suspected cases of communicable disease, except any venereal disease. The local board is required to notify both the State Board of Health and the Board of Education of the district in which the case occurs.

In Washington the State legislature passed an anti-cigarette law, making it a criminal offence to manufacture, buy, sell or give away, or to have in one's possession cigarettes or cigarette paper.

The Superior Court of New York City has ruled that when a married woman is so injured through the negligence of another person as to miscarry, her husband can recover damages for the loss of the child.

The Supreme Court of North Dakota has ruled that mental suffering is as properly considered in estimating damages as is physical pain. The impairment of mental powers, naturally a proper element when proved, is only to be considered by the jury when claimed in the suit and evidence.

The Supreme Court of Illinois has made the following ruling regarding expert medical testimony: "A practising physician who is shown to be a graduate of a regular college and to have practised his profession for many years, is competent to give his opinion upon a hypothetical question, setting forth the symptoms of a deceased person, whether the death was from the effects of arsenical poisoning, although he may not be shown to have had any case of such poisoning. A medical witness, in giving his opinion as an expert, is not confined to opinions derived from his own observation and experience, but may give an opinion based upon information derived from medical books."

The Supreme Court of Wisconsin has ruled that when a married woman sustains a personal injury, and her physician does not caution her to avoid pregnancy, and there is no evidence that her injury was such that he should have done so, her pregnancy occurring after the accident, even if it prolong her injury or delay her recovery, is not necessarily, and as a matter of law, sufficient to justify a reduction of damages.

The Legislative Assembly of the Island of Jersey declared by vote that quarantine is not preventive of cholera, and therefore refused to establish a quarantine against vessels from ports alleged to be cholera infected.

MISCELLANY.

Early in the spring an International Sanitary Conference was held at Dresden, on the initiative of the Austro-Hungarian Government, to discuss the control of cholera epidemics. Delegates were present from nineteen European Governments. A chief part of the time of the Conference was spent in devising regulations for the uniform administration of land quarantine and traffic between infected and non-infected countries. A convention was signed by a majority of the countries represented, by which the Governments agree to notify contracting States of every appearance of a cholera focus in their territory. They also agreed that medical surveillance shall be given to all passengers from such a district for a period corresponding to the incubation of cholera, and decided that this shall be taken as five days.

During the year Haffkine has continued his work upon chemical vaccination against Asiatic cholera, and has inoculated over four hundred persons at Agra, British India — a notorious home of cholera — with no untoward effects and apparently good results.

In the line of bacteriological diagnosis of disease is the establishment by the New York City Board of Health of a laboratory for the free diagnosis of membranous diseases of the throat and fauces. In Boston the Bacteriological Department of the Harvard Medical School has offered to make cultures of all suspected cases of diphtheria for the purpose of securing a more accurate diagnosis by the profession.

The British Leprosy Commission appointed in 1890 made its report in the spring of this year. In their investigations they personally examined over two thousand lepers in India and supplemented their inquiries by prolonged pathological and bacteriological researches. About nine per cent. of the cases offered for examination were found to be wrongly diagnosticated. They reported an actual and relative decrease in the spread of the disease in the last ten years. On the important question of contagiousness, they concluded that though leprosy must be classed as a contagious disease, yet the risk of contagion is so small that it may be disregarded, and that the attention should be directed towards the removal of predisposing factors.

The fiftieth anniversary of Pettenkofer's doctorate was celebrated in Munich on July 1st. Various orders were bestowed upon him by the Emperor, the Prince Regent of Bavaria and the King of Servia. The burgomasters presented him with the "Gold Bürger's Medal," the first time this honor has been given to a person holding an honorary citizenship. Congratulatory addresses were read from various European universities, and a banquet brought the celebration to a close.

On July 5th the centenary of the death of John Hunter was commemorated by an exhibition of relics associated with the great surgeon in the library of the Royal College of Surgeons. In addition to the articles belonging to the college, many valuable articles were loaned by private owners.

The tercentenary of the admission of William Harvey as a student of Gonville and Caius College, Cambridge, was celebrated on the 21st of June by the Master and Fellows of the College. A large and distinguished company were entertained at dinner, and a number of new and interesting Harvey relics were exhibited.

The disasters of the year have been numerous. The Strafford County Insane Asylum at Dover, N. H., was burned to the ground on the night of February 9th, and forty-four of the inmates were killed. Most of them were women who were locked in their rooms at night and were unable to escape owing to the rapid spread of the fire. In June the building in Washington, D. C., which was formerly Ford's Theatre (where President Lincoln was assassinated, but which for several years

had been used by the Medical Department of the Army) collapsed while five or six hundred employees were at work there, killing about twenty-five and wounding many more. In this month also occurred a collision between the British warships *Camperdown* and *Victoria* while manœuvering off the African coast. Admiral Tryon and nearly four hundred men were drowned, many being horribly mangled by the revolving propeller as the ship sank bow first. The first of September a terrible hurricane swept over the South Carolina coast, entirely inundating the low range of sea islands. Many hundred persons were drowned, and the destruction of crops and dwellings left the few who survived exposed to the perils of hunger and disease from the unburied bodies of men and beasts. The prompt assistance of the Marine-Hospital Service did much to prevent a widespread epidemic. An equally severe storm swept the English channel during the autumn, causing much damage to shipping and harbors and drowning many hundred seamen. The rush of travel to the World's Fair at Chicago was unfortunately attended by a great and unwarrantable loss of life from railroad accidents. The many extra excursion trains running out of schedule time were almost daily subject to collision.

MEDICAL CONGRESSES AND MEETINGS.

The most important meeting during the year was the first Pan American Medical Congress, which was held in Washington, D. C., September 5th, and opened by the President of the United States in person. The idea of thus bringing together in closer relationship the various nations of the Western Hemisphere was most successfully carried out. The constituent countries of the Congress, all of which sent official delegates in response to the invitation of the President, were Argentine Republic, Bolivia, Brazil, British North America, British West Indies (including British Honduras), Chili, Dominican Republic, Spanish Honduras, Mexico, Nicaraugua, Paraguay, Peru, Salvador, Republic of Colombia, Republic of Costa Rica, Ecuador, Guatemala, Hayti, Kingdom of Hawaii, Spanish West Indies, United States, Uruguay, Venezuela, Danish, Dutch and French West Indies. The work of the Congress was carried on in twenty-two sections; and at the close of the convention the foreign delegates visited different cities of the country as guests of the medical profession in each place.

Among other important meetings of Medical Congresses and Societies during the year were the following:

The American Gynæcological Society, in Philadelphia, May 16th; the American Laryngological Society, in New York, May 22d; the American Pediatric Society, at West Point, May 24th; the American Climatological Association, in Philadelphia, May 25th; the American Surgical Association, in Buffalo, May 30th; the Association of American Physicians, in Washington, May 30th; the American Association of Obstetricians and Gynæcologists, in Detroit, June 1st; the American Academy of Medicine, in Milwaukee, June 3d; the American Medical Association, in Milwaukee, June 6th; the Massachusetts Medical Society, in Boston, June 14th; the American Otological Society, in New London, July 18th; the American Ophthalmological Association, in New London, July 19th; the American Association of Genito-Urinary Surgeons, in Harrogate, June 20th; the American Neurological Association, in Long Branch, July 25th; the Association of Military Surgeons of the National Guard of the United States, in Chicago, August 8th; the American Dermatological Association, in Milwaukee, September 5th; the American Public Health Association, jointly with the World's Fair Auxiliary Congress of Public Health, in Chicago, October 10th.

The seventh French Surgical Congress met in Paris, April 3d; and the twenty-second Congress of the Association of German Surgeons was held in Berlin, April 12th. The twelfth German Congress of Internal Medicine was held in Wiesbaden, April 12th. The third French Congress for Tuberculosis, met in Paris, July 27th. The sixty-first annual meeting of the British Medical Association was held in Newcastle-on-Tyne, August 1st. The fourth International Congress for Temperance met at Haag, August 16th; and the Association of German Naturalists and Physicians in Nürnberg, September 11th. The eleventh International Medical Congress, which was to have been held in Rome, September 24th, was postponed on account of the prevalence of cholera in Italy, until March 29, 1894.

LECTURES.

In connection with established lectureships in the United States and Great Britain, the following lectures and orations were delivered:

The Mütter Lectures, in Philadelphia, by De Forest Willard, M.D., on "The Surgical Pathology and Surgery of the Spinal Cord, the Vertebræ and the Peripheral Nerves"; the Shattuck Lecture, before the Massachusetts Medical Society, by William Osler, M.D., on "Tuberculous Pleurisy"; the Lowell Institute Lectures, in Boston, on "Bacteriology," by William T. Sedgwick, Ph.D., Professor of Biology in the Massachusetts Institute of Technology. In Great Britain, the Croonian Lectures, on "The Pharmacological Action and Therapeutic Uses of the Nitrites and Allied Compounds," by D. J. Leech, M.D., Lond., F.R.C.P.; the Morton Lectures, on "The Parasitism of Protozoa in Carcinoma," by James Galloway, A.M., M.D., Aberdeen, F.R.C.S., M.R.C.P.; the Milroy Lectures, on "Changes of Type in Epidemic Diseases," by B. Arthur Whitelegge, M.D., B.Sc.; the Goulstonian Lectures, on "The Chemical Physiology of the Animal Cell," by W. D. Halliburton, M.D., F.R.C.P., F.R.S.; the Croonian Lectures, before the Royal Society, on "The Position of Pathology among the Biological Studies," by Rudolf Virchow; the Lettsomian Lectures, on "Syphilitic Affections of the Nervous System," by J. S. Bristowe, M.D., LL.D., F.R.C.P., F.R.S.; the Combe Lectures, on "Physiology," by Professor Stirling; the Cavendish Lecture, on "Some Changes in Surgical Opinion regarding the Diseases of the Urinary Organs," by Henry Morris, M.A., M.B., Lond., F.R.C.S., Eng.; the Bradshaw Lecture, on "Some Diseases of the Thyroid Gland," by William S. Greenfield, M.D., F.R.C.P.; the Lumleian Lectures, on "Aëro-therapeutics in Lung Diseases," by C. Theodore Williams, M.A., M.D., F.R.C.P.; the Harveian Oration, on "Pathology as the Basis of Rational Medicine," by Philip Henry Pye-Smith, M.D., F.R.C.P., F.R.S.; the Bowman Lecture, on the "Abandonment of Iridectomy in the Extraction of Hard Cataract," by T. Pridgin Teale, M.A., F.R.S., F.R.C.S.; the Hunterian Oration, on "The Life of John Hun-

ter," by Thomas Bryant, F.R.C.S., Eng. and I., M. Ch.; the Hunterian Lectures, on "Certain Branches of Operative Surgery," by Walter Rivington, M.S., Lond., F.R.C.S., and by M. Armand Ruffer, M.D., on "Recent Researches on Protozoa and Diseases"; the Romanes Lecture at Oxford, on "Evolution and Ethics," by John Huxley.

NECROLOGY. — FOREIGN.

Epaminonda Abate, M.D., well known for his study in the methods of petrifying human corpses, died in Naples, September 26, aged seventy.

Hjalmar A. Abelin, M.D., formerly professor of children's diseases in the Carolina Institute, Stockholm, died September 13, aged seventy-six.

Marcus Beck, M.D., F.R.C.S., professor of surgery in the University College Hospital, London, died May 25, aged fifty.

E. Warren Bey, M.D., an American physician and formerly surgeon-general in the Egyptian army, died in Paris, September 16.

Antoine Blanche, M.D., the distinguished French alienist, died at Auteuil, August 15.

Arnaldo Cantani, M.D., professor of clinical medicine in the University of Naples, died May 1, aged fifty-six.

Jean Martin Charcot, professor of the diseases of the nervous system at the Salpétrière, Paris, died at Morvan, August 16, aged sixty-eight.

Sir Andrew Clark, Bart., M.D., F.R.S., LL.D., president of the Royal College of Physicians of England, and consulting physician and lecturer on clinical medicine to the London Hospital, died in London, November 6, aged sixty-seven.

Charles Clay, L.R.C.S., Eng., L.R.C.P., Lond., who was considered in England as "the Father of Ovariotomy," died in Blackpool, September 19, aged ninety-two.

Robert Foster Dill, M.D., professor of midwifery in Queen's College, Belfast, died July 20, aged eighty-one.

Thomas R. Dupuis, M.D., professor of clinical surgery and anatomy in the Medical Department of Queen's University, Kingston, Ont., died June 25, aged sixty.

Alfred Hardy, M.D., professor of dermatology and of clinical medicine in the Paris Medical Faculty, died in Paris, January 22, aged eighty-one.

W. M. Grailly Hewitt, M.D., consulting obstetric physician to University College Hospital and emeritus professor of obstetric medicine in University College, died in London, August 27, aged sixty-five.

Otto Kahler, M.D., professor of clinical medicine in the University of Vienna, died January 24, aged forty-four.

Hans Kundrat, M.D., professor of pathological anatomy in the University of Vienna, died April 27, aged forty-nine.

Professor Le Fort, Vice-President of the Académie de Médecine of Paris, died at Paris, October 19, aged sixty-one.

Casimiro Manassei, M.D., professor of dermatology and syphilis in Rome, died January 14.

Jacob Moleschott, M.D., professor of physiology in the University of Rome, died in May, aged seventy.

Prof. Rawdon McNamara, one of the surgeons of the Meath Hospital and the representative of the Royal College of Surgeons in Ireland, in the General Medical Council, died in Dublin, April 12.

Césare Olivieri, M.D., director of the Pellegrini Hospital and one of the most prominent physicians of the Naples school, died in Naples, September 17, aged seventy-one.

Arnold Paltauf, M.D., professor of legal medicine in the University of Prague, died May 29.

Surgeon-Major Thomas Heazle Parke, who was chief medical officer under Stanley in the search for Emin Pasha, died at Alt-na-Craig, Scotland, September 10, aged thirty-six.

Charles Felix Michel Peter, M.D., professor of clinical medicine in the Faculty of Medicine, Paris, France, died June 15, aged sixty-nine.

John Rae, M.D., a noted Arctic explorer who had charge of one of the Sir John Franklin expeditions, died in London, July 24.

J. Schnitzler, M.D., professor extraordinary of internal medicine and laryngology at the University of Vienna, died May 4, aged fifty-eight.

John Tyndall died in Haselmere, England, December 4.

Walter Hayle Walshe, LL.D., M.D., F.R.C.P., emeritus professor of medicine and clinical medicine, University College, London, died December 14, 1892, in the eighty-first year of his age. He was for twenty-one years professor in University College, London, and was one of the most widely-known medical men of England.

Severin Wiciobycki, M.D., died in St. John's Wood, London, September 7, aged one hundred years and eight months.

NECROLOGY — UNITED STATES.

Henry W. Buell, M.D., at one time president of the Connecticut State Medical Society, died in Litchfield, Conn., January 30, aged seventy-two.

J. W. Branham, M.D., assistant surgeon in the Marine-Hospital Service, died at Brunswick, Ga., of yellow fever contracted while on quarantine duty August 20, aged twenty-five.

John J. Craven, M.D., once prominent in military and scientific circles, who superintended the building of the first telegraph line between New York and Philadelphia, died at Patchogue, Long Island, February 14, at the age of seventy-one.

J. S. Dorsay Cullen, M.D., professor of surgery and Dean in the Richmond Medical College, died in Richmond, Va., March 24, aged sixty.

Charles Warrington Earle, M.D., president of the board of directors of the College of Physicians and Surgeons and of the Women's Medical College of Chicago, died in Chicago, November 19, aged forty-eight.

Charles H. Fisher, M.D., secretary of the Rhode Island State Board of Health, died at Buffalo, N. Y., October 21, aged seventy-one.

Benjamin A. Fordyce, M.D., at one time president of the New York State Medical Association, died at Union Springs, N. Y., June 3, aged seventy.

Norvin Green, M.D., president of the Western Union Telegraph Company, died February 12, aged seventy-four.

Hermann August Hagen, M.D., professor of entomology at Harvard College, died in Cambridge, November 10, aged seventy-six.

David Harlan, M.D., a medical director in the

United States Navy, died at Churchville, Md., July 12, aged eighty-four.

Henry M. Harlow, M.D., for thirty-two years superintendent of the Maine Insane Asylum retiring in 1883, died in Augusta, Me., April 5, aged seventy-two.

Lyman B. How, M.D., of Manchester, professor of anatomy in the Dartmouth Medical School and at one time president of the New Hampshire Medical Society, died in Hanover, N. H., September 15, aged fifty-five.

Edward H. James, M.D., for twenty-seven years a member of the New York City Board of Health, died in New York, March 12, aged seventy-three.

John M. Keating, M.D., LL.D., formerly of Philadelphia, and well known as the editor of the "Cyclopædia of the Diseases of Children," died at Colorado Springs, November 17.

Charles Carroll Lee, M.D., professor of gynæcology at the New York Post-Graduate Hospital and School, died in New York, May 10, aged fifty-four.

Samuel Logan, M.D., professor of surgery in the Tulane University, New Orleans, died January 12, aged sixty-nine.

Samuel E. Mumford, M.D., at one time president of the Indiana State Medical Society, died in Princeton, Ind., July 31.

Charles W. Parsons, M.D., professor of physiology in Brown University, died at Providence, R. I., September 2, aged seventy.

Timothy Stone Pinneo, M.D., professor of belles lettres in Marietta College, Ohio, and the author of Pinneo's Grammars, died at Norwalk, Conn., August 9, aged ninety.

William H. Stokes, M.D., for thirty years in charge of the Mount Hope Retreat, the largest insane asylum in Maryland, died in Baltimore, May 7, aged eighty-one.

William B. Towles, M.D., professor of anatomy in the University of Virginia and the University of Vermont, died in Charlotte, Va., September 18, aged fifty-three.

Walter Vought, M.D., who was in charge of the Fire Island Quarantine Station during the cholera quarantine last year, died in New York, September 25, aged thirty-one.

James H. Wheeler, M.D., formerly president of the New Hampshire Medical Society, died in Dover, N. H., January 26, aged sixty-one.

NECROLOGY. — MASSACHUSETTS MEDICAL SOCIETY.

George Frederic Bigelow, M.D., of Boston, died August 10, aged seventy-three.

James Henry Bodge, M.D., of Newton Centre, died October 19, aged fifty-three.

Cyrus Faulkner Carter, M.D., of Boston, died June 14, aged thirty-one.

Henry Colman, M.D., of Lynn, died November 12, aged fifty-three.

Charles Frederick Crehore, M.D., of Newton Lower Falls, died November 8, aged sixty-five.

Nathan Brown Edwards, M.D., of North Chelmsford, died June 12, aged seventy-three.

David Sylvester Fogg, M.D., of Norwood, died August 30, aged seventy-two.

Richard Lord Hodgdon, M.D., of Arlington, died January 30, aged sixty-eight.

William Donnison Hodges, M.D., of Nahant, died March 6, aged thirty-nine.

Howland Holmes, M.D., of Lexington, died November 16, aged seventy-eight.

Chauncy Munsell Hurlbert, M.D., of South Dennis, died November 6, aged seventy-five.

John Furness Jarvis, M.D., of Boston, died February 10, aged sixty-six.

James Abercrombie Latimer, M.D., of East Cambridge, died August 10, aged forty-six.

Samuel Moore Logan, M.D., of Riverside, Cal., formerly of East Boston, died Nov. 20, aged sixty-five.

Jabez Baldwin Lyman, M.D., of Salem, died June 29, aged seventy-four.

Stephen Crosby Martin, M.D., of Brookline, died November 5, aged forty-three.

Asa Millet, M.D., of East Bridgewater, died March 21, aged eighty.

Joseph Howe Murray, M.D., of Jamaica Plain, died August 13, aged forty-three.

Samuel N. Nelson, M.D., of Revere, died February 25, aged thirty-six.

Horatio Nelson Page, M.D., of Chelsea, died September 6, aged eighty-seven.

John Renton, M.D., of Boston, died December 15, aged seventy-four.

Richard Henry Salter, M.D., of Boston, died August 4, aged eighty-six.

George Woodbury Sargent, M.D., of Lawrence, died January 1, aged fifty-eight.

George Cheyne Shattuck, M.D., of Boston, a former President of the Society, died March 22, aged seventy-nine.

Benjamin Shurtleff Shaw, M.D., of Boston, died May 3, aged sixty-five.

Andrew Francis Shea, M.D., of Lawrence, died July 25, aged thirty-five.

Thomas Foster Sherman, M.D., of Boston, died September 26, aged thirty-seven.

George Williams Snow, M.D., of Newburyport, died May 21, aged fifty-eight.

Walter Gay Stebbins, M.D., of Springfield, died October 8, aged twenty-eight.

Charles Pratt Strong, M.D., of Boston, died March 14, aged thirty-seven.

Charles Carroll Tower, M.D., of South Weymouth, died May 29, aged fifty-nine.

William Tecumseh Sherman Wardwell, M.D., of Roslindale, died June 24, aged thirty-two.

Albert Poland Weeks, M.D., of Chelsea, died April 7, aged fifty-four.

Moses Williams Weld, M.D., of Boston, died January 16, aged seventy-five.

Henry Wheatland, M.D., of Salem, died February 27, aged eighty-one.

Elbridge Gerry Wheeler, M.D., of Middlefield, died in December.

John Birtwistle Whitaker, of Fall River, died August 24, aged seventy-seven.

George Franklin Woodbury, M.D., of Worcester, died June 18, aged forty-two.

Samuel Lane Young, M.D., of Ferry Village, Me., died April 19, aged eighty.

Since our report of last year, thirty-eight members of the Society have died, three less than in the previous year. The average age is a little lower than in the past year, being sixty and four-tenths instead of sixty-one and a half. Five had lived to be eighty years old, but eight had not reached forty.

METEOROLOGICAL RECORD,

For the week ending December 16, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer.			Relative humidity.		Direction of wind.		Velocity of wind.		Weather. *		Rainfall in inches.
